Both NO₂ and NH₃ can be taken up by aboveground parts of plants, mainly via the stomata of leaves.^[5] In the aqueous phase of the apoplast, NO₂ is either disproportionated yielding equal amounts of NO₂⁻ and NO₃⁻, or it reacts with apoplastic ascorbate.^[8] Because disproportionation of NO₂ in water is slow at atmospheric NO₂ concentrations, the reaction with ascorbate may be of more importance. Upon conversion to NO₃⁻ or NO₂⁻ these anions are transported to the cytoplasm, where they are reduced by the assimilatory nitrate reduction pathway yielding NH₄⁺ and the amino acid glutamine. Atmospheric NH₃ dissolves in the aqueous phase of the apoplastic space to yield NH₄⁺, which is then taken up into the cytoplasm.

Both NH₃ and NO₂ can also be emitted by plants. NH₃ may be released from cellular NH₄⁺ pools when plants are exposed to excess nitrogen in the soil. In addition, it can be released from drying water films at the leaf surface. During this process the remaining NH₄⁺ concentrations on the surface will increase. In contrast, the chemical source of NO₂ emitted by the leaves is largely unknown; it has been proposed that nitrate reductase may be involved in the reduction of NO₂⁻ to NO₂.^[7]

The rate of trace gas emission does not necessarily depend on the actual rate of production. Some volatile compounds are produced and then stored in particular pools. For example, some plant reservoirs contain high amounts of monoterpenes, which can be emitted throughout the day and night independent of light-dependent biosynthesis.

Through their effect on biochemical pathways, biotic and abiotic factors (e.g., stress factors) and the developmental stage of plants influence the rate of trace gas emission. For example, stress caused by wounding, chilling, iron deficiency, O₂ deficiency, or induction of

**Fig. 1** Main access routes for trace gases to enter a leaf: Uptake via the stomata and cuticular uptake. (Modified according to Ref. 7.)

Table 2 Typical range of rates of exchange for different trace gases between crops and the atmosphere

Trace gas	Range of exchange ^a [$\mu\text{g g}^{-1}$ (leaf d.wt.) h^{-1}]
SO ₂	-300 to 0
H ₂ S	-2 to 2
O ₃	0 to -300
NO ₂	-3 to 1
NH ₃	-3 to 3
Isoprene	0 to 0.1
Monoterpenes	0 to 20
Oxygenated VOCs	-50 to 50

^aNegative values indicate deposition; positive values indicate emission of respective trace gas.

oxidative stress caused by exposure to O₃ or SO₂ can lead to the production of the VOCs hexenal, hexanal, formaldehyde, formate, ethene, ethane, ethanol, and acetaldehyde.^[9]

INTERNAL TRANSFER RESISTANCES

The transfer of gases in and out of plants is often described by a resistance analogy. Along the path from the sites of production (or consumption) to the atmosphere, a series exists of mainly internal plant resistances. Because biosynthesis and consumption of volatile compounds usually take place in the cytoplasm or in other compartments of the cell, the gas must pass across the bordering membranes. The diffusive flux through these membranes is determined by the molecular size and the lipophilic character of the particular compound. Polar molecules such as organic and inorganic acids are not likely to be dissolved in the lipophilic membranes; therefore, the diffusive flux should be slow. Carrier proteins can facilitate the transport of these polar compounds across membranes from the cytoplasm into the apoplastic space, similar to the transport of organic acids.^[10]

The compounds are transferred from the liquid phase in the apoplastic space to the gaseous phase in the substomatal cavity, or vice versa. The volatilization into the internal leaf air space depends on 1) chemical properties of both the aqueous phase and the individual compound to be emitted (e.g., its solubility in the apoplastic solution); and 2) physical factors such as the ambient concentration of the gas, its vapor pressure, and temperature.^[10] A reduction of the apoplastic pH reduces the resistance for inorganic and organic acids, because these compounds become protonated and thereby more volatile. When present in the gaseous phase of the apoplastic space, trace gases can escape from the leaves through either the cuticle

or the stomata. However, because of their polarity, the lipophilic cuticle constitutes a strong barrier, and therefore diffusion through the stomata is the main pathway. However, nonstomatal emission and deposition have also been observed in air pollutants such as NO, NO₂, and SO₂, but at much lower rates than stomatal exchange. For this reason, factors that influence the stomatal aperture exert a strong influence on the rate of gas exchange between plants and the atmosphere. The control by the stomata of emission and deposition of NO₂, SO₂, O₃, PAN, and other trace gases was observed in many studies, including in investigations of crop plants. Thus, concentration and time of exposure are not the only factors determining the effect of an air pollutant on vegetation. Plants usually close their stomata during hot, dry conditions when, for instance, O₃ levels are high. This may provide some protection for the plants from O₃ injury. Alternatively, in northern Europe where O₃ concentrations are lower than in southern and central Europe, the potential O₃ uptake at a given O₃ concentration may be higher because of higher air humidity, leading to high rates of stomatal O₃ uptake.

CONCLUSION

Trace gases influence not only natural ecosystems but also agricultural crops. Future studies should focus on the impact of different combinations of air pollutants (e.g., increased nitrogen input combined with elevated O₃ concentrations) on plants and should include aspects of global climate change (e.g., higher temperatures,

Fig. 2 Main processes involved in the assimilation of atmospheric NH₃ and NO₂ taken up by the leaves. 1: nitrate reductase, 2: nitrite reductase, 3: glutamine synthetase (cytoplasmatic and chloroplasmic isoforms). (Modified according to Ref. 7.)

droughts, and increased frequency of heavy rainfalls and droughts in combination with elevated CO₂ concentrations). Future management practices should allow for optimum plant growth, while simultaneously reducing the loss of pollutants from the plant–soil system.^[4]

Exciton Theory

Su Lin

Arizona State University, Tempe, Arizona, U.S.A.

INTRODUCTION

Excitons are electronic excitations capable of motion in a nonmetallic condensed medium. Their generation usually results from absorption of energy as photons. Exciton decay results in products such as light emission, charge-separated state formation, or heat. The theory of excitons is essential to the interpretation of spectroscopic properties and electronic excitation dynamics in complex systems.^[1] It is also essential to understanding the initiation of photochemical processes in photosynthesis.

Systems that perform photosynthesis contain large numbers of interacting pigments, mainly chlorophylls and bacteriochlorophylls. Photosynthesis is initiated by photon absorption in the region of 400–1100 nm, which generates excited states of these pigments. This is followed by many energy transfer steps. Exciton theory therefore plays an essential role in photosynthesis studies.^[2,3]

CONCEPT AND PROPERTIES

Excitons are quanta of electronic excitation energy traveling in a periodic structure such as a crystal lattice or diffusing in a less well-ordered array of biomolecules. They transfer excitation energy from one place to another without transferring charge. Different types of excitons exist.^[4] Only the Frenkel, or small radius, exciton is of importance to photosynthesis. It is an excited state of a condensed system closely resembling a molecular excited state, carrying the excitation energy either by hopping from site to site or by the motion of an exciton wavepacket.

Exciton coherence describes the degree of correlation of the phase of the excitation on different molecules. As the wavelength of the absorbed light is much greater than the dimensions of a typical pigment-protein complex, a certain degree of coherence is always present in excitons at the time of their creation. Exciton scattering by phonons and disorder within a complex leads to the loss of coherence. During the coherence time, a molecular system can be treated as a supercomplex. In the limiting case of a totally incoherent exciton, excitation energy can be transferred between individual molecules by the Förster mechanism, to be discussed shortly.

For a system consisting of excitonically coupled molecules, each having two energy levels, the K -th exciton state is given in terms of wavefunctions

$$\Psi_K = \sum_i c_{Ki} \phi_i^1 \prod_{j \neq i} \phi_j^0 \quad (1)$$

where the coefficients c_{Ki} represent the relative contribution of individually excited molecules to the exciton state, and ϕ_i^0 and ϕ_i^1 are the wavefunctions of the ground and excited states of the i -th molecule, respectively. The energy an exciton carries is the energy difference between the initial and the final states.

To describe the absorption strength of a material, the concept of transition dipole moment is used. Its square is a measure of the probability that the radiation will produce an excited state. For an excitonically coupled molecular system, the transition dipole moment of an excited state is a linear combination of those from the individual molecules:

$$\mu_K = \sum_i c_{Ki} \mu_i \quad (2)$$

where the coefficients c_{Ki} are the same as in Eq. 1. The integrated intensity of an absorption band correlates directly with the square of the transition dipole moment.

Excitonic coupling can be demonstrated in a molecular dimer, in which two identical molecules interact strongly, resulting in their excited states being completely mixed. The wavefunctions of the excited dimer are

$$\begin{aligned} \Psi_+ &= \frac{1}{\sqrt{2}} (\phi_1^1 \phi_2^0 + \phi_1^0 \phi_2^1) \\ \Psi_- &= \frac{1}{\sqrt{2}} (\phi_1^1 \phi_2^0 - \phi_1^0 \phi_2^1) \end{aligned} \quad (3)$$

and the corresponding energies are

$$\begin{aligned} E_+ &= E + V_{12} \\ E_- &= E - V_{12} \end{aligned} \quad (4)$$

where E_+ and E_- are the dimer excited state energies, E is the monomer excited state energy, and V_{12} is the coupling energy between the monomer excitations. The energy levels of a dimer are shifted away from the monomeric energy (Fig. 1a), which can be seen in the absorption spectrum (Fig. 1b). The amount of spectral shift and the intensity distribution over the exciton bands are

Fig. 1 (a) Energy levels of monomers and dimer (b) their corresponding absorption band positions.

determined by the monomers' geometric arrangement and electronic properties.

When the interactions between molecules are weak, excitations are essentially localized on individual molecules, corresponding to the incoherent exciton case. Förster theory^[2,3] is employed to find the energy transfer rate between a donor and acceptor molecule, separated by a distance R :

$$k_{d \rightarrow a} = \frac{1}{\tau_0} \left(\frac{R_0}{R} \right)^6 \quad (5)$$

where τ_0 is the excited-state lifetime of the donor in the absence of transfer and R_0 is a characteristic distance related to the overlap between the donor emission spectrum and acceptor absorption spectrum, the relative orientation of molecular transition moments, and the system refractive index. Typical values of R_0 are 20–60 Å. Transfer occurs when $R < R_0$. When $R > R_0$ the donor is more likely to lose energy by other means. The rate of transfer between identical molecules is the same in both directions, but when one (called #2) has an excited state at a higher energy, the back-to-forward rate ratio is the Boltzmann factor,

$$\frac{k_{1 \rightarrow 2}}{k_{2 \rightarrow 1}} = e^{-(\Delta G/RT)} \quad (6)$$

where $\Delta G = G_2 - G_1$ is the free energy difference of the excited levels. This equation governs the excitation distribution within a heterogeneous system, therefore determining the profiles of fluorescence and transient absorption spectra.

Excitation energy migration, whether coherent or incoherent, involves more than two molecules. In most cases, migration is a sequence of transfers. During the process of exciton transfer and migration, because of the system heterogeneity, the exciton's energy can be transferred to an excited state with an energy lower than that of the exciton. The excitation might thereby lose its mobility,

becoming trapped in that particular state. When more than one exciton is present in an excitonically coupled system, collisions between them can take place during their lifetime. Exciton-exciton interaction can result in the formation of a new exciton with twice the energy of one exciton, one exciton and heat, or heat alone. Although annihilation is of little importance under physiological light intensities, it has proved to be a useful effect in experimental work.

THE EXCITON IN PHOTOSYNTHETIC SYSTEMS

Initiating photosynthesis, the exciton transfers absorbed energy among neighboring chromophores (the "antenna") before it is trapped by the reaction center, where the energy is converted and stored as chemical energy.

An example of excitonic coupling effecting spectral changes is the LH2 antenna from purple bacterium *Rhodospseudomonas acidophila*, containing large numbers of interacting pigments. Fig. 2 illustrates that the Q_y transition of *monomeric* bacteriochlorophyll (Bchl)-*a* peaks at 780 nm, while the absorption of Bchl-*a* molecules in LH2 exhibits two bands at 800 and 850 nm. The pigments absorbing at 800 nm are from the B800 ring in which all the Bchl molecules are parallel to the plane of the ring. The pigments are separated approximately 21 Å from each other, resulting in weak interactions between molecules. The arrangement of pigments absorbing at 850 nm is quite different. The quantum mechanical calculation of excitonic properties in dimers can be used here to explain the spectral differences with the structure of LH2. Pairs of Bchl-*a* molecules form closely coupled dimers, and nine such dimers form the B850 ring with all molecules separated at a distance of 9 Å. All the pigments are approximately perpendicular to the plane of the B850 ring. The initial excitation is delocalized over the major

Fig. 2 Absorption spectra of Bchl *a* (gray) and LH2 (black).

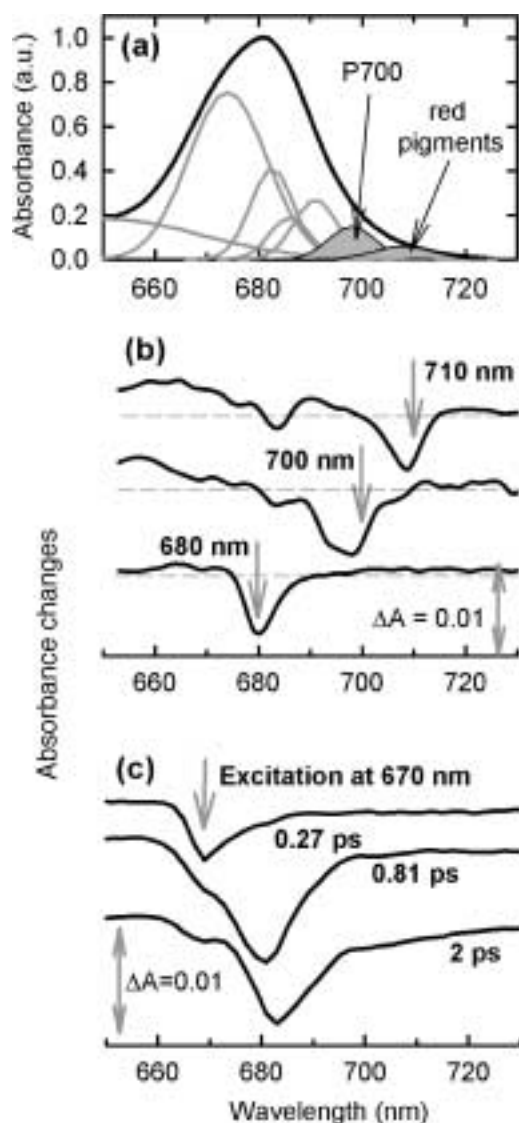

Fig. 3 (a) Room temperature Q_Y absorption band of PSI fitted with Gaussian components. (b) Transient absorption changes at 77 K recorded at 200 fs after laser excitations at marked wavelengths. (c) Time-resolved absorption spectra at 77 K with 670 nm excitation.

part of the B850 ring when excited directly, while the excitation of B800 creates much less coherence. The B850 coherence is partially lost within a few hundred femtoseconds because of electron-phonon interaction and scattering by disorder.

Another system studied extensively using exciton theory is PSI, one of the essential complexes in green plants and cyanobacteria. X-ray analysis of *Synechococcus elongatus* reveals that each unit of PSI complex contains about 100 chlorophyll (Chl)-*a* molecules. About 75% of the inter-pigment distances fall in the range of 10–20 Å.

Except for a moderate spectral shift due to the pigment-protein interaction, the molecules maintain their individual characteristics. Therefore, PSI is usually modeled as a loosely packed molecular crystal. However, the inter-pigment distances are small enough compared with the Chl-*a* R_0 , which is at least 50 Å, that the Förster mechanism is believed to govern the energy transfer between pigments. There are several clusters of Chl-*a* molecules showing inter-pigment distances of 6–9 Å, with their chlorin planes almost parallel to each other, including the special pair in the reaction center. Those geometric arrangements create strong excitonic coupling between the molecules in these clusters. Various inter-pigment interactions in PSI are clearly reflected in both steady-state absorption and transient absorption spectra. The Q_Y transition band fitted with Gaussian components (Fig. 3a) shows that two bands are shifted more than 20 nm away from their dominant absorption around 680 nm. The 700-nm band is identified as the absorption of a special pair called P700, formed by two parallel Chl-*a* molecules at a 3.6 Å interplanar distance. The redmost band at 710 nm is believed to originate in a group of strongly coupled molecules. The early-time transient absorption spectra in Fig. 3b show that 680-nm excitation induces a narrow bleaching band originating in the pigments with transition energies close to the 680-nm photon energy. Excitations at 700 or 710 nm induce much broader initial bleachings and spectral changes at the other wavelengths. The exciton delocalization features disappear within a few hundred femtoseconds. Excitation transfer and migration processes within PSI are reflected in its spectral dynamics in Fig. 3c. The initial bleaching at the excitation wavelength 670 nm is broadened and shifted to the red at later times. The dominant contribution to the spectral redistribution is from exciton migration within the complex governed by the Förster mechanism.

CONCLUSION

Exciton theory has been successfully applied to study the spectral dynamic properties of photosynthetic antenna and reaction center systems, thereby broadening and deepening our understanding of their structure-function relationships. Research on initial photochemical processes in photosynthesis not only is greatly benefited by exciton theory but also provides further understanding and tests of exciton theory.

Farmer Selection and Conservation of Crop Varieties

Daniela Soleri

David A. Cleveland

University of California, Santa Barbara, California, U.S.A. and

Center for People, Food and Environment, Santa Barbara, California, U.S.A.

INTRODUCTION

After domestication, plant species were often transported widely, and many genetically distinct farmers' varieties (FVs, crop varieties traditionally maintained and grown by farmers) developed in specific locations.^[1] FVs continue to be grown today by many small-scale farmers in traditionally-based agricultural systems (TBAS), fulfilling both local or regional consumption needs, as well as the larger social need for the conservation of genetic diversity.^[2]

Crop genetic variation (V_G) is a measure of the number of alleles and degree of difference between them, and their arrangement in plants and populations. A change in V_G over generations is evolution, though one form of this change, microevolution, is reversible. Farmers and the biophysical environment select plants within populations. Farmers also choose between populations or varieties. This phenotypic selection and choice together determine the degree to which varieties change between generations, evolve over generations, or stay the same. Conservation in a narrow sense means the preservation of the V_G present at a given time. However, in situ conservation in farmers' fields is commonly understood to mean that the specific alleles and genetic structures contributing to that V_G may evolve in response to changing local selection pressures, while still maintaining a high level of V_G .^[3] In contrast, ex situ conservation in genebanks attempts to conserve genetic diversity present at a given location and moment in time, preserving the same alleles and structures over time. Thus, different forms of conservation include different amounts and forms of change.

Sometimes farmers carry out selection or choice intentionally to change or conserve V_G . However, much of farmer practice is intended to further production and consumption goals and affects crop evolution unintentionally. Therefore, in order to understand farmer selection and conservation, it is important to understand the relationship 1) between production, consumption, selection, and conservation in TBAS, and 2) between farmer knowledge and practice and the basic genetics of crop

populations and their interactions with growing environments [genetic variation, environmental variation and genotype-by-environment interaction ($G \times E$), and response to selection] (Table 1).

FARMERS AND FVs IN TRADITIONALLY-BASED AGRICULTURAL SYSTEMS

TBAS are characterized by the integration within the household of production, consumption, selection, and conservation, whereas in industrial agriculture these functions are spatially and structurally separated. Farm households in TBAS typically rely on their own food production for a significant proportion of their consumption and this production is essential for feeding the population in TBAS now and in the future, even with production increases in industrial agriculture.^[4]—by 2025 three billion people will depend on agricultural production in TBAS.^[5]

TBAS are also characterized by marginal growing environments (relatively high stress, high temporal and spatial variability, and low external inputs) and the continued use of FVs, even when modern crop varieties (MVs) are available.^[6] FVs include landraces, traditional varieties selected by farmers, MVs adapted to farmers' environments by farmer and natural selection, and progeny from crosses between landraces and MVs (sometimes referred to as "creolized" or "degenerated" MVs). The V_G of farmer-managed FVs is not well documented, but is presumed to support broad resistance to multiple biotic and abiotic stresses, making them valuable not only for farmers because they decrease the production risks in marginal environments, but also for plant breeders and conservationists as the basis for future production in industrial agriculture.^[7] Farmers value FVs for agronomic traits, such as drought resistance, pest resistance and photoperiod sensitivity, as well as for traits contributing to storage, food preparation, taste, market value, and appearance (e.g., maize varieties grown for purple husks used in tamale production).

FARMER CHOICE: GENETIC VARIATION, CLASSIFICATION, GENOTYPE × ENVIRONMENT INTERACTION, AND RISK

The way farmers classify and value traits, which can vary between women and men, and between households in a community,^[2] affects adoption and abandonment of varieties and populations, farmers’ tolerance of intravarietal gene flow, and, thus, intraspecific V_G . Experimental evidence suggests that farmers can choose among large numbers of genotypes—in Syria, farmers were able to identify efficiently high yielding barley populations from among 208 entries, including 100 segregating populations.^[7] Farmers’ choice of varieties and populations when adopting or abandoning them from their repertoires, saving seed for planting, and procuring seed, does not change the genetic makeup of those units directly, and there is no evidence that farmers have any expectation of changing them. However, farmers’ choice of crops,

varieties, and populations does affect the total V_G farmers manage and the number of populations within which farmers can select plants.

The FV reproductive system, in combination with farmers’ propagation methods, are important determinants of interspecific and intraspecific V_G both directly and indirectly, because resulting differences in the consistency of the V_G present over generations affects farmers’ perception and management.^[8] V_G in asexually propagated outcrossing crops such as cassava is exactly replicated in amount and structure between generations with discrete, fixed types (clones) or groups of types maintained as distinct varieties,^[9,10] that may be either homo- or heterozygous. Intrapopulation V_G , affected by the genetics of the particular trait, becomes more dynamic and less structured with the intentional inclusion by farmers of sexually propagated individuals into clonal populations based on morphological similarity.^[10] The same increase in dynamism occurs with increasing rates of outcrossing in

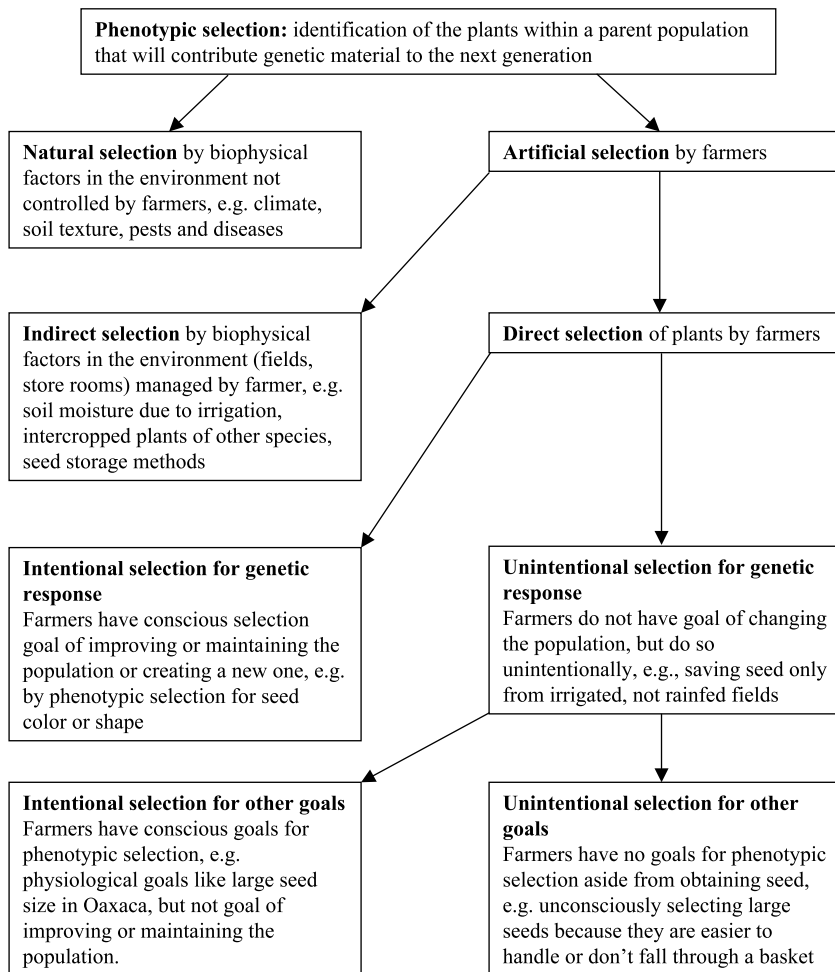

Fig. 1 Classification of farmer selection leading to genetic response, according to the agent of phenotypic selection and intent of farmer as agent.

sexually propagated crops, because variation can be continuous within a population. Moreover, segregation, crossing-over, recombination, and other events during meiosis and fertilization result in strong variability of V_G between generations. In predominantly allogamous crops such as maize, heterozygosity can be high, making it difficult to discern discrete segregation classes particularly in the presence of environmental variation, and retention of distinguishing varietal characteristics requires maintenance selection.^[11] Highly autogamous crops such as rice are predominantly homozygous, making exploitation of V_G and retention of varietal distinctions easier, even if varieties are composed of multiple, distinct lines.

Farmers' choices depend in part on the range of spatial, temporal, and management environments present, the V_G available to them, and the extent to which genotypes are widely versus narrowly adapted. In turn, environmental variation in these growing environments interacts with V_G ($G \times E$) to produce variation in yield of grain, straw, roots,

tubers, leaves, and other characteristics over space and time. As a result, farmers may have different criteria for different environments, as in Rajasthan, India, where pearl millet farmers realize there is a trade-off between panicle size and tillering ability: Farmers in a less stressful environment prefer varieties producing larger panicles, while those in a more stressful environment prefer varieties with high tillering under their conditions.^[12]

Farmers' seed management and choice of growing environments determine the possible extent of pollen flow between populations or varieties. In Jalisco, Mexico, farmers regularly mix maize populations together by classifying seed obtained from diverse sources as the same variety, which, together with planting patterns, leads to a 1–2% level of gene flow between maize plots during one crop cycle as detected by isozyme analysis, affecting genetic composition over several crop cycles.^[13] The morphological and genetic continuum across the four major local varieties suggests that traits from a variety introduced 40 years ago have introgressed into the other varieties.

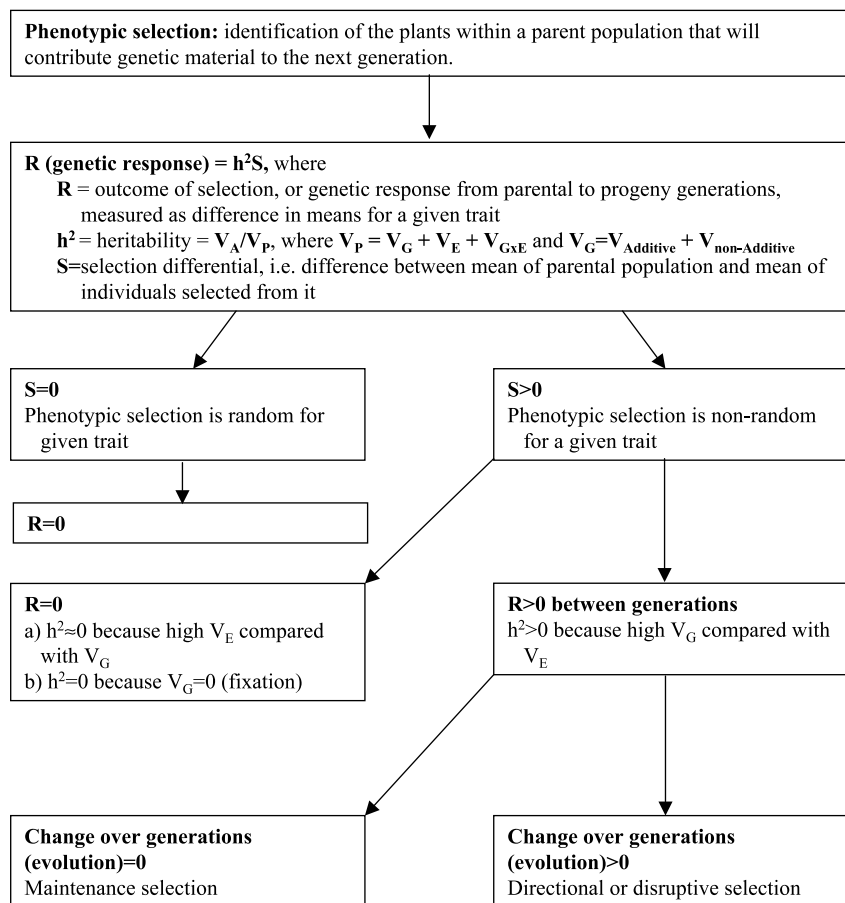

Fig. 2 Classification of farmer selection according to genetic response as an outcome of phenotypic selection. V_A = additive genetic variation, V_P = phenotype variation, V_G = genetic variation, V_E = environmental variation, $V_{G \times E}$ = variation in genotype by environmental interaction.

Patterns of variation in yield affect farmers' choice of crop variety via their attitude toward risk. In response to scenarios depicting varietal G×E and temporal variation, farmers from more marginal growing environments were more risk-averse compared to those from more favorable

environments, the former preferring a crop variety with low but stable yields across temporal environments, the latter choosing a variety highly responsive to favorable conditions but with poor performance under less favorable conditions.^[14]

Table 1 Farmer selection and choice and the change and conservation of crop varieties

Farmer knowledge (including values) on which practice may be based	Farmer practice	Potential effect of farmer practice on selection and conservation of populations/varieties	Example
<i>Indirect selection/conservation by farmer-managed growing and storage environment</i>			
Understanding of G×E	Allocation of varieties to spatial, temporal, and management environments	Selection pressures in environments result in maintenance of existing or development of new populations/varieties, including evolution of wide or narrow adaptation	<i>Spatial:</i> varieties specified for different soil or moisture types; rice, Nepal; pearl millet, India. <i>Temporal:</i> varieties with different cycle lengths, maize, Mexico
Risk, values, G×E	Management of growing environments Choice of environments for testing new populations/varieties	Changing selection pressures ↑ or ↓ V_G	Changes in fertilizer application, maize, Mexico. High stress, rice, Nepal; Optimal conditions, barley, Syria
Escape from economic or political pressure; desire for different way of life	Abandonment of fields or farms, reduced field size	↓ V_G within due to reduced area for planting, ↓ effective population size, genetic drift	Pooling of subvarieties, maize, Hopi and Zuni; Reduction in area, potatoes, Peru; maize, Mexico
<i>Direct selection/conservation, intentional re. population change</i>			
Discount rate (values re. future), altruism (values re. community)	Conservation of varieties for the future, for other farmers	↑ intraspecific V_G	Rice, Thailand; maize, Hopi
Interest and expertise in experimentation	Deliberate crossing	↑ V_G	Maize-teosinte, Mexico; MV-FV pearl millet, India; MV-FV and FV-FV, maize, Mexico.
Understanding of h^2	Selection of individuals (plants, propagules) from within parent population	↑ or ↓ V_G via R	Among seedlings, cassava, Peru; among panicles, pearl millet, India.
<i>Direct, selection/conservation, unintentional re. population change, but intentional re. other goals, as result of production/consumption practices</i>			
Attitudes towards risk re. yield stability	Adoption and abandonment of FVs, MVs	↑ or ↓ intraspecific diversity	Maize, Hopi Rice, Nepal
	Adoption and abandonment of lines in multiline varieties of self pollinated crops; seedlots in cross-pollinating crops	↑ or ↓ intravarietal diversity	Common bean, East Africa Maize, Mexico
Agronomic, storage, culinary, aesthetic and ritual criteria, implicit and explicit	Selection or choice based on production/consumption criteria	↑ or ↓ intra- and intervarietal diversity	Storage and culinary criteria: maize, Mexico; and ritual criteria, rice, Nepal
Choice criteria	Acquisition of seed, seed lots	Gene flow via seed then pollen flow, hybridization, recombination within varieties	Cycle length, maize, Mexico; cuttings and seedlings, cassava, Guyana

G×E: genotype by environment interaction

V_G : genetic variation

↑ or ↓: increase or decrease

h^2 : heritability in the narrow sense

R : response selection

MV: modern crop variety, product of formal breeding system

FV: farmer developed crop variety

SELECTION: HERITABILITY, PHENOTYPIC SELECTION DIFFERENTIAL, AND RESPONSE

Phenotypic selection is the identification of individual plants within a population that will contribute genetic material to the next generation. Phenotypic selection of FVs in TBAS can be classified according to the agent of selection (natural environment, farmer-managed environment, or farmer) and according to farmers' goals for selection (Fig. 1). Farmer selection can also be classified according to the outcome (Fig. 2). Geneticists and plant breeders tend to think of phenotypic selection as seeking to produce genetic change, but farmers often do not. Whether or not farmer selection changes the genetic makeup of the population (i.e., effects genetic response or R) depends on heritability (h^2), or the proportion of phenotypic variation that is genetic and can be inherited; and the selection differential (S), or the difference between the means of the parental population and sample selected from it: $R = h^2S$. The extent to which selection maintains potentially useful V_G is a measure of its contribution to in situ conservation.

Heritability is often understood by farmers who distinguish between high and low heritability traits and consciously select for the former, while often considering it not worth while or even possible to select for the latter, especially in cross-pollinating crops.^[14] When farmers' selection criteria centers on low heritability traits such as large ear size in maize, they may achieve high S , and little or no R . However, they persist in selection because they have other goals, such as improving the quality of planting seed, not high R .^[11,15]

In terms of seeking genetic response, farmers may practice intentional selection either to create new varieties, best documented in vegetatively propagated and self-pollinating crops,^[9] or for varietal maintenance or improvement, although much evidence for the latter is anecdotal. Unintentional selection—that is, not seeking genetic response—, as documented with maize farmers in Mexico, may be undertaken for varietal maintenance and/or to ensure planting seed quality, although this can also result in genetic response.

Quantitative research on the goals and outcomes of farmers' selection is relatively new. Selection exercises in two independent investigations of maize in Mexico found farmers' selections to be significantly different from the original population for a number of ear traits, resulting in high S values.^[11,15] However, R values calculated in the Oaxaca study were zero for these as well as other morpho-phenological traits.^[15] Similarly, the Jalisco study found that selection served to diminish the impact of gene flow, but not to change the population being selected on.^[11]

Indeed, a recent study across four sites each with different crops found that often a majority of farmers in a site did not see their seed selection as a process of cumulative, directional change.^[14]

However, intentional phenotypic selection for goals other than genetic response is practiced by nearly all farmers in that study and probably in TBAS, the reasons documented to date being seed quality (germination and early vigor) and purity and because this is “the way we know,” that is, because farmers may not want to change (viz. ‘improve’) a variety, although genetic response may result unintentionally. To understand this from the farmers' perspective, it is necessary to take into account the multiple functions of crop populations in TBAS: production of food and seed, consumption, conservation, and improvement.

CONCLUSIONS

Selection and conservation in TBAS contrast substantially with industrial agricultural systems, and understanding farmers' practices, and the knowledge and goals underlying them, is critical for supporting food production, food consumption, crop improvement, and crop genetic resources conservation for farm communities in TBAS and for long-term global food security. The urgency of understanding farmer selection and conservation will increase in the future with the on-going loss of genetic resources, the rapid spread of transgenic crop varieties with limited genetic diversity, the development of a global system of intellectual property rights in crop genetic resources, and the movement to make formal plant breeding more relevant to farmers in TBAS through plant breeding and conservation based on direct farmer and scientist collaboration.

Female Gametogenesis

Jagreet Kaur

Imran Siddiqi

Centre for Cellular and Molecular Biology, Hyderabad, India

INTRODUCTION

The female gametophyte or embryo sac in seed plants is a specialized structure containing the egg cell and a small number of associated cells that are essential for fertilization and seed development. In higher plants, the female gametophyte is encased within the ovule and represents an evolutionary reduction of a distinct gametophytic generation that in lower plants exists as separate free living organisms. The key events of fertilization, embryogenesis, and endosperm development leading up to the formation of a mature seed all take place within the embryo sac. We discuss here the stages in development of the embryo sac, its cellular organization and structure in the context of its unique function in plant reproduction, and its role in fertilization and seed development. We have emphasized recent advances that have come from the use of genetic approaches to understand biogenesis of the embryo sac and its control of seed development.

THE FORMATION OF THE EMBRYO SAC

The first step in the pathway leading to female gametophyte development is the specification of the archesporial cell at the tip of the growing ovule. The archesporial cell enlarges and either directly becomes the megaspore mother cell (MMC; also called the megasporocyte) or in many species undergoes an additional division to give rise to the MMC. The development of the embryo sac consists of two stages subsequent to the formation of the MMC: megasporogenesis comprising meiosis and formation of the functional megaspore, and megagametogenesis in which the functional megaspore develops into the female gametophyte (Fig. 1).

Megasporogenesis

The MMC undergoes meiosis to produce a tetrad of four spores. Most commonly in the monosporic type of development, three of the four spores degenerate, and the remaining one becomes the functional megaspore.^[1] Prior to meiosis, the MMC undergoes a process of polarization

with the movement of the nucleus and organelles (mitochondria and plastids) toward one end of the cell, the end that will generally give rise to the functional megaspore. During meiosis, the cell wall of the MMC forms a layer of callose, a $\beta(1,3)$ -glucan, which has low permeability and serves to insulate the MMC from the surrounding cells as well as to separate the megaspores after meiosis. Callose is removed from the cell wall of the functional megaspore early in megagametogenesis. Meiosis proceeds contemporaneously with the specification and development of the functional megaspore. Based upon studies in *Arabidopsis*, many of the genes required for meiotic chromosome organization and recombination are conserved between plants and other eukaryotes; however, others appear to be unique to plants.^[2]

Megagametogenesis

In the most common type of development, the functional megaspore undergoes three rounds of nuclear division without cytokinesis to produce eight nuclei, accompanied by extensive cell expansion to form a large embryo sac. A prominent vacuole occupies most of the central region of the embryo sac. The nuclei migrate to particular parts of the embryo sac and differentiate into specific cell types: an egg cell, synergids, and antipodal cells. The embryo sac is polarized and consists of the egg apparatus made up of an egg cell and two synergids in most species, at the end close to the micropyle. A cluster of antipodal cells occupy the opposite (chalazal) pole, and a central cell nucleus is found toward the middle. The dihaploid central cell nucleus is formed by fusion of two polar nuclei. The egg cell develops into the embryo and the central cell into the endosperm after double fertilization. In *Arabidopsis* the antipodals degenerate close to the time of fertilization, whereas in maize the antipodals proliferate and form a cluster of cells at the chalazal pole of the embryo sac.

The embryo sac is enclosed by the integuments and develops in very close contact with the sporophyte on which it depends for nutrition as well as developmental cues. The endothelium, which forms the inner layer of the inner integument of the ovule, closely contacts the embryo sac and acts as an interface between the female gametophyte and the maternal sporophyte. Plants are unique in

undergoing two distinct fertilization events for the formation of the embryo and endosperm, each having a different ploidy and maternal-to-paternal genomic ratio. This requirement is reflected in the development of the female gametophyte where fusion of the two polar nuclei sets up endosperm ploidy. The cytoskeleton plays an important role in the control of nuclear division and nuclear positioning, and mutants in which nuclear division and positioning are altered also show disruption of microtubules and the cytoskeleton in the embryo sac.

EMBRYO SAC FUNCTION

The embryo sac promotes fertilization and development of the embryo and the endosperm. In sexually reproducing species, both embryogenesis and endosperm development are initiated only after double fertilization takes place. However, in apomictic species, activation of one or both of these programs takes place without fertilization. In the *fis* class of mutants of *Arabidopsis*, endosperm development is initiated in the absence of fertilization.^[3] This suggests that the necessary elements for the early part of the program of embryogenesis and endosperm development are already established in the female gametophyte prior to fertilization and that fertilization may act as a trigger to overcome a block in the cell division cycle, as is the case for animal embryogenesis. Maternal control of embryogenesis in plants can be of two kinds: sporophytic

control, which is exerted by the ovule surrounding the female gametophyte, and gametophytic control, which comes from the female gametophyte. There is evidence for both types of control in plants.^[4]

An important function of the mature female gametophyte is to attract the pollen tube containing the two male sperm cells to enter the ovule through the micropyle. The pollen tube penetrates the wall of the embryo sac and one of the synergid cells, releasing the two sperm cells into the cytoplasm of the cell. The synergids play an accessory role in fertilization. Close to the time of entry of the pollen tube, the synergid cell degenerates and the cytoplasm undergoes reorganization to form a band of F-actin, which is thought to direct movement of the two sperm cells to fuse with the egg and central cells, respectively.^[5] The synergid cells also play a direct role in providing the signal to attract the pollen tube into the embryo sac.^[6]

DEVELOPMENTAL GENES AND MECHANISMS

In recent years, genetic and molecular approaches have led to significant advances in understanding the different stages in the pathway of female gametogenesis. Properties of the *mac1* mutant of maize suggest that the gene may play a role in a lateral inhibition process that restricts the number of archesporial cells to one per ovule.^[7] The *spl*

Table 1 Representative genes acting at different stages of female gametophyte development

Gene name	Species	Stage	Mutant phenotype	Affected sex	Gene product
<i>MAC1</i>	Maize	Sporocyte formation	Multiple megasporocytes; male meiotic arrest	Both	–

gene of *Arabidopsis* has been proposed to be a transcriptional regulator of sporocyte development.^[8] Genes affecting megagametogenesis can act by primarily affecting the ovule surrounding the embryo sac, or by acting directly on the female gametophyte. Mutant screens for genes that act in the female gametophyte and are required for its function (female gametophytic genes) were first carried out in maize and more recently in *Arabidopsis* using transposon and T-DNA tagging.^[9] The strategies have been based on a combination of reduced seed set and segregation distortion of a dominant antibiotic resistance marker present on the DNA used as the insertional mutagen. The rationale is that if a plant is heterozygous for a mutation in a gene that has an essential function in the female gametophyte at the haploid stage of development after meiosis, then half the ovules (those in which the female gametophyte carries the mutant allele) would be sterile and the mutant allele would be transmitted only through the pollen. Further, if the mutation is due to insertion of DNA carrying a dominant antibiotic marker such as Kanamycin resistance, then the seeds from the plant would give a Kanamycin-resistant–Kanamycin-sensitive segregation ratio that departs from the normal 3:1 and is closer to 1:1. The use of differential cDNA screening has also proved to be a successful approach in isolating embryo sac specific genes.^[10] These approaches are beginning to reveal the molecular players behind the

developmental events at different stages in the pathway of female gametophyte development (Table 1).

CONCLUSION

The pathway of female gametogenesis provides a well-defined system to address basic issues in plant development in the context of a small number of specialized cells that make up the female gametophyte. Questions whose answers are the goals of future research include the following:

1. How are the megasporocyte and, later, the functional megaspore specified?
2. What is the mechanism underlying the control of programmed cell death in the remaining megaspores?
3. What is the basis of polarity and the nature of positional information in the developing embryo sac that leads genetically identical nuclei to adopt distinct cellular identities?
4. What are the cell cycle controls that trigger embryo and endosperm development after fertilization and how are these altered in apomictic plants?

The understanding of apomixis in relation to female gametogenesis is also of considerable practical importance with respect to its potential application in plant breeding.

Fire Blight

John L. Norelli

USDA—ARS, Appalachian Fruit Research Station,
Kearneysville, West Virginia, U.S.A.

INTRODUCTION

Fire blight, caused by the bacterium *Erwinia amylovora* (Burr.) Winslow et al. is a destructive disease of apple, pear, and woody ornamentals. The disease has been reported to occur on approximately 130 species of plants, all of which are in the rose family (*Rosaceae*). The name “fire blight” was derived from the characteristic blackening of vegetative tissue caused by the disease, often making trees appear as if they are burnt.

DISCUSSION

Fire blight is indigenous to North America. It was first reported in 1780 on pear and quince in the Hudson Valley of New York. Research to determine the causal agent of fire blight conducted by Thomas J. Burrill and J.C. Arthur between 1877 and 1886 played an important role in acceptance of bacteria as plant pathogens.^[1] The disease currently occurs throughout North America, in most of Europe, in the Middle East, and in New Zealand. Asian pear blight (also known as bacterial shoot blight of pear), caused by the closely related pathogen *E. pyrifoliae*, is a fire blight-like disease that occurs in Korea and Japan.^[2]

Since the mid-19th century, fire blight has caused serious economic losses for apple and pear growers. In 1914 in Illinois, fire blight caused losses of apples and pears valued at \$1.5 million.^[3] From 1900 to 1910 the loss of pear trees resulting from the introduction of the bacterium to California was catastrophic; the U.S. Census indicated a 28% decline in total pear trees in California during this period.^[1] In 2000, a fire blight epidemic in Michigan caused the death of approximately 350,000 trees resulting in a total economic loss of \$42 million.^[4] These examples illustrate why fire blight is one of the plant diseases most feared by fruit growers.

SYMPTOMS

E. amylovora can infect blossoms, stems, immature fruits, woody branches, tree trunks, and root crowns. Infected

blossoms and peduncles first appear water-soaked or gray-green, then shrivel and turn brownish to black (Fig. 1A). Droplets of ooze (plant sap and *E. amylovora*) sometimes exude from the blossom peduncle. Similarly on immature fruit, symptomatic tissues first appear water-soaked and later become brown to black, with droplets of ooze frequently present (Fig. 1B). Symptoms on shoots generally appear first in young leaves with a blackening of the petiole and leaf midrib. Blackening will spread through the secondary veins, and the entire leaf blade will become necrotic. Blighted shoots often wilt and form a shepherd's crook (Fig. 1C). Stem tissue will shrivel and blacken. Droplets of ooze sometimes exude from stem or leaf petioles (Fig. 1D). In addition, aerial bacterial strands that can be dispersed by wind can form on stems. Necrosis can spread downward from infected blossoms, shoots, and fruits through the current season's growth and into older wood. Infected wood will appear shriveled or sunken and eventually turn dark brown to black. Abundant ooze can sometimes flow along the bark of infected branches, trunk, or the rootstock shank (Fig. 1E). In general, symptoms on apple appear brown and those on pear appear black.

In addition to Asian pear blight, other disorders with fire blight-like symptoms include pear blast, caused by *Pseudomonas syringae* pv. *syringae*; *Nectria* twig blight; European pear dieback, caused by *Phomopsis tanakae*; and damage resulting from the twig borer beetle (*Polycaon confertus*).

DISEASE EPIDEMIOLOGY

E. amylovora most commonly overwinters in fire blight cankers (infected woody tissue from the previous season). In spring, bacteria multiply at the margin between infected and healthy tissue. Usually only a small proportion of the cankers in an orchard will produce inoculum. Although the production of ooze is common, *E. amylovora* can be isolated from active cankers in the absence of ooze. In addition to cankers, bacteria have been reported to overwinter in dormant buds and in internal nonsymptomatic plant tissue (endophytic bacteria). Although contaminated planting material is an important factor in the

Fig. 1 Fire blight symptoms on apple and pear. A: infected pear blossoms (photo courtesy of Dr. Tom van der Zwet, USDA, ARS, AFRS, Kearneysville, WV); B: infected immature apple fruits with bacterial ooze (photo courtesy of Dr. Alan Jones, Michigan State Univ., East Lansing); C: blighted pear shoot with typical form of shepherd's crook (photo courtesy of Dr. Ken Hickey, The Pennsylvania State University, Biglerville); D: bacterial ooze exuding from infected apple shoot (photo courtesy of Dr. Alan Jones); and E: infected apple rootstock crown with abundant ooze. (View this art in color at www.dekker.com.)

introduction of the pathogen to new areas, infested buds and endophytic bacteria are not considered important sources of primary inoculum in orchards with a prior history of fire blight (Fig. 2).

During bloom, bacteria can be transferred from active cankers to blossoms by water (rain, irrigation, or dilute chemical sprays) or by insects (ants and flies). Bees are important in spreading bacteria among blossoms. In blossoms, *E. amylovora* can multiply on the surface of the

stigma without causing disease.^[5] Large epiphytic populations can develop when warm temperatures occur during bloom, enhancing the likelihood of blossom infection. Blossom infection usually occurs when bacteria are washed by rain to nectaries located in the hypanthium (floral cup), although other flower parts can also be invaded.^[2,5]

Much less is known about the process by which shoots become infected by *E. amylovora*. Shoot infection

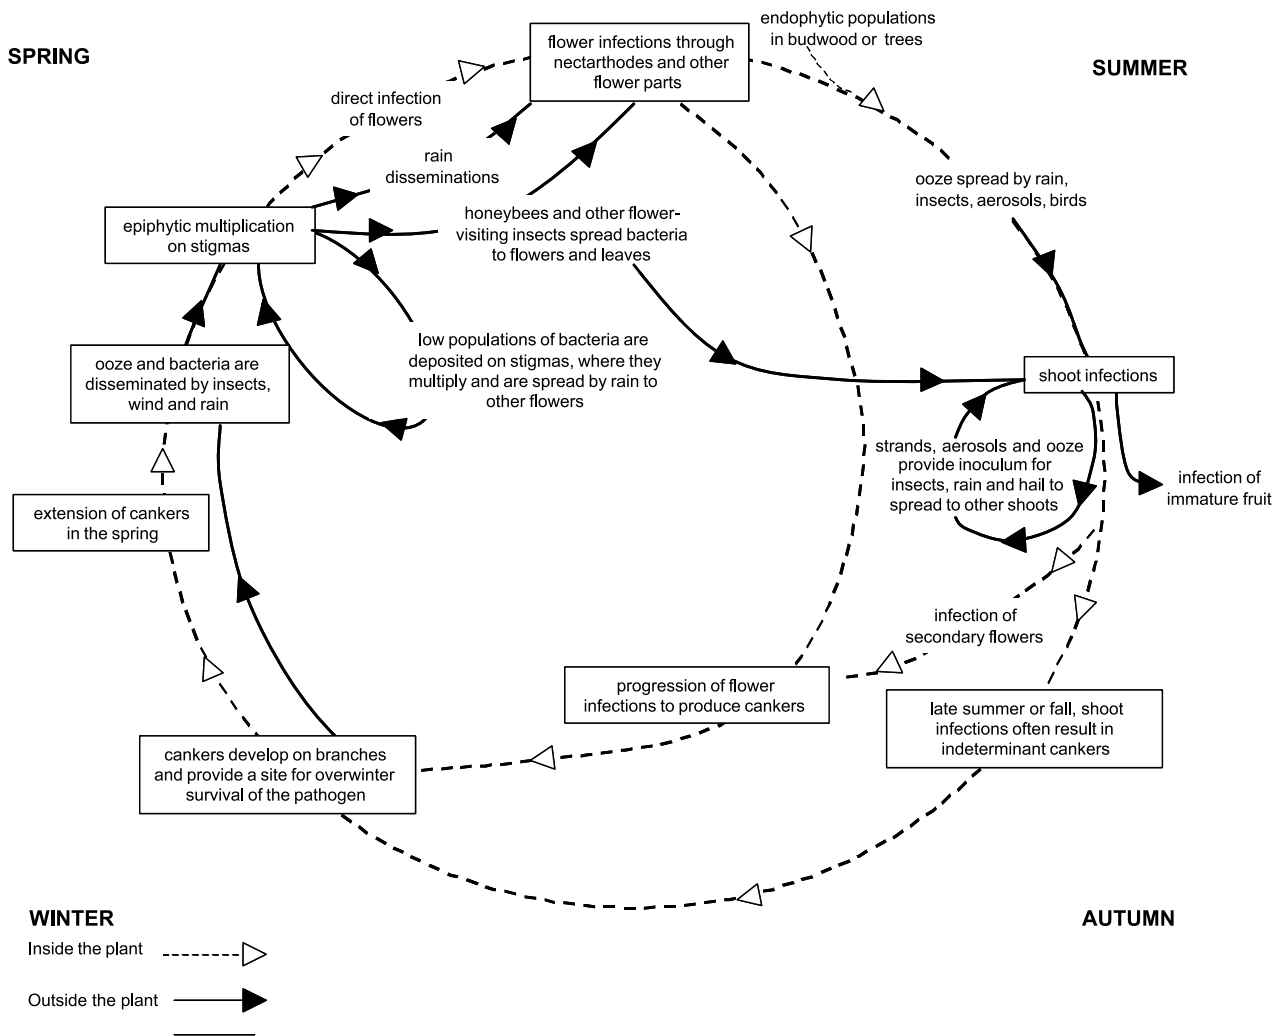

Fig. 2 Disease cycle of fire blight. (From Ref. 5.)

can occur following injury caused by hail or high winds if inoculum is present. *E. amylovora* can also move systemically from blossom infections to proximal shoots to initiate infection. Endophytic *E. amylovora* can also be isolated from more distal symptomless shoots; however, the role of endophytic bacteria in initiating new shoot infections is poorly understood. In addition, it is thought that insect feeding in the presence of inoculum can result in shoot infection.^[6] Although almost 100 species of insects have been reported to be associated with the dissemination of fire blight,^[2] there is a lack of information demonstrating the importance of specific species in the shoot-blight phase of the disease.

Recently, fire blight of apple rootstocks has become a serious economic problem in high-density orchards. Most apple growing regions have adopted the use of

high-density orchard systems that depend on dwarfing rootstocks to control tree size. The commonly used dwarfing rootstocks, Malling (M.) 9 and M.26, are highly susceptible to *E. amylovora*, and infection usually kills trees by girdling the rootstock. Several avenues of rootstock infection have been demonstrated, including infection of rootstock suckers (vegetative shoots developing from the rootstock), internal spread of endophytic bacteria, or direct infection of the rootstock through discontinuities in the bark caused by growth or various injuries.

Several terms refer to the various phases of fire blight. Blossom, shoot and rootstock infections are referred to as “blossom blight,” “shoot blight,” and “rootstock blight,” respectively. “Trauma blight” describes fire blight infections due to wounding by hail or high wind. “Canker blight” refers to the renewed activity of

overwintering cankers that can result in oozing from bark and infection of new shoot growth.^[7]

DISEASE MANAGEMENT

Despite the destructive potential of fire blight, it is sporadic in its occurrence. The disease can cause little damage in an area for several years, followed by severe epidemics once environmental conditions are favorable. Effective management of fire blight requires the integration of several practices aimed at reducing the amount of initial inoculum, imposing barriers to successful establishment of the pathogen, and reducing host susceptibility to infection.

Removal of cankers during winter pruning is a critical component of fire blight management. Management strategies also include the application of early-season copper sprays to reduce primary inoculum in the orchard and pruning out early season infections after bloom to reduce inoculum available for shoot infection.^[6]

Preventing blossom infection is also a critical component of fire blight management. Antibiotics are effective in preventing blossom infection, but must be applied precisely to coincide with fire blight infection periods. Several models including the Thomson mean temperature line, Maryblyt™, Cougar Blight, and the Billing Integrated System can predict the occurrence of blossom infection periods.^[8] In general, antibiotic applications are recommended during bloom when weather has been relatively warm and there is a high probability of rain and temperatures higher than 18°C in the next 24 hours. Although blossom blight control has relied heavily on antibiotic sprays, significant progress has been made in the biological control of blossom infection, and commercial products are currently available.^[9] In general, biological control agents should be applied during early bloom so they can become established prior to the occurrence of infection periods. Antibiotics are not recommended for the control of shoot infection due to their limited efficacy and to reduce the chance of antibiotic resistance developing within *E. amylovora* populations. However, antibiotic application is recommended following a hailstorm in orchards with fire blight infections.

Management practices that minimize excessive vegetative growth will reduce host susceptibility to *E. amylovora* infection. Gibberellin biosynthesis inhibitors that reduce shoot growth also reduce fire blight intensity.^[10] Excessive applications of nitrogen, including barnyard manure, should be avoided. Serious fire blight damage can usually be avoided by planting scion varieties and rootstocks with resistance. Unfortunately, current markets and production economics are encour-

aging the fruit industry to move in exactly the opposite direction.

CONCLUSION

After more than a century of research, a great deal is known about fire blight and its causal agent, *E. amylovora*, yet the disease remains a serious threat to the pome fruit industry. The ability of *E. amylovora* to infect different host tissues and the limited number of effective management practices make it difficult to stop or slow the progress of epidemics. In addition, the sporadic nature of the disease encourages growers to become lax in implementing costly control practices after long periods without serious fire blight outbreaks.

Due to the widespread use of streptomycin to control fire blight, streptomycin-resistant *E. amylovora* strains are now common in several regions of the United States.^[11] Finding alternative control agents to replace (or supplement) streptomycin is an important goal for future research. Currently, no effective cultural practices or chemical treatments are available to control the rootstock phase of fire blight. Development of apple rootstocks that combine desirable pomological characteristics with resistance to *E. amylovora* has the potential to provide practical control for rootstock blight in the future. Chemical treatments that enhance host resistance,^[10] biological control,^[9] and cultivars with genetically engineered resistance^[12] hold great promise for the future control of fire blight.

Fixed-Nitrogen Deficiency: Overcoming by Nodulation

Michelle R. Lum

Ann M. Hirsch

University of California, Los Angeles, California, U.S.A.

INTRODUCTION

One of the most studied symbioses is that between plants and bacteria of the gram-negative Rhizobiaceae (*Rhizobium*, *Azorhizobium*, *Sinorhizobium*, *Bradyrhizobium*, and *Mesorhizobium*). This association is restricted to the family Fabaceae, with the exception of *Parasponia* (Ulmaceae). The association culminates in the formation on plant roots of a novel organ, the nodule, that houses the bacteria in a protected and specialized environment. The bacteria provide fixed nitrogen to the plant in exchange for carbohydrates. Gram-positive, filamentous, actinomycetes (Frankiaceae) also engage in a symbiotic nitrogen association, but with actinorhizal plants, a diverse group of dicotyledons represented by eight different families. Nodules are again the key plant structure formed in response to the symbiosis. The benefits of these nitrogen-fixing symbioses have long been recognized. It is known that the Greeks engaged in agricultural practices utilizing leguminous plants as early as the 5th century B.C.

NITROGEN

Nitrogen is required for amino acid, nucleotide, protein, and nucleic acid production, necessary for the fundamental processes governing plant growth and development. However, soils become readily depleted of available nitrogen, particularly if nitrogen-containing plant parts are not plowed back into the field. Over 70% of the atmosphere is made up of molecular nitrogen (N_2). However, the triple bond holding the two nitrogen atoms together results in a very stable molecule. Only some prokaryotes—those that synthesize nitrogenase—fix N_2 and reduce it to ammonia (NH_3), which is then converted to nitrate (NO_3^-), a form used by plants. Most nitrogen in the fertilizer supplied to crop plants is in the form of NH_3 , produced by the energy-consuming Haber-Bosch process. However, the high cost associated with producing nitrogen fertilizer and the problems associated with its application (such as nitrification of the soil and runoff into water supplies) make biological nitrogen fixation significant, particularly in countries where fertilizers are not subsidized.

THE *Rhizobium*-LEGUME SYMBIOSIS

The process leading to the development of the nodule involves constant communication between the partners. Under nitrogen-limiting conditions, leguminous plants secrete flavonoids—phenolic compounds composed of two benzene rings linked by a heterocyclic pyran or pyrone ring. There are more than 4000 flavonoids, differentiated by the number of hydroxyl substituents, methyl groups, sugars, and other substituents (Fig. 1A).^[1] The release of flavonoids causes *Rhizobium* in the rhizosphere to be attracted to the plant roots. Specific flavonoids induce rhizobial *nod* genes, resulting in the production of Nod factor—monoacylated chains of 3–5 β -1,4 linked, N-acetyl glucosamines with various chemical modifications (Fig. 1B). Nod factor is the key signaling molecule produced by *Rhizobium* because it is absolutely required for progression of the symbiosis.^[2] Specific rhizobia attach to the plant root, causing root hair deformation, root hair curling, and 360° curls (shepherd's crooks). In addition, plant early nodulin (*ENOD*) genes are induced.^[3] An infection thread, through which the bacteria enter the root hair, is formed from the invagination of the plant plasma membrane accompanied by the deposition of cell wall material. Either inner or outer cortical cells of the root begin to divide and eventually the nodule develops (Fig. 2A, Figs. 3A and B). The infection thread elongates and branches within the newly divided cells, and the bacteria become endocytosed into infection droplets. In the differentiated parts of the nodule, the rhizobia develop into bacteroids and fix atmospheric nitrogen. The peribacteroid membrane (PBM) always separates the bacteria from the cytoplasm of the plant cell and is the location at which nutrient exchange occurs. The bacteroid, the PBM, and the interface between are referred to as the symbiosome (Fig. 2C).

THE *Frankia*-ACTINORHIZAL SYMBIOSIS

In contrast to legume nodules, in which the central infected tissue is surrounded by nodule parenchyma and peripheral vascular bundles (Fig. 2A), actinorhizal nodules resemble lateral roots, having a central vascular bundle. The peripheral infected tissue is surrounded by cortical

Fig. 1 Signal molecules involved in the *Rhizobium*-legume symbiosis. (A) Generic structure of flavonoids. R refers to the various substituents. (B) Generic structure of Nod factor; n = number of glucosamine residues in the backbone.

nodule parenchyma (Figs. 2B, 3C). Cell divisions that initiate the nodule primordium take place in the pericycle instead of the cortex. Root hair deformation and infection thread formation also characterize the *Frankia*-actinorhizal symbiosis; however, the early signals involved are not well understood, although flavonoids may be involved. In the nitrogen-fixing zone of the nodule, filament branches differentiate into specialized structures known as vesicles that express nitrogenase and fix nitrogen (Fig. 2D).^[4] To date, *Frankia* genes involved in establishing the nodule have not been identified.

VARIATIONS IN THE PROGRESSION OF THE SYMBIOSES

Entrance of the bacteria in both symbioses can occur by intercellular infection through gaps in the epidermis where

Scale bars (A, B) represent 100 μ M; scale bars (C, D) represent 10 μ M. (View this art in color at www.dekker.com.)

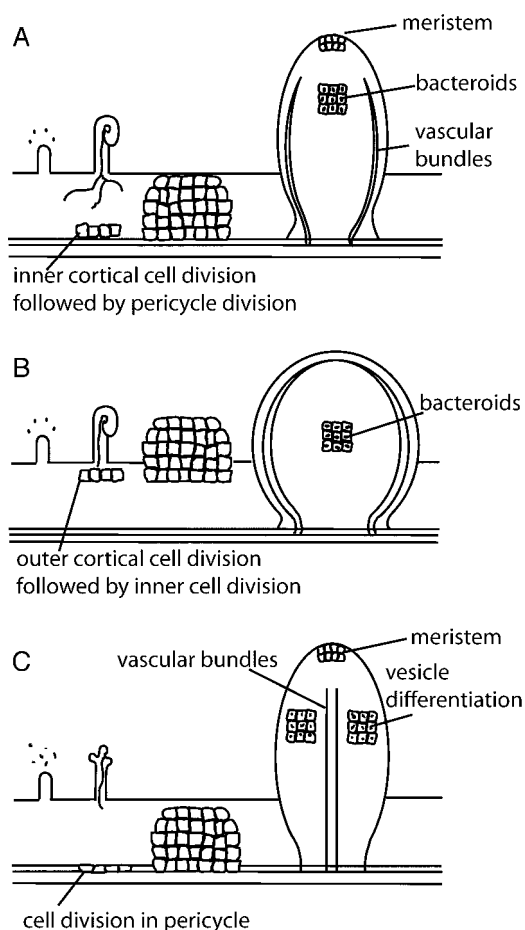

Fig. 3 Schematic of different types of nodules. (A) Indeterminate nodule in which the infected central tissue is surrounded by the nodule parenchyma and peripheral vascular bundles. (B) Determinate nodule in which cell divisions initiate in the outer cortex. (C) Actinorhizal nodule in which the central vascular bundle is flanked by infected cells and cell divisions originate from the pericycle. (Based in part on Ref. 5.)

lateral or adventitious roots emerge from roots or stems, or by penetration of the middle lamella of intact cells. *Parasponia*, the only nonlegume known to associate with *Rhizobium*, develops nodules that resemble modified lateral roots. Nodule morphology depends on the host. For example, indeterminate nodules are produced in *Medicago*, *Melilotus*, *Pisum*, and *Trifolium*, where initial cell divisions in the inner cortex (usually opposite the protoxylem pole) result in the formation of the nodule primordium (Fig. 3A). Because of a persistent nodule meristem, nodules are usually elongated. In contrast, *Phaseolus*, *Glycine*, and *Lotus* produce determinate nodules. Cell divisions initiate in the outer cortex, followed by division of the inner cortical cells. The nodule meristem stops dividing early in nodule development, resulting in a spherical nodule (Fig. 3B).

METABOLISM

Nitrogenase is highly sensitive to oxygen, and the nodule provides a specialized environment for rhizobia. Oxygen is maintained at low levels in the cell, partially due to nodule structure and to leghemoglobin, which acts as an oxygen scavenger. In contrast, *Frankia* bacteria provide oxygen protection for themselves via the lipid envelope that surrounds the nitrogen-fixing vesicles. In addition, the high rate of respiration in infected cells and the action of hemoglobin may limit the presence of oxygen.^[6]

The peribacteroid membrane that surrounds the bacteroids is the site of nutrient exchange in the rhizobia-legume symbiosis. Channels have been identified that catalyze the transport of fixed nitrogen to the plant, which is then fed into the glutamine/glutamate synthase cycle. Nitrogen is subsequently transferred to the rest of the plant through the vascular system. Carbohydrates are imported to bacteroids as dicarboxylic acids by active transporters found in the bacteroid membrane.^[7]

The details of nitrogen and carbon metabolism and transport in the actinorhizal symbiosis are not as well defined. However, in both symbioses, carbon is critical for energy and reducing power. Globally, the nitrogen contribution by the *Rhizobium*-legume symbiosis is an estimated 24–584 kg N ha⁻¹ y⁻¹, whereas the *Frankia*-actinorhizal symbiosis contributes 2–362 kg N ha⁻¹ y⁻¹.^[8]

EVOLUTIONARY ASPECTS

All the plant species that engage in nitrogen-fixing nodule symbioses are members of the Rosid I clade. Thus evolutionarily, there appears to be a single origin for the plant's susceptibility to entrance by bacteria.^[9] However, nodulation may have multiple origins of evolution, as

indicated by varying nodule morphology and infection methods used by different hosts. Within the Rosid I clade, there are four major lineages of nodulating plants:^[10] One encompasses legumes and the others consist of nonlegumes, including the actinorhizal families Casuarinaceae and Myricaceae, as well as the rhizobia-nodulated *Parasponia*. Within the three subfamilies of the Fabaceae—the Papilionoideae, Mimosoideae, and Caesalpinioideae—over 80% of the first two groups nodulate, whereas less than 25% nodulate in the more basal Caesalpinioideae. Based on phylogenetic analysis of *rbcL*, nodulation may have had three evolutionary origins: at the base of the papilionoids, prior to the evolution of the mimosoids, and in the branch leading to *Chamaecrista*, one of the few caesalpinoid genera that nodulates.^[9]

CONCLUSION

Nitrogen is critical for plant growth and development, and some plants have the advantage of engaging in a symbiotic association with nitrogen-fixing bacteria. Interaction with rhizobia is primarily restricted to legumes, but *Frankia* bacteria associate with different dicotyledonous families. Both types of symbioses culminate in the formation of a novel plant organ, the nodule. Although nodule structure and the form in which the bacteria fix nitrogen varies between the symbioses, an evolutionary predisposition for nodulation seems likely. Advances made in determining the common mechanisms involved in both associations will further our understanding of biological nitrogen fixation.

Floral Induction

Joseph Colasanti

University of Guelph, Guelph, Ontario, Canada

INTRODUCTION

The switch from vegetative to reproductive growth signifies an important change in the life cycle of higher plants. In terms of agricultural production, coordinated timing of the transition to flowering is essential for optimal fruit set and seed production. Numerous physiological studies based on specific floral inductive treatments have defined key features of the transition event. Yet, despite the importance of understanding flowering time and the large amount of research devoted to its study, there is much to be learned about the genetic and biochemical signals that underlie the transition to reproductive growth. Recent molecular genetic approaches are yielding insights about the genes that control floral induction.

THE NATURE OF THE FLORAL INDUCTION EVENT

By observing plants growing throughout a season cycle it seems obvious that flowering time is synchronized with environmental cues. Most plants flower at a particular time in the season, often in the spring or summer in temperate climates, in order to produce the next generation of progeny before harsh winter conditions ensue. It was assumed that the reason for this seasonal timing of flower formation was due to an increase in photoassimilate production resulting from longer days. However, in the early 1920s Garner and Allard first reported a genetic connection between flower induction and environmental cues, and suggested the causes of flowering were more complex than the buildup of resources to a critical level.^[1] They discovered a mutant of tobacco, Maryland Mammoth, that flowers only when plants are exposed to short days. The discovery of this phenomenon, which they called photoperiodism, prompted physiologists to classify plants as either short-day plants (SDPs), long-day plants (LDPs), or day-neutral plants (DNPs). SDPs and LDPs require a critical length of night or day, respectively, to induce flowering, whereas DNPs flower regardless of the photoperiod to which they are exposed. Plants that do not flower unless they receive an inductive photoperiod are termed obligate SDPs or LDPs. Most plants are facultative

SDPs or LDPs; that is, flowering time is accelerated by inductive photoperiods, but even in the absence of such treatment they will flower eventually.

The identification of photoperiod-responsive plants provided physiologists with a tool that allowed them to apply precise inductive stimuli and then evaluate the flowering response in a quantitative way. Numerous experiments based on this premise were carried out with both SDPs and LDPs in an attempt to determine the nature of the floral stimulus. The ability to graft parts of induced plants to uninduced plants, and to apply specific photoperiod treatments to individual leaves, was particularly useful in dissecting the mechanisms of the flowering process (Fig. 1). Based on these compelling studies, several important features of floral induction were elucidated. First, it was confirmed that the shoot apex is the target of the floral stimulus and, for floral evocation to occur, the shoot apex must become competent to receive the floral stimulus. Another significant finding is that the floral stimulus originates in leaves and is transported to the shoot apex. Grafting experiments indicated that the floral stimulus had properties of a substance with a measurable mobility that is transported only through living tissue. Therefore the phloem—in addition to its role of transporting photoassimilates from source to sink tissues—also acts as a conduit for flower-inducing signals. Given these characteristics, and in light of the discovery that plant-growth regulators such as gibberellins and auxin are relatively simple chemical compounds, attempts were made to isolate this putative flower-inducing compound, sometimes referred to as “florigen.” Although these studies generated a considerable body of data supporting the mechanism of action of the floral induction process, the biochemical nature of the floral stimulus remained elusive.^[2]

MUTATIONS THAT AFFECT FLORAL INDUCTION

While the search for the floral stimulus continued, studies with garden pea investigated the genetic basis of floral induction. The ability to graft peas, and the availability of a variety of mutants defective in various aspects of the transition to flowering, reinforced the findings of

physiological studies that a leaf-generated floral stimulus moved to the shoot apex.^[3] Studies of pea mutants with altered flowering times laid the groundwork for molecular genetic studies in other species. In particular, many mutations that affect flowering time have been characterized in the small crucifer *Arabidopsis thaliana*. Genetic analysis of these mutants has allowed the construction of a model of floral induction that incorporates previous findings of physiologists. The *Arabidopsis* model divides the floral induction process into two basic components: the endogenous pathway and the environmental pathway (Fig. 2). Endogenous signals include properties intrinsic to plant growth such as size, leaf number, and age. DNPs probably utilize these factors when assessing the appropriate time to flower. Environmental signals such as photoperiod or temperature play a critical role in informing the plant that the correct season for flowering has arrived. Genetic studies of *Arabidopsis* have identified genes that act in the endogenous pathway, the environmental pathway, or both (discussed later).

As with past physiological studies, much of the recent work with *Arabidopsis* has focused on the genes that act in the environmental pathway. Genes that regulate photoperiod, light perception, and circadian rhythms have been studied extensively.^[4] Significant progress has been made in establishing that photoreceptors such as phytochromes and cryptochromes are important links between the photoperiod signals and the ultimate floral inductive response. Temperature perception is another facet of the environmental pathway, and a web of interacting genes that coordinate regulation of the vernalization response is being revealed. Vernalization plays a critical role in signaling the correct season to flower in important crops such as wheat.

Genes that regulate gibberellic acid (GA) biosynthesis are essential components of the endogenous pathway in *Arabidopsis* and other plants. However, the role GA plays

Fig. 1 Floral induction by exposing single leaf to short days. Left: a short-day (SD) plant grown under long-day (LD) conditions continues to grow vegetatively. Center: if given short-day inductive treatments (SD) the plant will flower. Right: an SD plant grown under long days but with one leaf (shaded box) exposed to inductive short days will flower (LD+). in controlling flowering in many other plant species is uncertain. Because it is not a universal inducer of flowering, and because it is not expressed exclusively in leaves in response to inductive external signals, GA does not possess the traits required of the presumed mobile floral stimulus. More likely, GA acts as an accessory to the floral inductive response in certain species. Overall, the genetic control of the endogenous signaling pathway is less well understood than the environmental pathway.

INSIGHTS ABOUT THE MOLECULAR NATURE OF THE FLORAL STIMULUS

Arabidopsis is the first plant to have its genome sequenced and it has become a valuable model for the molecular genetic dissection of the floral induction process.^[5,6] Many of the genes that control flowering in *Arabidopsis* have been isolated and their gene products identified. In some cases the functional equivalents of *Arabidopsis* flowering-time genes have been found in other plants, including important crop plants such as rice^[7] (Table 1). Several *Arabidopsis* flowering-time genes were found to encode regulatory proteins; that is, they function by controlling the expression of other genes. Some of the first genes isolated in *Arabidopsis* were found to encode proteins that appear to function as regulators of other genes. For example, *CONSTANS* (*CO*), one of the most intensely studied *Arabidopsis* genes, encodes a transcription factor that has been found to directly activate the expression of genes involved in the transition to flowering.^[6] The *CO* gene plays an important role in transducing

Table 1 Genes from different species that control flowering time

Gene ^a	Species	Flowering phenotype ^b	Possible role of gene product	Pathway	Mechanism of action
<i>CO</i>	Arabidopsis	Late	Transcription	Photoperiod	Perceives circadian rhythms, activates genes
<i>LD</i>	Arabidopsis	Late	Transcription	Endogenous	Activates genes
<i>CRY2</i>	Arabidopsis	Late	Photoreceptor	Photoperiod	Perceives blue light
<i>EMF1</i>	Arabidopsis	Early	Transcription	Endogenous	Unknown

<i>Hd1</i>	Rice	Early	Transcription	Photoperiod	Perceives photoperiod
<i>Hd6</i>	Rice	Early	Kinase	Photoperiod	Photoperiod perception
<i>id1</i>	Maize	Late	Transcription	Endogenous	Regulates leaf derived mobile floral stimulus

^a*CO*, *CONSTANS*; *LD*, *LUMINEDEPENDENS*; *CRY2*, *CRYPTOCHROME 2*; *EMF1*, *EMBRYONIC FLOWER 1*; *VRN2*, *VERNALIZATION 2*; *Hd1* and *Hd6*, *Heading Date 1* and *6*, respectively; *id1*, *indeterminate 1*.

^bPhenotypes are for loss of function alleles.

(From Refs. 5 and 10.)

photoperiod signals; thus, loss of *CO* gene function results in mutants that do not flower early under the long day conditions that accelerate flowering in wild type Arabidopsis. The importance of the *CO* gene in controlling flowering may extend to other species as well. Recently a gene in rice that controls flowering time (or *heading date*), *Hd1*, was found to encode a protein with similarity to *CO*. Like *CO*, *Hd1* acts in a pathway that senses day length, although the exact mechanism of its action is still being determined.

Other genes that may act as gene regulators were found in the vernalization pathway as well. Most recently it was

discovered that the Arabidopsis *VRN2* gene encodes proteins that affect gene expression by controlling chromatin structure.^[5] Given the widespread changes associated with the transition to flowering, it might be expected that mutations in important regulatory genes, such as transcription factors, might have the greatest effect on the transition to flowering.^[8] Discovering the genes controlled by these regulators is a crucial first step in revealing the metabolic and biochemical changes associated with the transition to reproductive growth.

Analysis of Arabidopsis flowering time mutants has generated a complex model that includes both

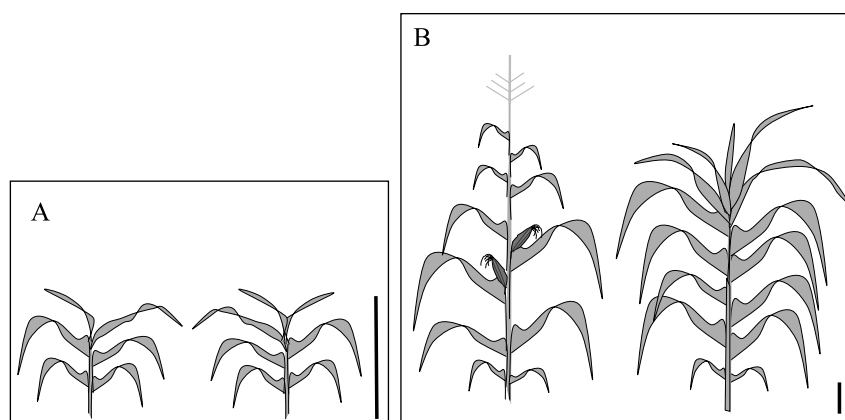

Fig. 3 Comparison of normal and *id1* mutant maize. A. Drawing of maize seedlings at seedling stage (about 3 weeks). Normal plant on the left, *id1* mutant plant on the right. Mutant and normal plants are indistinguishable at this early seedling vegetative stage of growth. B. Mature maize plants (about 12 weeks). A normal plant (left) has made a tassel and ears (male and female inflorescences, respectively) and fertilization has occurred. An *id1* mutant (right) continues to grow vegetatively. (Scale: bar = approx. 30 cm.) (View this art in color at www.dekker.com.)

environmental and endogenous elements in the control of floral induction.^[5,6] However, so far this model provides no explicit clues about the nature of the floral stimulus. Analysis of a flowering time mutant in maize, *indeterminate1* (*id1*), may lead to a better understanding of the floral stimulus. Maize plants that have lost *id1* gene function remain in a prolonged state of vegetative growth and flower extremely late (Fig. 3). As was found with many Arabidopsis flowering time genes, the *id1* gene encodes a transcriptional regulator.^[9] However, unlike the Arabidopsis regulatory genes that control flowering time, the *id1* gene is unique in that it is expressed only in maize leaves, and not at the shoot apex. Therefore the ID1 protein may regulate the expression of genes that mediate the production and/or transmission of a leaf-derived floral stimulus.^[10] The maize *id1* gene is also unique in that it does not appear to have a functional equivalent in Arabidopsis. Therefore *id1* may be a flowering time regulator unique to maize, or perhaps grasses in general.

CONCLUSION

Physiological studies have established a solid framework for understanding the floral induction process, and genetic analysis reveals many loci with specific roles in regulating the transition to flowering. Significant progress has been made in identifying genes that are important regulators of the endogenous and environmental signals that bring about the onset of flowering. Further progress will rely on comparisons of normal and nonflowering plants in order to establish the biochemical and metabolic profiles associated with the flowering transition. Understanding how floral inductive signals are produced, perceived, and transmitted could eventually reveal intricate connections between basic plant processes such as general metabolism, nutrient flow, and source/sink relations in plants. The ability to control time to flowering, or to prevent it completely, could have significant agricultural applications.

Floral Scent

Natalia Dudareva

Purdue University, West Lafayette, Indiana, U.S.A.

INTRODUCTION

Flowers of many plants attract pollinators by producing and emitting volatile compounds, which belong to a broad category of secondary metabolites. Floral scent is a key modulating factor in plant–insect interactions and plays a central role in successful pollination, and thus in fruit development, of many crop species. The composition and total output of floral scent changes during the life span of the flower in relation to flower age, pollination status, environmental conditions, and diurnal endogenous rhythms. Biochemistry, physiology, and molecular biology of floral scent, as well as molecular mechanisms controlling its accumulation and release, are discussed in this article with regard to implications for future directions in this field.

FLORAL SCENT AND ITS IMPORTANCE

Floral scent is typically a complex mixture of low molecular weight compounds [100–200 (Daltons)] emitted by flowers into the atmosphere. The relative abundances of and interactions between these compounds give the flower its unique, characteristic fragrance. Flowers of many plant species produce floral scent to attract pollinators. Volatiles emitted from flowers function as both long- and short-distance attractants and play a prominent role in the location and selection of flowers by insects, especially in moth-pollinated flowers, which are detected and visited at night.^[1] To date, little is known about how insects respond to individual components found within floral scents, but it is clear that they are capable of distinguishing complex scent mixtures. In addition to attracting insects to flowers and guiding them to food resources within the flower, floral volatiles are essential in allowing insects to discriminate among plant species and even among individual flowers of a single species. Closely related plant species that rely on different types of insects for pollination produce different odors, reflecting the olfactory sensitivities or preferences of the pollinators. By providing species-specific signals, flower fragrances facilitate an insect's ability to learn particular food sources, thereby increasing its foraging efficiency. At the same time, successful pollen transfer and thus,

sexual reproduction—which are beneficial to plants—are ensured. About 73% of cultivated plant species is pollinated at least partially by a variety of bees; many others are dependent on other pollinators such as flies, beetles, butterflies, moths, or other animals.^[2] Moreover, one-third of our total diet depends, directly or indirectly, on insect-pollinated plants including most fruit trees, berries, nuts, oilseeds, and vegetables. Pollination not only affects crop yield, but also the quality and efficiency of crop production. Many crops require most, if not all, ovules to be fertilized for optimum fruit size and shape (e.g., apple, berries, and watermelon). A decrease in fragrance emission reduces the ability of flowers to attract pollinators, whereas intensifying the flower odor can increase the pollinator's recruitment rate. In addition, floral scent plays a significant role in the food, flavor, floriculture, cosmetic, and fragrance industries.

Some volatile compounds found in floral scent also have important functions in vegetative processes.^[3] They may attract natural predators to herbivore-damaged plants. As a consequence, some plants reduce the number of herbivores more than 90% by releasing volatiles.^[4] They may also function as repellents against herbivores or as airborne signals that activate disease resistance via the expression of defense-related genes in neighboring plants and in the healthy tissues of infected plants.

BIOCHEMISTRY OF FLORAL SCENT

The investigation of the chemical composition of floral scents has been conducted by headspace analysis.^[5] In this procedure, a flower that is still connected to the rest of the plant is placed inside a small glass or plastic chamber and its emitted volatiles are collected by continually purging the air inside the chamber through a cartridge packed with polymer that binds these volatiles. After a fixed period of time, trapped volatiles are extracted from the cartridge with an organic solvent (a variation of this procedure—the highly sensitive solid phase microextraction method, or SPME—allows for “instant” sampling of headspace volatiles).^[6] The eluted solution is injected into a gas chromatograph that separates the different volatiles, and then each volatile is identified by mass spectrometry.

Headspace analysis in combination with gas chromatography and mass spectrometry have revealed over 700 compounds from 441 taxa in 174 genera in 60 plant families.^[7] Floral fragrances belong to a broad category of secondary metabolites and are dominated by terpenoids (monoterpenes and sesquiterpenes), phenylpropanoid, and benzenoid compounds. Fatty acid derivatives and a range of other chemicals, especially those containing nitrogen or sulfur, are also sometimes present. Each of these classes is, in turn, represented by compounds having different functional groups, e.g., hydrocarbons, alcohols, aldehydes, ketones, acids, ethers, and esters.^[7] Terpenoids are synthesized from isopentenyl diphosphate by different mono- and sesquiterpene synthases.^[8] Phenylpropanoids, including benzenoids, derive from L-phenylalanine through the action of the pivotal enzyme phenylalanine ammonium lyase. Although the biosynthetic pathways to these volatile compounds have not yet been completely characterized, common modifications such as hydroxylation, acetylation, and methylation reactions have been described. Other fragrance compounds, such as short-chain alcohols and aldehydes, are formed by metabolic conversion or degradation of phospholipids and fatty acids

through the concerted action of lipoxygenases, hydroperoxide lyases, isomerases, and dehydrogenases.

The chemical composition of flower fragrances varies widely among species in terms of the number, identity, and relative amounts of constituent volatile compounds^[7] and is correlated with the type of visiting pollinators. Species pollinated by bees and flies have sweet scents, whereas those pollinated by beetles have strong musty, spicy, or fruity odors.^[1] The most common constituents of floral scents (Fig. 1) are monoterpenes (linalool, limonene, myrcene, trans- β -ocimene, and geraniol); some sesquiterpenes (farnesene, nerolidol, caryophyllene, and germacrene); and benzenoid compounds (benzylacetate, eugenol, (iso)methyl Eugenol, methylsalicylate, and methylbenzoate).

PHYSIOLOGY OF FLORAL SCENT

In the flowers of many plant species the petals are the principal emitters of volatiles, although various other parts of the flower may also participate in fragrance emission.^[1,9] Whereas the same floral scent components are often emitted from all parts of the flower (although not

Fig. 1 Structures of representative floral scent volatile compounds.

necessarily the same amount or at the same rate), sometimes specific compounds may be emitted from only a subset of the floral organs. Some plants—orchids for example—have developed highly specialized anatomical structures, called scent glands (i.e., osmophores), for fragrance production; in other plants, the nonspecialized floral epidermal cells are recruited for scent production and emission.^[3]

The composition of floral scent—as well as total output—changes during the life span of the flower. These changes occur in relation to flower age, pollination, environmental conditions, and diurnal endogenous rhythms.^[9] Plants tend to have their scent output at maximal levels only when the flowers are ready for pollination and concomitantly when their potential pollinators are active. During flower development newly opened and young flowers, which are not ready to function as pollen donors because their anthers have not yet dehisced, produce fewer odors and are less attractive to pollinators than older flowers.^[9] Once a flower has been sufficiently pollinated, quantitative and/or qualitative changes of floral bouquets lead to lower attractiveness of these flowers and help to direct pollinators to the unpollinated flowers, thereby maximizing the reproductive success of the plant. The rhythmic release of flower scent during the daily light/dark cycle generally coincides with the foraging activity of potential pollinators. Plants that are pollinated by insects with maximum activity during daytime (e.g., bees) show a diurnal rhythmicity, whereas flowers pollinated by nocturnal insects such as moths tend to have maximal scent output during the night. While the circadian clock controls the nocturnal emission

of volatiles, daytime emission in most cases is noncircadian and controlled by irradiation levels. However, circadian control of fragrance production has been shown for rose and snapdragon, both diurnally emitting plants.

MOLECULAR BIOLOGY OF FLORAL SCENT

Whereas the chemistry of plant volatiles is well understood, less is known about the biosynthesis of this diverse group of compounds. The initial breakthrough began in 1994 when (S)-linalool synthase (LIS), an enzyme responsible for the formation of the acyclic monoterpene linalool, was purified from *Clarkia breweri* flowers. This first enzyme of floral volatile formation provided information on an amino acid sequence that facilitated the isolation of the corresponding gene. A similar protein-based cloning strategy was used for isolation of four additional genes (Table 1): S-adenosyl-L-methionine (SAM):(iso) eugenol O-methyl transferase (IEMT), acetyl-coenzyme A:benzyl alcohol acetyltransferase (BEAT), S-adenosyl-L-methionine:salicylic acid carboxyl methyl transferase (SAMT), and S-adenosyl-L-methionine:benzoic acid carboxyl methyl transferase (BAMT), which encode the enzymes responsible for the formation of methyl(iso)eugenol, benzylacetate, methylsalicylate, and methylbenzoate, respectively.^[3] All of these genes were isolated from *C. breweri*, except for BAMT, which was cloned from flowers of snapdragon in which methylbenzoate is one of the major fragrance compounds. The isolation of genes responsible for the formation of

Table 1 Current isolated and characterized genes involved in floral scent production^a

Gene	Product	Species	Approach used
Linalool synthase (LIS)	(S)-Linalool	<i>Clarkia breweri</i>	Protein-based cloning
S-adenosyl-L-methionine: (iso) eugenol O-methyl transferase (IEMT)	Methyl(iso)eugenol	<i>Clarkia breweri</i>	Protein-based cloning
acetyl-coenzyme A:benzyl alcohol acetyltransferase (BEAT)	Benzylacetate	<i>Clarkia breweri</i>	Protein-based cloning
S-adenosyl-L-methionine:salicylic acid carboxyl methyl transferase (SAMT)	Methylsalicylate	<i>Clarkia breweri</i>	Protein-based cloning
S-adenosyl-L-methionine:benzoic acid carboxyl methyl transferase (BAMT)	Methylbenzoate	<i>Antirrhinum majus</i>	Protein-based cloning
Benzoyl-coenzyme A:benzyl alcohol benzoyl transferase (BEBT)	Benzylbenzoate	<i>Clarkia breweri</i>	Functional genomic

Orcinol O-methyl transferase (OOMT1 and OOMT2)	Orcinol dimethyl ether (3,5-dimethoxytoluene)	<i>Rosa hybrida</i>	Functional genomic
Germacrene D synthase	Germacrene D	<i>Rosa hybrida</i>	Functional genomic

^aFunction of the gene was confirmed by overexpression in *Escherichia coli*.

floral scent volatiles allowed investigation of the regulation of scent biosynthesis. It has been shown that the flowers synthesize scent compounds *de novo* in the tissues from which these volatiles are emitted. The emission levels, corresponding enzyme activities, and the expression of genes encoding scent biosynthetic enzymes are all temporally and spatially regulated during flower development. Although highest in petals, expression of scent genes is relatively uniform and restricted to surfaces of floral tissues (epidermal cells), from which volatile compounds can easily escape into the atmosphere after being synthesized. Transcriptional regulation of the expression of these genes at the site of emission and the level of supplied substrates for the reactions were found to be the major factors controlling scent production, and indirectly, scent emission during flower development. When regulation of rhythmic emission of methylbenzoate was investigated, it was found that the level of substrate (benzoic acid) also plays a major role in the regulation of circadian emission of methylbenzoate in diurnally (snapdragon) and nocturnally (*Petunia* cv Mitchell and *Nicotiana suaveolens*) emitting flowers.

FUTURE DIRECTIONS IN FLORAL SCENT

Research into floral scent genes using high throughput technologies has recently been initiated in *C. breweri*, snapdragon, and rose.^[10] These projects combine detailed fragrance analyses with the creation of petal expressed sequence tag (EST) databases. In addition, the *Escherichia coli* expression system allows rapid functional characterization of fragrance genes. The integration of a functional genomic approach with floral scent research will lead to high-throughput identification of novel scent genes. Indeed, this approach has already successfully accelerated discovery and characterization of new scent genes in *Clarkia*, roses, and snapdragon (Table 1). The identification of genes for the production of floral scent opens up new opportunities for its manipulation, which would have great economic impact on ornamentals that have reduced floral scent due to decades of classical breeding.

Flow Cytogenetics

Jaroslav Doležel
Marie Kubaláková
Jan Vrána
Jan Bartoš

Institute of Experimental Botany, Olomouc, Czech Republic

INTRODUCTION

Flow cytogenetics uses flow cytometry and sorting to classify and purify isolated mitotic chromosomes. The chromosomes are analyzed while moving at high speed in a liquid stream. This gives high resolution and statistical precision, because large populations of chromosomes can be analyzed in a short time. Flow sorting allows purification of large quantities of specific chromosomes according to their fluorescence, which can be used for physical genome mapping, production of recombinant DNA libraries, and protein analysis. Chromosome classification by flow cytometry (flow karyotyping) may be used to detect structural and numerical chromosome changes.

PRINCIPLES

Flow Cytometry

Flow cytometry involves the optical analysis of microscopic particles, constrained to flow in single file within a fluid stream (sheath fluid) through a narrow beam of excitation light (Fig. 1). During the short time each particle is in the light beam, the light is scattered and fluorescent molecules bound to the particle are excited. The scattered light and the fluorescence are collected, spectrally filtered through dichroic mirrors and filters, and converted to electrical pulses by photodetectors. The rate of analysis ranges from hundreds to thousands of particles per second. Flow sorters can, in addition, remove any selected particle from the suspension. The liquid stream emerging from the flow chamber into air is broken into droplets by the action of a vibrating transducer. Droplets containing particles of interest are electrically charged as they separate from the stream and are deflected by passage through an electric field. Charges can be negative or positive, so that two categories of particles can be sorted simultaneously.

Preparation of Chromosome Suspensions

Preparation of an aqueous suspension of intact, dispersed chromosomes consists of induction of cell-cycle synchrony,

accumulation of cells in metaphase, and release of chromosomes into isolation buffer.^[1] Chromosomes have been isolated from suspension-cultured cells, leaf mesophyll protoplast cultures, and root-tip meristems.^[2] Because root-tip cells are karyologically stable and roots can be easily obtained from seeds,^[3] these have been used most frequently. Cell-cycle synchrony is induced by treatment with a DNA synthesis inhibitor that accumulates cycling cells at the G₁/S interface. After its removal, the cells transit S and G₂ phases and enter mitosis synchronously, where they are accumulated at metaphase by the action of a mitotic spindle inhibitor. Intact chromosomes are released from metaphase cells either by hypotonic lysis of protoplasts prepared by enzymatic removal of cell walls, or by mechanical tissue homogenization.^[1,3] The latter is more popular, because it is rapid and suitable for root tips.

Flow Cytometric Analysis

Chromosomes in suspension are stained with a DNA-binding fluorochrome and classified according to their relative DNA content.^[2] The result is displayed as a histogram of relative fluorescence intensity (flow karyotype). Ideally, each chromosome is represented by a single well-discriminated peak on the flow karyotype. Chromosomes can also be stained by a pair of fluorochromes that bind preferentially to A + T-rich and G + C-rich DNA, and classified by DNA base composition.^[2] Bivariate flow karyotypes thus obtained may be displayed as contour plots, dot plots, or isometric plots. However, due to negligible differences in DNA base content between chromosomes, bivariate flow karyotyping has not often been used in plants. Another possibility is to classify chromosomes according to the number of copies of DNA repeats after fluorescent labeling.

Chromosome Sorting

To sort a specific chromosome, its peak is selected on a flow karyotype and marked as a sort window. In most plant species, only a few chromosome types can be resolved; the others form overlapping composite peaks. Translocation lines, deletion lines, and chromosome addition lines can be

Fig. 1 Schematic view of a flow cytometer and electrostatic droplet sorter capable of simultaneous analysis of two fluorescence signals and forward-scattered light. Two categories of particles may be sorted simultaneously.

used to overcome this problem.^[4] The usefulness of a sorted chromosome fraction depends on its purity, which is primarily determined by the resolution of the chromosome peak (the degree of overlap with other peaks), and by the presence of clumps and fragments in the chromosome suspension. Simultaneous analysis of light scatter and chromosome length helps to discriminate such particles. Purities >95% have been achieved. The rate at which a chromosome can be sorted depends on its frequency of occurrence and the resolution of its peak; it is possible to purify specific plant chromosomes at rates up to 20 per second. The identity and purity of sorted chromosomes are best determined microscopically after labeling the DNA repeats, which allows unambiguous chromosome identification (Fig. 2).^[5] Microscopic analysis is usually complemented by polymerase chain reaction (PCR) with primers for chromosome-specific markers.

APPLICATIONS

Flow Karyotyping

Flow karyotyping was first developed for *Haplopappus gracilis*^[6] and subsequently for a number of species,

including economically important legumes and cereals.^[4] Flow karyotyping provides unbiased, representative data on the frequency of occurrence of individual chromosome types. As the peak position on the abscissa of the flow karyotype reflects chromosome DNA content, and peak area reflects the frequency of occurrence of that chromosome, both structural and numerical chromosome aberrations can be detected. Successful applications include quantitative analysis of the frequency of occurrence of B chromosomes, and identification and transmission stability of translocation chromosomes, deletion chromosomes, and alien chromosomes in chromosome addition lines (Fig. 2). Flow karyotyping can identify structural chromosome changes that result in detectable changes in DNA content. The method is sensitive enough to detect chromosome polymorphism in wheat.^[7]

Chromosome Sorting

Chromosome sorting has proven useful for assigning peaks on the flow karyotype to specific chromosomes, and for preparation of purified chromosome fractions. Because most agricultural plant species have complex genomes, chromosome sorting facilitates their analysis. Flow-sorted chromosomes have been used for physical mapping of

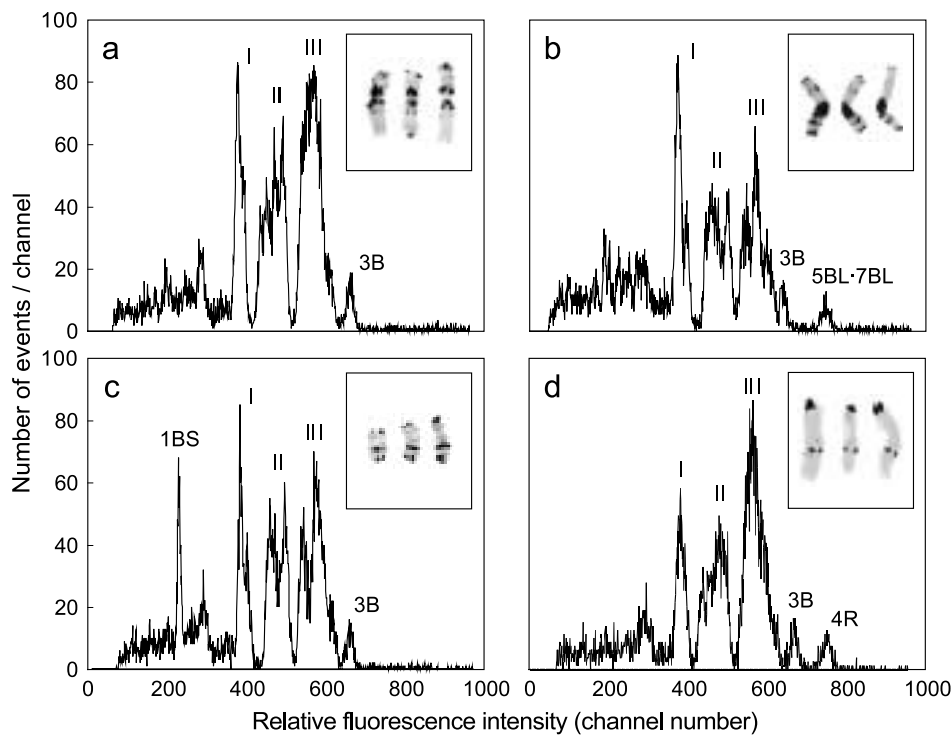

Fig. 2 Flow karyotypes obtained after analysis of 4', 6-diamino-2-phenylindole (DAPI)-stained chromosome suspensions from three hexaploid ($2n=6x=42$) wheat lines (a–c) and from a wheat–rye chromosome addition line (d). (a) The “Chinese Spring” karyotype contains three composite peaks (I–III) representing groups of chromosomes that cannot be discriminated individually, and a peak representing chromosome 3B. (*Insert*: chromosomes 3B after GAA banding); (b) “Cappelle Desprez” has three composite peaks (I–III) and well-discriminated peaks representing 3B and translocation chromosome 5BL·7BL. (*Insert*: chromosomes 5BL·7BL after GAA banding); (c) “Pavon,” ditelosomic for 1BS, shows three composite peaks (I–III), the peak of 3B, and a clearly discriminated peak of 1BS. (*Insert*: GAA-banded 1BS); (d) The peak of rye chromosome 4R is well-discriminated on the flow karyotype of the “Chinese Spring”/“Imperial” addition line (*insert*: chromosome 4R after FISH with a probe for pSc119.2 repeat.)

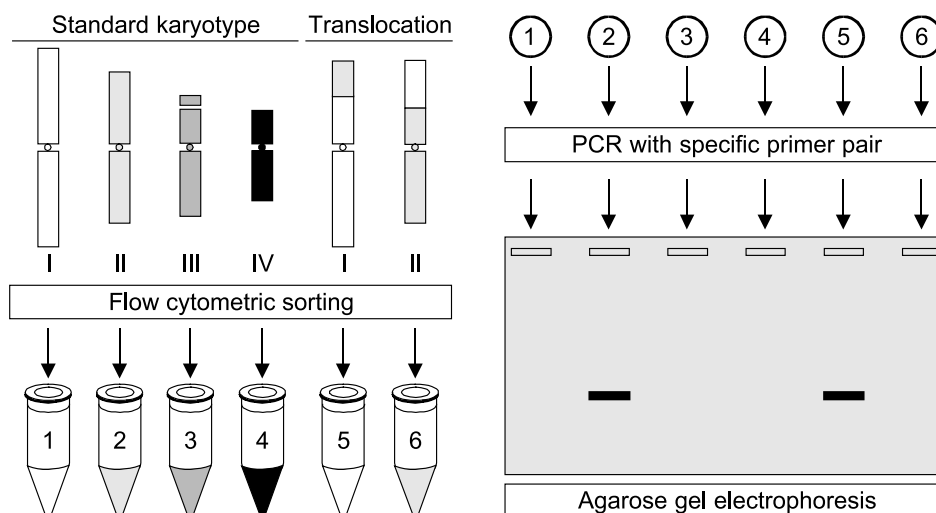

Fig. 3 Schematic representation of gene mapping using flow-sorted chromosomes and PCR. All chromosome types of a standard karyotype (I–IV) are sorted and subjected to PCR with a pair of specific primers. After ethidium bromide-stained agarose gel electrophoresis of PCR products, the chromosome fraction containing the target sequence shows a bright band of the appropriate size. All other chromosome fractions are negative. Availability of translocation chromosomes permits localization of the DNA sequence to a specific chromosome region.

DNA sequences using dot-blot hybridization or PCR.^[8] The use of translocation chromosomes facilitates mapping to subchromosomal regions (Fig. 3). Targeted isolation of molecular markers for saturation of genetic linkage maps and preparation of chromosome-specific DNA libraries are other important uses.^[9,10] Flow cytometry is the only method that can purify chromosomes in microgram quantities, which are needed for direct cloning and construction of large-insert DNA libraries. Sorted chromosomes are also used for physical mapping of DNA sequences using fluorescence in situ hybridization (FISH) and primed in situ DNA labeling (PRINS), preparation of linearly stretched chromosomes for high-resolution physical mapping, and localization of chromosomal proteins using immunofluorescence.

CONCLUSION

Flow cytogenetics has been developed for a number of species, including economically important legumes and cereals, and is becoming increasingly useful for plant genome analysis. Flow karyotyping facilitates analysis of the frequency of occurrence and transmission stability of specific chromosome types, including translocation and deletion chromosomes. Chromosome sorting simplifies the analysis of complex plant genomes, and the use of sorted chromosomes for physical mapping of DNA sequences and targeted isolation of molecular markers is now routine. The biggest potential is in the construction of large-insert chromosome-specific DNA libraries cloned in bacterial artificial chromosome (BAC) vectors. Such libraries would be extremely helpful for construction of physical maps and for map-based cloning in crops with large genomes.

Flower and Fruit Feeding Insects

Antônio R. Panizzi

National Center for Agricultural Utilization Research, Peoria, Illinois, U.S.A.

INTRODUCTION

Flowers are frequently visited by insects searching for food, such as pollen and nectar.^[1] The impact of such insects can be detrimental, beneficial, or mutualistic. Some insects will feed on flowers and damage them. Fruits are damaged by a great variety of insects, which look for seeds that are very rich in nitrogen.^[2] Others will feed on the fruit itself.^[3,4]

Every year, millions of dollars are spent to control the insect pests of flowers, and, in particular, those feeding on fruits and seeds. However, insects visiting flowers are also beneficial, by dispersing seeds and pollinating several major crops and vegetables.^[5] Mutualistic interactions occur between flowers and honey bees, *Apis mellifera* L. Whereas bees facilitate pollination, flowers provide pollen and nectar for developing bees in hives. This mutualistic interaction led to domestication of the honey bee.

DETRIMENTAL INSECTS

Hundreds of different species of insects feed on flowers and fruits. These include larvae and adults of beetles (Coleoptera), butterflies and moths (Lepidoptera), flies (Diptera), sawflies, wasps, ants, and bees (Hymenoptera), and the “true bugs” (Heteroptera) (Fig. 1). In addition, scale insects (Homoptera) feed on the surface of fruits, and the so-called thrips (Thysanoptera) damage flowers.^[3,4,6–9]

Mouthparts

Insects feeding on flowers, fruits, and seeds have different types of mouthparts that allow them to obtain different types of food. The most common one is the chewing mouthparts, when insects use their mandibles to cut the plant tissue to penetrate the hard surface of fruits and seeds. Chewing mouthparts also allow some beetles to feed on flowers, by cutting the petals.

A second type is the sucking mouthparts where mouthparts are modified into a long sharp tube with two internal openings, one used to pump in saliva into the plant tissue, and the other is used to suck up the fluids. Sucking insects will feed in the following ways: stylet-

sheath feeding, lacerate-and-flush feeding, macerate-and-flush feeding, and osmotic pump feeding.^[7] In the stylet-sheath feeding the bugs insert their stylets in the tissue, mostly in the phloem, destroying few cells, and a stylet sheath is produced, which remains in plant tissues. In the lacerate-and-flush feeding, the bugs move their stylets vigorously back and forth, and several cells are lacerated. In the macerate-and-flush feeding type the cells are macerated by the action of salivary enzymes. In the last two cases, the cell contents are injected with saliva, resulting in several cells damaged. Finally, the osmotic pump feeding occurs through the secretion of salivary enzymes injected in the plant tissue to increase osmotic concentration of intercellular fluids, which are then sucked, leaving empty cells around the stylets.

A third type of mouthparts is the rasping-sucking. In this case the insects scratch the plant tissue and suck up the emerging plant fluid. This type of mouthpart is less common and is typical of the small insects called “thrips.”

Parts Damaged

Flowers, fruits, and seeds are damaged in many different ways. For instance, flowers may be damaged by chewing insects that either destroy the petals or may feed on the pollen. Many insects feed on the nectar, but in this case they do not damage the flowers.

Fruits are damaged in many ways, such as on the surface, by scale insects (Homoptera) or chewing insects, or to the inner parts, in particular by boring pests.^[3,4]

Seeds on the plant and in storage are a preferred feeding site, because of their great nutritional value.^[2] Seed damage is variable, depending on the type of feeding. For instance, sucking insects feed on the cotyledons, and if the feeding punctures reach the radicle or the hypocotyl it can prevent the seed germination.^[2,10] Chewing insects will consume the seed/fruit tissues either by feeding on the outer surface or by boring into the seeds and fruits.

Types of Damage

There are several types of damage caused by insects feeding on flowers, fruits, and seeds. Larvae of chewing bruchids bore into the seeds and the adults emerge through round holes cut in the seed. The “sap beetles” cause

Fig. 1 The southern green stink bug, *Nezara viridula* (L.) (Heteroptera). It feeds on seeds and on fruits of a wide variety of crops, vegetables, and fruit trees worldwide. (View this art in color at www.dekker.com.)

damage by feeding and are also known to transmit fruit-degrading microorganisms, such as brown rot *Monolinia fruticola*, in stored fruits.^[3,4]

Sucking insects feed by inserting their stylets into the food source to suck up the nutrients. By doing this, they cause injury to plant tissues, resulting in plant wilt and, in many cases, abortion of fruits and seeds. The damage to plant tissues, including seeds and fruits, results from the frequency of stylet penetration and feeding duration, associated with salivary secretions that can be toxic and cause tissue necrosis.^[2,6,7,10]

During the feeding process, sucking insects also may transmit plant pathogens, which increase their damage potential. For instance the “cotton stainers” transmit a series of fungi and bacteria, the most important one called the internal boll disease is caused by *Nematospora gossypii*. The feces of adults are yellowish and stain the cotton lint, which is another type of damage they cause. The direct damage varies with the age of the boll, with young bolls having the seeds destroyed and drying up as a result of the feeding activity.^[7]

BENEFICIAL INSECTS

Beneficial insects involved with flowers and fruits include mostly species associated with pollination (see “Mutualistic Associations” section) and production of honey. These insects in general belong to the Order Hymenoptera.

This order includes all different species of bees, such as the honey bee (*A. mellifera* L.), the stingless bees (*Melipona* and *Trigona*), the bumble bees (*Bombus*), the carpenter bees (*Xylocopa*), the mining and cuckoo bees (Anthophoridae), the leaf cutting bees (Megachilidae),

and others, which are frequent visitors of flowers.^[1,5] Among the hymenopterans there are the so-called pollen wasps (masarine wasps) which are the only wasps that provision their nest cells with pollen and nectar, as bees do.^[11]

Honey is perhaps the greatest benefit produced by insects as they visit the reproductive structure of plants. Honey is used as food by bees, and it is explored by man as one of the most popular and beneficial food.

Another benefit that insects associated with flowers and fruits may do to plants is disperse their seeds. Small seeds might get attached to the insects’ body and be taken elsewhere, helping the dispersion of the plant species.

MUTUALISTIC ASSOCIATIONS

Insects may have a mutualistic relationship with plants, where both insects and plants have advantages of the association.^[1,5] Plants are the source of food for insects, and in return they pollinate the flowers. Pollination is the transfer of the male parts (anthers) of a flower to the female part (stigma) of the same or different flowers. More seeds develop when large numbers of pollen grains are transferred.

Insects, in general, play an important role in pollination (entomophily), as well as wind (anemophily). Beyond the hymenopterans (bees, wasps and ants), dipterans (flies), lepidopterans (butterflies and moths), coleopterans (beetles), thysanopterans (thrips), and other minor orders are also engaged in pollination.^[5] Other pollination agents include birds and bats.

About 130 agricultural plants are pollinated by bees only in the United States. The annual value of honey bee pollination to U.S. agriculture has been estimated at over 9 billion. The honey bee pollination in Canada is estimated at Can\$443 million, and over 47,000 colony rentals are taken every year. In the United Kingdom at least 39 crops grown for fruit and seed are insect pollinated, by honey bees and bumble bees. The European Union has an estimated annual value of 5 billion euros, with 4.3 billion attributable to honey bees.^[5]

As flowers are visited by insects and get pollinated, flowers provide proteinaceous pollen and sugary nectar, which are used by insects as food source to larvae and adults.

CONCLUSION

Insects feeding on flowers/fruits/seeds can cause severe damage to many plants of economic importance worldwide. Despite the many efforts to control these insects, they still remain a challenge to economic entomologists.

Because of their feeding habits, i.e., the feeding on the reproductive structures of plants, their economic importance is much greater than that of insect pests that feed on other plant parts, such as leaves, from whose damage some plants can compensate for at least partially. Moreover, for some pests such as the heteropterans that suck plant juices, the damage is difficult to detect early on compared to damage by leaf chewing insects. Therefore, sometimes, damage by sucking insects is noticed only at harvest, when control measures are too late to avoid economic losses.

In conclusion, while insects feeding on reproductive structures of plants cause enormous damage, they can also be of enormous benefit to humankind. Honey production is a source of a healthy and nutritional food for humans. Pollination caused by insects feeding on flowers is responsible for the development of fruit/seeds of hundreds of plant species, several of them of highly economic importance. Moreover, without pollination, many of the plant species we know today would have disappeared a long time ago.

Flower Development

Thomas Jack

Dartmouth College, Hanover, New Hampshire, U.S.A.

INTRODUCTION

Experiments over the last 15 years in genetically tractable plants, primarily *Antirrhinum* and *Arabidopsis*, have elucidated the general mechanisms of floral induction, floral meristem identity, and floral organ identity. In *Arabidopsis*, four inputs stimulate the transition from vegetative growth to reproductive growth: long-day photoperiod, gibberellins, vernalization, and the age of the plant. Pathways mediating these four inputs have been genetically dissected. These pathways feed into three key floral integrators: *FT*, *SOC1/AGL20*, and *LFY*. The identity of the floral meristem itself is determined primarily by expression of *LFY* together with a second gene, *AP1*. In addition to playing a key role in integrating floral inductive signals, *LFY* also plays an important role in activating the floral organ identity genes *AG* and *AP3*.

SHIFT FROM VEGETATIVE TO REPRODUCTIVE GROWTH

For the majority of the 20th century, plant biologists were interested in trying to isolate and characterize substances that could induce plants to shift from vegetative growth to reproductive growth. Experiments in the 1930s demonstrated that a transmissible substance referred to as “florigen” was capable of inducing flowering. Efforts to purify florigen in subsequent decades were unsuccessful. Obviously, the identification of floral-promoting substances has important agricultural implications for controlling the timing of flowering of crop plants.

Molecular genetic experiments in *Arabidopsis* have led to the identification of a number of key genes whose activity is sufficient to accelerate flowering (Fig. 1).^[1,2] *Arabidopsis* is a facultative long-day plant in that long days accelerate flowering, but even under noninductive short days, *Arabidopsis* does flower, though flowering is delayed. Expression of any of five key genes—*LEAFY* (*LFY*), *APETALA1* (*AP1*), *FLOWERING LOCUS T* (*FT*), *CONSTANS* (*CO*), and *SUPPRESSOR OF OVEREXPRESSION OF CO* (*SOC1*) (also referred to as *AGL20*)—is sufficient to induce flowering in vegetative *Arabidopsis* (Table 1). Collectively, these five genes are responsive to four flower-promoting pathways: a long-day photoperiod

promotion pathway, a gibberellin responsive pathway, a vernalization promotion pathway, and an autonomous pathway.

The components of the day-length promotion pathway were identified based on mutants that flower late under long-day photoperiods but exhibit a flowering time similar to wild type under short-day photoperiods. Day length is sensed by *Arabidopsis* by a combination of photoreceptors such as phytochromes and cryptochromes. Mutations in *PHYTOCHROME A* (*PHYA*) and *CRYPTOCHROME 2* (*CRY2*) result in late flowering in long days. Light input feeds into a circadian oscillator that regulates the daily rhythm of a large number of genes. Mutations in circadian clock components *GIGANTEA* (*GI*) and *LHY* result in late flowering in long-day photoperiods. One gene regulated by the circadian clock is *CONSTANS* (*CO*). Mutations in *CO* are late flowering in long days. The circadian peak in *CO* RNA expression occurs in the evening. When plants are grown in short-day photoperiods, the circadian peak of *CO* RNA expression occurs in the dark. By contrast, under long-day photoperiods, the peak of *CO* expression occurs in the light.^[3] In addition to controlling the circadian rhythm of *CO*, light also directly activates *CO* (the molecular basis of this activation is unclear at present), but direct activation by light occurs only under long-day growth conditions. Thus, *CO* is active only when the circadian clock is functional and when the photoperiod exceeds a certain minimum length.

CO directly activates the floral activator/integrator *FT*. To a lesser degree, *CO* also functions to activate a second floral activator/integrator, *SOC1/AGL20*.

In *Arabidopsis*, gibberellins (GA) are required for flowering under short-day photoperiods but play only a minor role in stimulating flowering in long days. Mutants that are unable to synthesize active GA (e.g., *gal1*) do not flower when grown under short-day photoperiods. The promotion of flowering by GA occurs, at least in part, by activating *LEAFY* (*LFY*), a third floral activator/integrator. A *cis*-acting element in the *LFY* promoter is responsive to GA. *LFY* is also upregulated by long-day photoperiods, but the *cis*-acting promoter element that responds to long-day photoperiods is separable from that which is responsive to GA.^[4]

Even under noninductive photoperiods, *Arabidopsis* does flower, suggesting that endogenous factors such as

Fig. 1 A) The major pathways mediating floral induction are indicated. The four major input pathways are shown in red (at www.dekker.com) or gray with underline (long-day promotion, autonomous, vernalization, and GA). These pathways are integrated primarily at three floral activators/integrators (*FT*, *LFY*, and *SOC1/AGL20*) shown in green or outline type. *LFY* is upregulated in the floral meristem after the floral transition and functions to activate floral organ identity genes such as *AP3* (pink/light gray) and *AG* (blue/dark gray). The thickness of the lines indicates the relative strength of the regulatory interaction; in general terms, thicker lines predominate over thinner lines. B) Combinations of A, B, C, and E activities specify organ identity in the flower. (View this art in color at www.dekker.com.)

age of the plant are important for the stimulation of flowering. Mutants in the autonomous pathway flower later than wild type under both long- and short-day conditions (i.e., these mutants are still responsive to photoperiod). The autonomous pathway (or pathways) functions by downregulating the *FLOWERING LOCUS C (FLC)* floral repressor. In autonomous pathway mutants such as *fca*, the levels of *FLC* RNA and protein are high, which represses flowering resulting in a late-flowering phenotype.^[5] A second input to *FLC* is *FRIGIDA (FRI)*, a positive activator of *FLC*. There are many ecotypes of *Arabidopsis* that represent the wide geographical distribution of this species. Some ecotypes are early flowering; for example, the common lab strains Landsberg and Columbia flower after about 20–25 days when grown in long-day photoperiods. By contrast, other ecotypes flower

much later, at 50–60 days under inductive long-day conditions. Late-flowering ecotypes of *Arabidopsis* contain wild-type copies of both *FLC* and *FRI* and are very late flowering, while early-flowering ecotypes have naturally occurring mutations in *FRI* and/or *FLC*.^[6]

The vernalization response also acts primarily via *FLC*. Vernalization accelerates flowering after an extended cold period (e.g., six weeks at 4°C). The extended cold period mimics overwintering and results in rapid flowering in the spring when the plant encounters inductive photoperiods. Vernalization results in a quantitative and cumulative reduction in *FLC* RNA. The reduction in *FLC* RNA occurs epigenetically. The present model is that exposure to cold demethylates the *FLC* gene, which alters chromatin structure and leads to transcriptional inactivation of *FLC*. The inactivation of *FLC* is maintained throughout the life of the plant, but *FLC* is reactivated in progeny plants. *FLC* functions primarily by repressing the floral activator/integrator *SOC1/AGL20*. Although the primary inputs to *SOC1* are via the autonomous/vernalization pathways, *SOC1* is activated secondarily by both gibberellins and the photoperiod promotion pathway acting via *CO*. Similarly, although *FT* is activated primarily by the long-day promotion pathway, *FT* also receives inputs via *FLC*. One clear message that is emerging is that there is considerable cross talk among the four major floral inductive pathways.

Table 1 Critical genes in flower development in *Arabidopsis*

Gene	Gene product
<i>PHYA</i>	Phytochrome red/far-red photoreceptor
<i>CRY2</i>	Cryptochrome blue-light photoreceptor
<i>LHY</i>	single myb domain protein, Sequence-specific DNA-binding protein
<i>GI</i>	Putative transmembrane protein
<i>CO</i>	Zn finger, nuclear protein
<i>FT</i>	Similarity to kinase inhibitor proteins
<i>FCA</i>	RNA-binding protein
<i>FLC</i>	MADS transcription factor
<i>SOC1/AGL20</i>	MADS transcription factor
<i>FRI</i>	No similarity to proteins in databases
<i>LFY</i>	Sequence-specific DNA-binding protein
<i>AP1</i>	MADS transcription factor
<i>TFL1</i>	Similarity to kinase inhibitor proteins
<i>CAL</i>	MADS transcription factor
<i>WUS</i>	Homeodomain transcription factor
<i>UFO</i>	F-box protein
<i>AP2</i>	AP2 domain transcription factor
<i>AP3</i>	MADS transcription factor
<i>PI</i>	MADS transcription factor
<i>AG</i>	MADS transcription factor
<i>SEP1, SEP2, SEP3</i>	MADS transcription factor

SPECIFICATION OF THE FLORAL MERISTEM

FT and *SOC1* are broadly expressed in the plant. By contrast, RNA and protein expression of *LFY* and *API* is highest in the floral meristem primordia. *LFY* is dramatically upregulated in the floral meristem primordia prior to the morphological differentiation of the floral primordia from the shoot apical meristem. Presumably, this spatial upregulation of *LFY* is dependent on broadly expressed activation signals dependent on GA, *FT*, and *SOC1* combined with repression of *LFY* activation in the shoot apex, which likely is mediated by genes such as *TERMINAL FLOWER 1 (TFL1)*. In the floral meristem anlagen, *LFY* activates a second gene, *API*. Like *LFY*, *API* is necessary for proper execution of the floral development program. Although *LFY* activates *API*, *API* also responds to floral inductive pathways independently of *LFY*. Consistent with this idea, both *lfy* and *ap1* mutants exhibit a partial conversion of flowers to shoots. In *lfy* mutants, the basal positions on the inflorescence are converted to shoots, while in more apical positions, abnormal flowers develop. The flower-to-shoot transformation observed in *ap1* mutants is different from *lfy* in that the flowers themselves exhibit indeterminate growth characteristics; specifically, secondary flowers develop in the axils of the first whorl organs. *API* functions redundantly with a closely related gene called *CAULIFLOWER (CAL)*. *cal* single mutants exhibit a wild-type phenotype, but *cal* dramatically enhances the *ap1* phenotype resulting in the replacement of flowers with proliferating masses of meristem tissue that resemble the vegetable cauliflower. Similarly, *lfy ap1* double mutants also exhibit an enhanced phenotype; all positions on the inflorescence normally occupied by flowers instead develop as shoots that exhibit only slight floral character. This residual floral character is removed in the *lfy ap1 cal* triple mutant that exhibits vegetative, but lacks floral, characteristics.

SPECIFICATION OF FLORAL ORGAN IDENTITY

As described above, activation of *LFY* is dependent on floral inductive signals. In turn, *LFY* functions as a key activator of floral organ identity genes.^[7] The identity of the sepals, petals, stamens, and carpels is specified by four broad classes of organ identity genes referred to as A-, B-, C-, and E-class genes (Fig. 2). A-class genes specify the identity of sepals and petals; in A-class mutants such as *apetala2 (ap2)*, sepals and petals fail to develop with the correct identity. B-class genes specify the identity of petals and stamens; in *apetala3 (ap3)* and *pistillata (pi)* mutants, petals develop as sepals, and stamens develop as

Fig. 2 A) Photograph of an *Arabidopsis* flower. B) Floral diagram of an *Arabidopsis* flower indicating the positions of the sepals, petals, stamens, and carpels that develop in whorls 1, 2, 3, and 4, respectively. C) The ABC model of flower development, as well as the revised ABCE model, postulates that combinations of A, B, C, and E activities specify organ identity in the four whorls of the flower. (View this art in color at www.dekker.com.)

carpels. The C-class gene *AGAMOUS (AG)* specifies the identity of stamens and carpels. In *ag* mutants, stamens develop as petals and the carpels develop as a new flower; thus, *ag* mutants are indeterminate. Unlike mutants in the A-, B-, and C-class genes, single mutants in any of the three E-class genes, *SEPALLATA1 (SEP1)*, *SEP2*, or *SEP3*, fail to exhibit a dramatic floral phenotype. However, when mutations in all three *SEP* genes are combined together in a *sep1 sep2 sep3* triple mutant, the petals, stamens, and carpels develop as sepal-like organs and the flowers are indeterminate. This demonstrates that *SEP1*, *SEP2*, and *SEP3* redundantly specify petals, stamens, carpels, and floral meristem determinacy.^[8]

The floral organ identity genes are expressed in region-specific patterns in the developing floral primordia. For example, *AG* RNA is expressed in the floral meristem in the precursor cells of the stamens and carpels while *AP3* and *PI* are expressed in the precursor cells of the petals and stamens. In *lfy* mutants, *AP3* and *PI* expression is dramatically reduced and petals and stamens fail to develop, suggesting that *LFY* is a critical positive regulator of *AP3* and *PI*. *LFY*, which is expressed throughout the floral meristem, leads to the activation of *AP3* and *PI* in a subset of floral meristem cells destined to develop into

petals and stamens. The present model is that *LFY* functions together with the *UNUSUAL FLORAL ORGANS (UFO)* coregulator. *UFO* encodes an F-box protein and is postulated to function by targeting a repressor of *AP3* for ubiquitin-mediated protein degradation.

LFY also plays a role in the direct activation of *AG*. *LFY* activates *AG* together with *WUSCHEL (WUS)*, a gene that is necessary for maintaining meristem cells in an undifferentiated state. Organ identity in the flower is specified from outside to inside, i.e., the sepals are specified first, followed by petals, stamens, and carpels. *WUS* is expressed in the floral meristem prior to floral organ differentiation. The combination of *LFY* plus *WUS* in the stamen and carpel primordia directly activates *AG*. *AG* leads to the specification of stamen and carpel identity, and one of the functions of *AG* is to downregulate *WUS*, which leads to elimination of the stem cell identity in the flower.

Once activated, the ABCE genes are postulated to function combinatorially to specify floral organ identity. The original version of this model involved only the A-, B-, and C-class genes and was called the ABC model.^[9] With the discovery of the important role of the SEP genes, the ABC model has been expanded to include the SEP genes as an E class. According to the revisionist ABCE model,^[10] sepals are specified by A alone, petals by A + B + E, stamens by B + C + E, and carpels by C + E.

CONCLUSION

Until recently, the molecular basis for the combinatorial nature of the ABCE model was unclear. *AG*, *AP3*, *PI*, and the three SEP proteins are all members of the MADS transcription factor family. Although MADS proteins are capable of binding to DNA as dimers, several lines of evidence support a model that postulates that MADS proteins are capable of functioning in higher-order complexes, e.g., trimers or tetramers. This raises the possibility that different tetramers of MADS proteins might be specifying organ identity; for example, stamens might be specified by *AP3+PI+AG+SEP* while carpels are specified by *AG+AG+SEP+SEP*. Future work should tell us whether such complexes exist and are functional in plants.

Fluorescence In Situ Hybridization

Yasuhiko Mukai

Osaka Kyoiku University, Osaka, Japan

INTRODUCTION

Fluorescence in situ hybridization (FISH) was first applied to visualize DNA sequences on plant chromosomes more than one decade ago.^[1] In that time, the technique has become very important in genome analysis of plants to assess the homology between genomes and localize genes and DNA sequences on individual chromosomes or extended DNA fibers. Genomic in situ hybridization (GISH), an offshoot of the FISH technique, is a powerful tool where total genomic DNA is used as a probe for visualizing genome homology between polyploid species and their progenitors and to supplement information on the genomic origin of polyploids. With improvements in detection sensitivity and resolution of FISH technique, it is now possible to detect even unique sequences. Mapping of genes or DNA sequences on extended DNA fibers and intact cloned DNA has further increased the resolution power of the FISH technique. FISH was successful in showing the position of agronomically important genes on the chromosomes of crop plants. The technique has also revealed gene synteny in different crops.

PRINCIPLE AND METHODS OF FISH

In situ hybridization (ISH), pioneered by Gall and Pardue,^[2] provides a sensitive method for the detection of DNA or RNA sequences in cytological preparations. In this technique, radioactive probes were initially used for localizing genes or specific DNA sequences on metaphase chromosomes. The chromosomal DNA and probes are denatured, and then complementary sequences in the probe and target DNA are allowed to reanneal. After washing and autoradiographic detection, signals are visible at the site of probe hybridization. In the 1980s, nonradioactive probes labeled with biotin, digoxigenin, and fluorochrome were developed for ISH. The advantages of using nonradioactive probes over hybridization with isotope-based probes include longer probe stability, speed, higher sensitivity, spatial resolution, and simultaneous detection of more than one probe. In detection by FISH, fluorescently labeled affinity reagents are used.

FISH is rapidly replacing standard ISH procedures and becoming a conventional cytogenetic tool.

Mitotic cells from root-tip meristems or meiotic cells from pollen mother cells are used for cytological preparations. Slides are incubated at 70°C for 2 min in a solution containing 70% formamide/2xSSC to melt the chromosomal DNA into single strands. For probes, cloned DNA from plasmid, lambda phage, phase cosmid, BAC libraries, amplified DNA by PCR, and genomic DNA are used. The two types of ribosomal RNA genes (rDNA), 18S-5.8S-26S rDNA and 5S rDNA, have been used extensively as probes for physical mapping in higher plants because these genes are arranged in tandem arrays clustered at some sites per haploid genome (Fig. 1). Parts of these sequences are highly conserved beyond families. Probes are labeled with reporter molecules (biotin-16-dUTP or digoxigenin-11-dUTP) by means of nick-translation or random primer method. Probe mixtures are applied to slide, and the slide is placed in a humid chamber at 37°C for 6 h or longer to facilitate probe hybridization in situ. After hybridization, probes are detected with fluorochrome-conjugated avidin or antibody (Table 1). The hybridization signals are observed under a fluorescence microscope.

APPLICATIONS OF FISH

Multicolor FISH

Currently, a large number of probe-labeling and fluorescent reagents are available in different colors for simultaneous detection of multiple-target sequences (Table 1). Two or more sequences can be detected in the same cell by using fluorochromes of different colors (Fig. 1). Reid et al.^[3] succeeded in simultaneously visualizing different DNA probes on human chromosomes by FISH using a combination of fluorescence and digital-imaging microscopy. Using three haptens (single, double, and triple labeling and three fluorochromes), a total of seven probes can be resolved ($2^3 - 1 = 7$). Increasing the number of hapten-fluorochromes to four would allow 15 different probes to be detected ($2^4 - 1 = 15$; five hapten-fluorochromes would detect 31 probes).

Fig. 1 Simultaneous mapping of 18S-5.8S-26S rRNA (green fluorescence, light grey) and 5S rRNA genes (red fluorescence, dark grey) on mitotic chromosomes and an interphase nucleus of hexaploid wheat using multicolor FISH. Chromosomes were counterstained by DAPI. (View this art in color at www.dekker.com.)

Multiple visualization of targets in a single hybridization experiment is of major importance for the physical mapping of genes along plant chromosomes. Using repeated sequences or chromosome-specific marker DNA for chromosome identification, another DNA probe la-

beled with a different reporter molecule can be allocated onto a single metaphase plate, dispensing with the need for further chromosome identification by banding analysis.^[4]

FISH Using Total Genomic DNA

Genomic in situ hybridization (GISH) has been an excellent technology for visualizing whole genomes, because the total genomic DNA used as a probe reflects the overall molecular composition of the genome.^[5] The classical methods of genome analysis, involving cumbersome analysis of meiotic pairing behavior and pollen fertility of F₁ hybrids have various limitations. The GISH technique has overcome all these problems and has helped in the unequivocal discrimination of genomes of many polyploid species including wheat, oat, rice, finger millet, cotton, peanut, tobacco, coffee, and banana. Furthermore, because GISH can be successfully applied at somatic cell level to discriminate between genomes, it can be used as a promising tool in the genome analysis of woody species, which otherwise require a long time to reach sexual reproductive phase in order to observe chromosome association at meiosis. We can obtain more information about the molecular characterization of chromosomal abnormalities by combining the total genomic DNA

probe as a genome marker with a cloned DNA probe, over chromosome banding. Translocations and insertions between different genomes are detected mostly in interspecific hybrids or alien chromosome-transfer lines.^[6]

In Situ PCR

The in situ polymerase chain reaction (in situ PCR) is a newly developed method that combines the extreme sensitivity of PCR with the cytological localization of DNA or RNA sequences through in situ hybridization. This technique was first used to map plant genes by Mukai and Appels,^[7] where the in situ location of rye-specific spacer region on metaphase chromosomes was determined using two pairs of primers designed for rye Nor-R1 and rye 5S-RNA-R1 sequences with the size of amplicants being 386 bp and 107 bp, respectively. The in situ PCR is a useful method for amplifying the small regions of DNA sequences of specific plant chromosomes and for mapping low-copy genes of interest.

FISH Using BAC Clones (BAC FISH)

The construction of large-insert genomic DNA libraries is essential for analyzing complex plant genomes. Bacterial artificial chromosome (BAC) libraries are used most widely at present because of several advantages over yeast artificial chromosomes (YACs). In FISH-mapping studies of plants, probes containing less than several kb of single-copy DNA do not reliably produce detectable signals using current FISH techniques in spite of its amenability of coupling with CCD camera and digital-imaging analysis. Alternative methods for detecting unique sequences involve the use of large genomic clones such as lambda phages, cosmids, BACs, and YACs. The signals from repeated sequences are suppressed by competitive hybridization with unlabeled total genomic or Cot1 DNA. Physical mapping by FISH using BAC clones as probes has been successful in plant species with relatively small genomes, such as sorghum, cotton, rice, *Arabidopsis*, tomato, and potato. In crops with large genomes such as wheat and onion, however, physical mapping of BAC clones is not successful even if the signals from repeated sequences are suppressed by competitive hybridization with unlabeled Cot1 DNA.

FISH on Extended DNA Fibers

In physical-mapping studies, FISH on extended DNA fibers from interphase nuclei is a useful tool for determining the sizes of target DNA sequences, the order of genes or clones, and their distances in a large chromosome

Table 2 Detection sensitivity and mapping resolution in FISH in plants

	Detection sensitivity	Mapping resolution
Mitotic chromosomes	10 kb	5.0 Mb
Pachytene chromosomes	2.0 kb	1.0 Mb
Extended DNA fibers	700 bp	1.0 kb

region.^[8] Currently, fiber FISH has the potential to trace the target sequences with lengths of up to 2.0 Mb on single, extended DNA fibers, a spatial resolution of 1 kb between adjacent targets, and a target detection sensitivity of as little as 700 bp in plants (Table 2). In transgenic plants, fiber FISH can physically map the transgenes directly on extended DNA fibers. This method is complementary to PCR, Southern blot, and sequence analyses. The fiber FISH technique contributes to the construction of BAC contigs, in chromosome walking, and map-based cloning. Molecular combing, a recently evolved method, has enabled direct mapping of purified BAC DNA molecules.^[9]

Limitation of FISH Mapping

At present, target sequences less than 10 kb on a chromosome cannot reliably be detected through conventional FISH methods (Table 2). However, low-copy sequences, such as agronomically important genes encoding starch synthetic enzymes, seed storage proteins, and grain hardness, have been routinely mapped in wheat and rye using lambda phage clones containing inserts of 11 to 20 kb of genomic DNA sequence.

FUTURE PROSPECTS

FISH is now the technique of choice to physically visualize genomes and chromosomes and the order of chromosome segments, genes, and DNA sequences. Many applications and refinements in the technology now are available for microscopic visualization of DNA manifestation in situ, previously confined to gel-blot hybridization. With the various modifications and refinements for higher-resolution FISH now available, identifying genomes, chromosomes, and genes through sequence localization and orientation is suited to specific experimental objectives, including identifying agronomically useful genes and their localization, integration sites, and copy number in transgenics.

Through FISH analysis using human chromosome-specific painting probes, chromosome synteny between human and other mammalian species has been studied. This comparative chromosome painting was termed zoo-FISH. Lately, chromosome painting has been applied successfully in *Arabidopsis* using chromosome-specific BAC clones and multicolor FISH.^[10] This method could help establish chromosomal homologies between *Arabidopsis* chromosomes and other Brassicaceae species. FISH using total repetitive DNA of a reference species as a probe, such as rice/*Arabidopsis* DNA, also could be used to identify repetitive-DNA and bar-coding markers for chromosome identification and comparative mapping between species.^[11] This would have tremendous implications in the microidentification of cryptic structural changes and chromosome diversity over populations. Pooled BAC DNA clones derived from individual chromosomes of an anchor species are used as probes for FISH on chromosomes of other related species. This innovative FISH technology visualizes cytogenetic homologies that refine the comparative maps constructed by molecular gene mapping of individual loci and opens new avenues for genomics by facilitating the extrapolation of results from the genome projects.

Fluorescence: A Probe of Photosynthetic Apparatus

J. Kenneth Hooper

Arizona State University, Tempe, Arizona, U.S.A.

INTRODUCTION

Absorption of light by chlorophyll is the cardinal event in photosynthesis. The absorption of a photon, with the exact amount of energy required to raise an electron to a higher orbital, generates an excited state from which chlorophyll molecules readily donate an electron to another molecule. The process of transferring an electron to an acceptor, a photochemical oxidation–reduction reaction, results in productive initiation of the process of photosynthesis. This reaction, in which the energy of the photon is trapped by a chemical reaction, is often referred to as photochemical quenching of the excited state. However, when an electron acceptor is not available, the excited state of the chlorophyll molecule decays, in part by release of heat and in part by emission of a photon of lower energy—the process of fluorescence.

FLUORESCENCE TRANSIENTS IN GREEN CELLS

Chlorophyll *a* is a highly fluorescent molecule (Fig. 1). In organic solvents, an environment that minimizes quenching by the solvent, the quantum yield (the number of photons emitted per number of photons absorbed) is in the range of 0.31 to 0.35. Chlorophyll is relatively insoluble in water, and thus it functions within the nonpolar environment provided by thylakoid membranes. The interior of the membrane is rich in the hydrocarbon portions of the membrane lipids, and thus provides an organic phase within the chloroplast. Although free chlorophyll in a membrane can retain much of its inherent fluorescence, most if not all chlorophyll is attached to proteins that position the molecules in such a fashion that absorbed energy is readily transferred to other molecules and thus eventually trapped. More than 90% of absorbed light quanta are productively converted to electrons in photosynthesis. Therefore, chlorophyll in thylakoid membranes *in vivo* exhibits a low level of fluorescence, with a maximal quantum yield of only 0.03 to 0.05.^[1] This level is reached when the photosynthetic apparatus is saturated, a physiological state that does not allow further trapping of energy.

Changes in the low level of fluorescence of chlorophyll in chloroplasts reflect its functional state, and thus measurement of fluorescence under a variety of conditions is a sensitive means to monitor photosynthetic activity. The fluorescent yield depends upon the ability of the remainder of the photosynthetic system to trap absorbed energy. Fig. 2 illustrates measurements made on a short time scale that describe the status of the reaction centers of photosystem II. In this experiment, cells of the green alga *Chlamydomonas reinhardtii* were dark-adapted for several minutes and then exposed to a modulated red light source (wavelength of maximal intensity, 650 nm) at a low intensity of 2.5 $\mu\text{mol photons m}^{-2}\text{s}^{-1}$.^[2] (Light of this wavelength is absorbed primarily by chlorophyll *b* in the light-harvesting antenna. Because of the close association of chlorophyll *b* with chlorophyll *a* within light-harvesting complexes of the antenna, energy is rapidly transferred to chlorophyll *a* on a time scale of several hundred femtoseconds to a few picoseconds.) A low, intrinsic level of fluorescence, designated F_o , is released by the antenna when the reaction centers and electron acceptors are fully oxidized. Upon exposure to a higher intensity (80 $\mu\text{mol photons m}^{-2}\text{s}^{-1}$) actinic red light, a rapid increase in fluorescence was observed on the time scale of several hundred milliseconds.

The first group of antenna complexes to become fully fluorescent were those not functionally connected to reaction centers, indicated by F_{pl} , a plateau level that varies with conditions; these unconnected complexes were relatively highly fluorescent. The rise in fluorescence to the peak value, F_p , is a measure of the rate at which a plastoquinone molecule designated Q_A , the primary acceptor of photosystem II, is reduced. When the rate of reduction of Q_A is greater than the rate at which electrons can be removed from the reaction center by subsequent electron carriers, the reaction center becomes saturated and any additional energy absorbed by the antenna, which cannot be trapped, is then released by heat and/or fluorescence. The rate at which fluorescence rises from F_{pl} to F_p is a function of the intensity of actinic light as well as the size of the antenna that absorbs the light.^[3] The subsequent fall from the peak level of fluorescence occurs when the pathway for carbon fixation is activated by light and electrons are transported through photosystem I to NADP^+ . Opening the gate at the end of the photochemical

Fig. 1 Absorption and fluorescence of chlorophyll *a*. A. Energy levels within the molecule allow absorption of photons, which are described by the absorption spectrum shown in B. Increases in energy states by $h\nu_1$ to $h\nu_4$ describe absorption bands referred to as the B_y and B_x Soret and the Q_x and Q_y peaks, respectively. C. Return to the ground state from higher excited states initially occurs by internal, radiationless decay to the lowest excited state, from which the molecule achieves the ground state by emission of energy as fluorescence, whose spectrum is shown in D. (Adapted from Ref. 9.)

Fig. 2 Fluorescence induction kinetics displayed by green cells of the alga *Chlamydomonas reinhardtii*. Fluorescence was measured at room temperature in the absence (curve 1) or presence (curve 2) of 10 μM DCMU, a herbicide that blocks exit of electrons from photosystem II. (From Ref. 2.)

pathway results in re-oxidation of the plastoquinone pool and thus makes more electron acceptors available for photosystem II. The final steady-state level of fluorescence (F_s) is an indication of how well the two photosystems are connected, or how readily electrons can be transferred through the complete system to the carbon fixing pathway.

Curve 1 in Fig. 2 describes the typical fluorescence transient for healthy chloroplasts. Deviation from this pattern is diagnostic of a change in the physiological status of photosystem II. For example, some herbicides act by blocking the transfer of electrons from Q_A of photosystem II to the next electron carrier. Curve 2 in Fig. 2 shows the change in fluorescence upon exposure to actinic light when such an inhibitor was added. The electron acceptor Q_A no longer donated electrons to Q_B and thus rapidly became reduced. Energy flow through the reaction center from the antenna was blocked, and all the energy absorbed by the antenna had to be reemitted, some of it as fluorescence. This condition, therefore, yields the maximal amount of fluorescence that can be generated in the assay, which is termed F_m . Maximal fluorescence of the system can also be obtained by exposure to an intense burst of white light, which floods the reaction center with excitons at a higher rate than Q_A can release electrons.^[4]

The maximal quantum yield of photosystem II is expressed by a simple relationship:

$$\Phi_F = \frac{F_m - F_o}{F_m} \quad (\text{variable fluorescence, } F_v)$$

This value is between 0.7 and 0.8 for healthy leaves. When the reaction center is damaged, one result is an increase in F_o , which reduces the value of F_v . The decrease in this ratio indicates a reduced yield of photosynthesis.

State 1 is the condition in which the protein–chlorophyll complexes of the major light-harvesting antenna (LHCII) are connected to photosystem II. When the intensity of incident light is very high and Q_A exists in a relatively reduced state, LHCII dissociates from photosystem II and transfers more energy into photosystem I. This arrangement is designated state 2. Photosystem I is kinetically a faster complex than photosystem II,^[5] and thus trapping of energy absorbed by LHCII is more efficient in state 2. The maximal level of fluorescence of the antenna that can be achieved with an intense flash of light is thereby reduced. Because photosystem II is located within the granal stacks of thylakoid membranes, whereas photosystem I is more peripherally distributed,^[6] the term ‘state transition’ implies a reorganization of membrane components.

A reduction in the maximal emission intensity, F_m , is also achieved by the process of nonphotochemical quenching, by which absorbed light energy is dissipated as heat. This mechanism requires the LHCII-associated protein PsbS, the xanthophyll zeaxanthin, and a relatively low pH within the thylakoid lumen. The extent of nonphotochemical quenching is determined from the attenuation of F_m to lower values, termed F'_m , during a series of light flashes.

FLUORESCENCE SIGNATURE OF DEVELOPING THYLAKOID MEMBRANES

The change in pattern of the fluorescence transient provides important information on the status of photosystems during chloroplast development. During the early phase, thylakoid membranes initially form as small vesicles, which expand into lamellar structures that eventually adhere to form grana.^[7] Segregation of photosystems I and II does not occur until granal stacks are formed. Thus, in the separate, initially formed vesicles, reaction centers and antenna complexes should be distributed randomly within the membrane, with the light-harvesting complexes feeding exciton energy to photosystem I as

well as photosystem II. Electrons produced by photosystem II are then rapidly pulled through the electron transport chain connecting the photosystems, and Q_A remains oxidized. This arrangement is characteristic of a state 2 condition. As shown in Fig. 3A, at the beginning of chloroplast development in *yellow* mutants of *Chlamydomonas reinhardtii*, reaction centers were not available for the small number of antenna complexes present, and addition of DCMU, an inhibitor of electron transfer from Q_A to Q_B , had no effect. After a short period of chloroplast development, actinic light caused a rise to the same plateau level of fluorescence (Fig. 3B). The typical rise in fluorescence to F_p was not observed, even though a large increase to F_m occurred upon addition of DCMU, which demonstrated that functional photosystems had formed and some of the energy absorbed by LHCII was efficiently trapped by photosystem II. In these experiments, the typical fluorescence transient shown in Fig. 2 emerged gradually as the growing thylakoid membranes adhered to form grana.^[2]

Fig. 3 Fluorescence induction displayed by yellow cells of the alga *Chlamydomonas reinhardtii* (A) at the beginning of chloroplast development and (B) after one hour of exposure to light. The cellular content of chlorophyll increased approximately four-fold during this period. Curve 1 in each panel was obtained with cells in the absence of DCMU, whereas curve 2 in each panel was obtained with cells treated with 10 μ M DCMU. (From Ref. 2.)

CONCLUSION

Short-term fluorescence transients provide a sensitive and detailed probe with which to monitor the functional state of photosystem II. These measurements can also be used to monitor changes over extended periods of illumination. The general concept of chlorophyll fluorescence as a functional probe of the physiological state of photosystem II can be used to monitor a number of different parameters in addition to those shown here.^[8]

F

Functional Genomics and Gene Action Knockouts

Jacqueline Heard

Mendel Biotechnology, Hayward, California, U.S.A.

INTRODUCTION

Functional genomics describes an organism-wide approach to the experimental characterization of gene function that capitalizes on information gathered as a consequence of genome sequencing. An era of intense genomic analysis of plant species has just begun. In 2000, the first complete genome sequence of a model plant, *Arabidopsis thaliana* (Arabidopsis), was released.^[1] Very recently, a publicly available draft sequence of the rice genome was also released.^[2] Arabidopsis and rice represent model species for the study of dicots and monocots, respectively—the two most important lineages in the plant kingdom with respect to the commercial application of genomic research. These two genomes provide the first view into which genes and proteins shape the growth and development of plants. Functional genomics seeks to uncover gene function using tools on a genome-wide scale, placing the transcripts, proteins, and metabolites into complex control networks with the goal of dissecting and understanding mechanisms that control key plant traits.

GENOMICS, STRUCTURE TO FUNCTION, AND THE CONVERGENCE OF THEORETICAL AND EXPERIMENTAL BIOLOGY

Structural and comparative genomics provide a foundation for the organism-wide analysis of gene function, and are vital to our ability to leverage the information we learn from model species to other genomes of commercial value. It is generally anticipated that by examining structural components of genomes—understanding the degree of synteny or colinearity between model species and crop species—the functional analysis of a protein in a model system will lead to the subsequent identification of the functional ortholog in crops. Certainly, the shortcomings of any model system will become especially apparent as the evolutionary distance between organisms increases. As a result, several plant species are being developed for genomic-scale analysis across major crop taxa, including the Brassicaceae, Poaceae, Fabaceae, and Solanaceae (Table 1).

Particularly vital to the functional characterization of genomes is the determination of the complement of coding regions—one of the first steps to the structural characterization of a genome. Gene structure predictions based on current gene-finding algorithms are correct only about half the time.^[3] It is clear that at this time, predictive algorithms must be supplemented by various experimental approaches, such as the use of microarray technology and the collection of full-length cDNAs in order for the genome annotation to be accurate and comprehensive.^[3]

Once the complement of genes that make up a genome has been predicted, sophisticated methodologies that have come to “define” functional genomics research facilitate the characterization of expressed genes (transcriptome), proteins (proteome), and metabolites (metabolome) of a model organism in the context of their cellular and subcellular location, a given environment, and genotypic background. The uses of microarray analysis, proteomics, and metabolomics for genome-wide analyses in plants have been reviewed recently.^[4–7] These approaches, combined with the phenotypic characterization of gene action knockouts and transgenic lines ectopically expressing a gene of interest, will provide the experimental basis for the assignment of gene function.

Massive data collection efforts and computational modeling of pathways will be needed to finally place the transcripts, proteins, and metabolites into complex control networks. It is likely that functional genomics research will increasingly challenge the way we process data, requiring data integration across several diverse disciplines, and will require an unprecedented level of convergence between theoretical and experimental approaches.

ASSIGNING FUNCTIONS TO GENES: INSERTIONAL MUTAGENESIS AND GENE ACTION KNOCKOUTS

An estimated 30–40% of the genes in a given genome encode proteins of unknown function, those for which no functional information is available, and those for which a putative function cannot be predicted based on

Table 1 Examples of model plants across major crop taxa: EST count was accessed June 2002 from GenBank at http://www.ncbi.nlm.nih.gov/dbEST/dbEST_summary.html

biochemical properties. For the remaining roughly 50–60% of the proteins—those with a putative function to which no true functional assignment has been made—a fairly simple database search of a model organism would mine the genome for a biochemical functionality of interest. However, simply knowing that a gene encodes a MADS-box type transcription factor, for example, does not inform us about the function it actually performs in the plant. Transcript profiling and proteomics will allow predictions to be made regarding gene function, but in the end the hypotheses generated will need to be validated *in planta*. Gene function must ultimately be assigned on the basis of phenotypic evidence, and is most easily done in model organisms. Insertion mutagenesis is probably the most technically feasible approach for the systematic analysis of gene function in the context of the whole organism. A variety of mutagenesis strategies have been devised to create and screen for tagged knockouts in genes of interest using transfer-DNA (T-DNA) and transposons.^[8] For over a decade, Arabi-

dopsis has been used intensively as a model plant species for the determination of gene function. Forward genetics has generated functional information for less than 5% of the Arabidopsis genes to date.^[9] A reverse-genetics approach, where a collection of knockouts in all genes in a genome can be screened for a mutation in a gene of interest, allows a large-scale systematic assignment of function to genes in the genome—an organism-through-phenotype characterization.

Once function has been assigned to a protein in a model organism such as Arabidopsis, examining the function of the putative ortholog in a crop species will almost certainly follow. Knockout collections have been and are being generated that allow the retrieval of a mutation in a gene of interest through PCR screening in a variety of plant species including Arabidopsis, maize, petunia, Lotus, alfalfa, tomato, snapdragon, rice, and *Brachypodium*. Table 1 summarizes information regarding a number of the species listed above. In the case of Arabidopsis, a variety of screenable collections exist and more recently, a catalog of

sequenced insertion events from individual lines is being created where a scientist simply requests seed for a particular mutant of interest.^[10] This resource is being created as part of the ambitious multinational project, the Arabidopsis 2010 project funded by The National Science Foundation. The goal of the 10-year endeavor is to complete the functional analysis of the Arabidopsis genome by the year 2010.^[9] This academic project is unconventional by design, in that it plans for “technology centers” to provide resources such as insertional mutants and microarray data.^[9] The participants recognize the efficiency gains that can be made by centralizing work that is best suited for efficient high-throughput methods.^[9] The project also plans for the development of databases and bioinformatics tools that will facilitate public access to the data. The information and tools generated will be used for computer modeling in an effort to move toward the creation of a “virtual plant.”^[9]

OTHER MUTAGENESIS STRATEGIES FOR REVERSE GENETICS

The limitations to creating and using a collection of insertional mutants in any organism are genome size, transformability, the degree of redundancy, and ease of growth. When creating a saturating population of insertional mutants is problematic due to genome size and the lack of efficient gene transfer methods, other mutagenesis strategies such as high-density fast neutron^[11] and chemical mutagenesis can be used. An elegant technique called Targeting Induced Local Lesions in Genomes (TILLING) has recently been developed wherein a point mutation in any gene of interest in theoretically any plant of interest can be detected by heteroduplex analysis, provided some gene sequence knowledge is available.^[12]

Another common characteristic of plant genomes that limits the power of insertional mutagenesis is the degree of duplication. This problem can be quite substantial in plants in which many proteins have co-expressed isovariants, making it difficult to identify function through a single insertion event in any one of the isovariants.^[13] Having the complete genome sequence available allows for predictions of functional redundancy wherein gene knockouts would be needed in several genes in order to reveal function; however, many genes for isovariants will be closely linked and therefore difficult to make double insertion mutant knockouts. Where ease of gene transfer is not an issue, gene-silencing approaches such as post-transcriptional gene silencing (PTGS) or RNA interference (RNAi) could be used to knock out the activity of several genes simultaneously.^[14]

The reader is referred to other articles in the section on Structural and Functional Genomics for a detailed description of the mutagenesis strategies discussed here.

CONCLUSION

The goal of functional genomics is not only to improve our basic knowledge of plants, but also to provide plant biotechnology with the information and technology needed to create improved crop cultivars. Clearly, one of the steps needed to facilitate the application of our knowledge is the development of new strategies to manipulate plant genomes and to reduce the time and expense for commercial development of new traits. Controlling the integration of transgenes through recombinase-directed plant transformation offers a way to reduce the unpredictability in transgene expression levels, and allows for the removal of unwanted selectable markers.^[15] Gene-targeting approaches offer similar advantages; however, homologous recombination occurs at extremely low frequency in higher plants and is not a feasible strategy at this point for either gene discovery or commercial applications.^[16] Targeted mutations can also be created using RNA/DNA oligonucleotide hybrids^[17] and with efficiency improvements, the technique offers another potentially promising tool to facilitate the application of the knowledge gained through functional genomics research to the improvement of crop species.

Fungal and Oomycete Plant Pathogens: Cell Biology

Adrienne R. Hardham

Australian National University, Canberra, Australian Capital Territory, Australia

INTRODUCTION

Plants have developed many strategies to stop potential pathogens from being able to infect and establish disease. These strategies include preformed and induced physical barriers (such as strong cell walls) and chemical inhibitors. However, there are many thousands of species of eukaryotic microbes, such as fungi and funguslike organisms, that have evolved mechanisms to overcome these defenses. They are able to colonize and reproduce in selected host plants, causing huge economic losses in important food and commodity crops as well as environmental damage in natural ecosystems.

Traditionally, the fungal kingdom included six major groups of organisms: Basidiomycetes, Ascomycetes, Zygomycetes, Deuteromycetes, Chytridiomycetes, and Oomycetes. All form hyphae that grow by extension at the hyphal apex, and all have an absorptive mode of nutrition. In all but the Oomycetes, chitin is the main microfibrillar component of the cell wall, and all but the Oomycetes are haploid during a major part of their life cycle. Recent molecular sequence analysis has confirmed that the structural, biochemical, and genetic differences between the Oomycetes and the other five groups are indicative of the distinct phylogeny of the Oomycetes, which are more closely related to brown algae than they are to true fungi. Nevertheless, Oomycete plant pathogens—and there are many that cause devastating plant diseases—must overcome the same range of plant defenses encountered by the true fungi. As details of the cellular and molecular basis of the infection process unfold, the similarities and differences in the infection strategies employed by these two groups of plant pathogens will become increasingly clear.

THE INITIATION OF PLANT INFECTION

Spore Adhesion

Fungal and Oomycete pathogens usually reach a potential host plant as spores that are dispersed in wind or water.

Having made initial contact, it is important that the spores quickly become attached to the plant surface so that they are not blown or washed away before establishing infection. In some cases, including the highly successful and destructive pathogens *Magnaporthe grisea* (causing rice blast) and *Phytophthora infestans* (causing late blight of potato), the spores release adhesive material within minutes of making contact with the plant. *M. grisea* conidia store preformed adhesive in the periplasm at the spore tip^[1] and release it upon hydration. *Phytophthora* species store preformed adhesive in small vesicles under the ventral surface of motile spores that are able to position themselves with precision on the plant surface before secreting the adhesive (Fig. 1: 1–4).^[2] In other cases, the adhesive material is released more slowly and is apparently synthesized after contact with the potential host. Pathogen spores also secrete other compounds onto the host surface, including mucilaginous material that may prevent desiccation (Fig. 1: 4) and enzymes (such as cutinases) that may degrade the plant surface.^[3]

Spore Germination and Hyphal Tip Growth

Once attached to the plant surface, spores germinate and seek suitable sites from which to attempt to penetrate the plant's outer surface. In many cases, the site of spore germination is determined by physical and chemical factors in the spore's environment, but in other cases, the site of spore germination is predetermined. The spores of some rust fungi, for example, have preformed germination pores; in *Phytophthora* spores, the germ tube emerges from the center of the ventral surface, which has been oriented toward the plant surface.^[2] Germ tubes grow by extension at the hyphal tip, achieved by the localized fusion of numerous small apical vesicles carrying wall materials and enzymes. Many pathogens orient their hyphal growth according to the topography of the underlying plant surface. Hyphae may grow along (Plate II (5)) or perpendicular to the grooves formed by the anticlinal walls of the epidermal cells.^[4] This thigmotropic growth is believed to enhance the pathogen's chances of finding a suitable infection site.

Fig. 1 (1) Zoospore of *Phytophthora cinnamomi* labeled with an antibody (Vsv1) that reacts with adhesive proteins stored in small vesicles under the ventral surface of the spore. Immunofluorescence micrograph ($\times 700$). (2) Encysted spore of *P. cinnamomi* attached to the surface of an onion root. Differential interference contrast micrograph ($\times 700$). (3) The same spore as shown in (2). Adhesive material secreted by the spore is labeled by an antibody (Vsv1) that reacts with the adhesive protein (arrow). Immunofluorescence micrograph ($\times 700$). (4) Spores of *P. cinnamomi* that have preferentially settled over the grooves formed by the anticlinal walls of onion root epidermal cells. Remnants of mucilaginous material can be seen surrounding the spores (arrows). (Scanning electron micrograph ($\times 500$) courtesy of Division of Entomology, CSIRO.)

HOST COLONIZATION

Host Penetration

Many fungal and Oomycete species that are foliar pathogens enter the leaf through the stomatal pore between two guard cells (Fig. 2: 5 and 6). Other species invade the plant surface, be it root or shoot, by growing between the epidermal cells along the anticlinal wall (Fig. 2: 7) or by penetrating directly through the outer epidermal cell wall. In each of these situations, the hyphal apex often differentiates into an appressorium (Fig. 2: 5 and 6; Fig. 3: 7 and 8), a cell specialized to overcome the formidable barrier presented by the outer epidermal cell wall. In rust fungi, appressorium differentiation is triggered by contact with the ridges formed by the stomatal guard cells (Fig. 2: 5 and 6), a response that can also be induced by ridges of similar dimensions on inert substrata,

Fig. 2 (5) Urediniospores of the flax rust fungus, *Melampsora lini*, germinated on the surface of a flax leaf. The germ tubes have grown along the grooves formed by the anticlinal walls of the epidermal cells. Contact with a guard cell has triggered the formation of an appressorium (ap) from which the fungus has grown into the stomatal pore. (Cryo-scanning electron micrograph ($\times 600$) courtesy of Dr. I. Kobayashi and the Division of Plant Industry, CSIRO.) (6) A *M. lini* appressorium has produced a germ tube that has grown through a stomatal pore into the substomatal cavity in a flax leaf. Infection hyphae have contacted a mesophyll cell (m) and have differentiated into haustorial mother cells (hmc). (Cryo-scanning electron micrograph ($\times 860$) courtesy of Dr. I. Kobayashi and the Division of Plant Industry, CSIRO.)

Fig. 3 (7) *P. cinnamomi* cyst (c) that has germinated on the surface of an onion root and formed an appressoriumlike structure (ap) before penetrating the root surface along the anticlinal wall between two epidermal cells. indicating a purely physical signaling mechanism.^[4] In the rice blast fungus, *M. grisea*, contact with a hydrophobic surface can trigger appressorium formation, and it is in this organism that appressorium development and function have been studied in greatest detail.^[1] In *M. grisea*, the wall of the appressorium becomes melanized, a feature that makes the wall impermeable to virtually all molecules except water. Within the cytosol, the appressorium accumulates high concentrations of glycerol (up to about 3 M), which leads to the buildup of extraordinarily high hydrostatic (turgor) pressures. In *M. grisea*, a pressure as high as 8 MPa has been measured. The base of the appressorium is attached tightly to the plant surface, and at its center a fine penetration peg pierces the underlying plant cell wall. Experimental studies have shown that the penetration pegs of *M. grisea* appressoria are capable of puncturing inert surfaces (such as mylar sheets) of hardness similar to that of a rice leaf surface.^[1] However, it has also been found that a rice leaf is penetrated more quickly than a mylar sheet of similar hardness, indicating that enzymatic weakening of the plant cell wall accompanies the mechanical puncturing of the plant surface. Once inside the plant tissues, the pathogen hyphae may grow intercellularly (Fig. 3: 9 and 10) or intracellularly (Fig. 3: 10–12).

Haustroria and Nutrient Acquisition

Necrotrophic pathogens obtain the nutrients they need from dead cells, and thus necrotrophic infections are characterized by widespread damage to plant cells and large expanding necrotic lesions. Biotrophic pathogens, on the other hand, establish a stable relationship with living plant cells in order to obtain the nutrients they require for growth and development. In foliar biotrophs such as the rust fungi, an infection hypha that has developed from the substomatal vesicle makes contact with the surface of a mesophyll cell and differentiates to form a haustorial mother cell (Fig. 2: 6). The haustorial mother cell produces a fine penetration peg that grows through the mesophyll

cell wall but does not penetrate the plant cell plasma membrane. Lack of mechanical disruption in the plant cell wall suggests that the penetration peg secretes enzymes that locally degrade the cell wall. The penetrating hypha then evaginates to form a haustorium, a cell specialized for nutrient uptake from the host plant cell. Because the plant plasma membrane has not been breached, the fungal haustorium remains surrounded by the host plasma membrane, which becomes specialized and is termed the extra-haustorial membrane (Fig. 3: 12). The extrahaustorial matrix lies between the extrahaustorial membrane and the wall of the haustorium. The pathogen orchestrates structural and biochemical changes in the infected plant cell in order to enhance the synthesis of nutrients (especially sugars and amino acids) by the host cell and facilitate their secretion into the extrahaustorial matrix, from where they can be absorbed by the haustorium. Molecular evidence of this process has been recently obtained following the cloning of genes from the rust fungus, *Uromyces fabae*, that encode a proton-pumping ATPase, and amino acid and sugar transporters.^[5] These proteins have been shown to reside in the haustorial plasma membrane. It is believed that the H⁺-ATPase powers the uptake of amino acids and sugars through the membrane-bound transporters. Colonization of host tissues and acquisition of nutrients allows the pathogen to sporulate and initiate a new cycle of plant infection.

CONCLUSION

Fungal and Oomycete plant pathogens are able to detect and respond to both chemical and physical signals from potential host plants and to regulate the polarity of their growth and the development of specialized infection structures accordingly. Modern approaches to studies of pathogenesis in these organisms are rapidly increasing our understanding of the molecules involved in signal exchange between host and pathogen, and in the induction, differentiation, and function of the specialized infection structures that form a vital part of the strategies to

overcome plant defenses and establish disease in susceptible plants.

Gene Banks: Utilization in Plant Breeding

Margaret E. Smith

Cornell University, Ithaca, New York, U.S.A.

INTRODUCTION

The fundamental basis of crop improvement through plant breeding is genetic diversity—the variation in genes and chromosomes that gives rise to useful and predictably inherited differences in plant appearance or phenotype. Plant germplasm collections (or “gene banks”), which include old varieties, land races, and wild and weedy relatives of crops, provide a tremendous reservoir of genetic diversity (Fig. 1). The collections in gene banks are adapted to different environments, insect and disease pressures, stresses (e.g., drought, heat, cold, poor fertility), crop management systems, and end uses. These variations in adaptation are all conditioned by genetic differences, which in turn provide the raw material for breeding new crop varieties that are improved for these types of traits.

WHY DO BREEDERS NEED TO UTILIZE GENE BANKS?

For many crops, the number of different varieties being marketed would suggest that plenty of genetic diversity is found within current commercial varieties. For example, there are hundreds of different dent maize varieties marketed in the United States alone each year. This suggests that U.S. dent maize should be extremely diverse, but in fact many of these varieties originate from a small number of ancestral inbred lines and the genetic base of commercial maize in the United States is relatively narrow.^[1] The predominant approach used by corn breeders in the U.S. seed corn industry is to cross “the best by the best”—a sound breeding practice that ensures a high probability of deriving new good inbred parents, but also limits the diversity present among commercial varieties because the same outstanding parents tend to be used repeatedly in breeding. Goodman^[2] estimated that U.S. commercial maize contains only 2.9% “exotic” germplasm, most of which was temperate germplasm from South America and Europe. Only about 0.31% of the U.S. commercial maize seed market constituted tropical germplasm. This serves to illustrate the limited diversity that is actually present in U.S. commercial maize.

Limited diversity brings with it the risk of susceptibility to an insect or pathogen that is especially virulent on

the predominant genetic types. An extreme case of this occurred in the United States in 1970 when an epidemic of southern corn leaf blight occurred.^[3] In this case, susceptibility to the pathogen was linked to genes located in the cytoplasm of the plants’ cells rather than in the nucleus. Certain genes located in the cytoplasm cause the pollen of maize plants to be sterile. Such plants are very convenient for producing hybrid seed on a large scale, because any seed they set must come from crosses with a different genetic type that has fertile pollen. Use of sterile cytoplasm maize in hybrid seed production became increasingly popular during the 1950s and 1960s. By 1970, one cytoplasmic genotype (called T) was used to produce 75% to 90% of U.S. maize seed, so 75% to 90% of U.S. maize plants had identical cytoplasmic genes. A new variant of the southern corn leaf blight pathogen, called race T, was uniquely well adapted to attack plants with the T cytoplasm and caused more severe disease symptoms than the original pathogen. Race T pathogens in 1970 encountered a year with favorable environmental conditions and an almost uniformly susceptible maize crop because such a large share of it carried the genetically identical T cytoplasm. The resulting epidemic destroyed 15% of the U.S. maize crop.

A narrow spectrum of genetic diversity among commercial types also complicates future breeding efforts, in that new genes and gene combinations needed to address emerging problems must be sought from outside the commercial germplasm base—something that requires a more lengthy and difficult breeding process. So both for stability in the face of changing pest and environmental pressures and for ease of future breeding efforts, having a diverse commercial germplasm base is advantageous.

Gene banks have often provided genetic variation that was not available within the commercial germplasm base of crops. The following examples from a survey of recent literature over just a 4-month period amply illustrate this point. Researchers working on spring wheat in the northwestern United States note that no wheat germplasm with resistance to *rhizoctonia* root rot, a yield-limiting problem, had been found.^[4] They identified promising levels of resistance in *Dasypyrum villosum*, a Mediterranean annual grass that can be crossed (albeit with difficulty) with wheat. A survey of *Pisum fulvum*, a wild

Fig. 1 Example of phenotypic diversity in maize ears. (View this art in color at www.dekker.com.)

relative of the cultivated pea, uncovered sources of natural weevil resistance after no such resistance had been found in cultivated pea germplasm.^[5] Cucumber accessions from the U.S. National Plant Germplasm System were screened for fruit yield and quality, as U.S. cucumber yields have not been significantly increased through breeding over the past two decades.^[6] Collections were identified that had higher total yield, higher marketable yield, and in some cases competitive fruit quality as compared to commercial cucumber varieties. Screening of a broad range of *Phaseolus* spp. including both cultivated and wild types revealed a wide spectrum of variation in tolerance to saline conditions.^[7] Various other examples could be cited from just this 4-month time period and many more have been documented over the years. Clearly, the gene banks contain genetic variation that breeders did not have available in their locally adapted commercial germplasm. Incorporation of genes from these source materials has provided for long-term improvement of many traits in our crop plants.

GENE BANK CONTRIBUTIONS TO NEW CROP VARIETIES

The extent of gene bank contributions to improved crop varieties varies quite dramatically, as illustrated by the following selected examples. In the case of U.S. maize, very limited use of exotic germplasm in U.S. commercial maize suggests that little use is being made at this point of the gene bank collections.^[2] U.S. maize represents a crop where the commercial seed market is dominated by single-cross hybrids developed by the private sector. These hybrids are the product of many years of genetic tailoring for maximum yields under U.S. growing conditions. The need to succeed in this highly competitive

seed market means that most private company breeding programs rely heavily on crosses between very elite parents, to give them the best chance of developing a hybrid that will just edge out the competition. Introducing gene bank collections disrupts the desirable blocks of genes that have been assembled over this lengthy period of hybrid improvement, requiring a more complex and long-term breeding process to regain these needed traits.

The genetic base of cultivated germplasm is also estimated to be narrow for potato in the United States, and this narrow base may account, in part, for the lack of improvement in yield potential of released varieties during the 20th century.^[8] Nonetheless, potato breeders have utilized wild species in their search for pest resistance and there are some released varieties that have as much as 50% wild species germplasm in them.^[9] For millet, a crop that has probably received less breeding attention than either maize or potato but still is the subject of significant breeding programs worldwide, estimates are that only a small fraction of the available genetic diversity has been utilized in breeding.^[10] This is particularly true for the photoperiod sensitive millets.

The examples above stand in contrast to a couple examples from crops that have received much less breeding attention. Cassava ranks fifth in production of food crops worldwide, but has been the subject of relatively little research. The cassava breeding program at the International Center for Tropical Agriculture in Colombia, which also holds a significant cassava germplasm collection, has used close to 10% of all its collections in its breeding program.^[11] Breeding of *Musa* spp. (including bananas, cooking bananas, and plantains) makes extensive use of both cultivated and wild diploids in the development of triploid varieties.^[12] Much of this work has focused on improving resistance to insects and diseases, which are major constraints to banana and plantain production. The extensive use of diverse germplasm sources for these two crops is likely a reflection of the limited breeding attention they have received to date. The cultivated varieties are not as vastly different from the collections as would be the case for a crop such as maize or potato, where extensive breeding effort has refined the cultivated germplasm very highly, and using the gene bank collections requires a lengthy breeding process to regain the traits needed to make cultivated varieties acceptable.

NEW APPROACHES TO GENE BANK UTILIZATION IN PLANT BREEDING

Both crop physiology and molecular genetics provide new approaches to tease out the useful genes from germplasm

collections despite what is often poor phenotypic performance. Each approach will be illustrated with an example.

A study of maize landraces under different levels of nitrogen stress examined various physiological components of yield under stressed and nonstressed conditions.^[13] Although the landraces generally yielded less than improved varieties at both adequate and low nitrogen levels, examination of the components of yield revealed potentially useful variation. The landraces had greater grain nitrogen concentrations under low nitrogen conditions and were sometimes superior to the cultivated varieties in total nitrogen recovery, aboveground biomass, and nitrogen harvest index. Landraces with superior values for these physiological components of yield are potentially useful sources for breeding programs designed to improve maize yields under nitrogen stress conditions. Teasing out the underlying physiological components of a trait such as yield can reveal useful variation that would not be apparent from simply observing the yield itself.

Molecular genetic markers can provide a means to more effectively identify useful genes from gene bank collections that appear undesirable. Using phenotypically poor parents in a classical breeding program results in progenies that are almost all phenotypically undesirable as well, so they are not selected and thus drop out of the breeding program. However, molecular markers allow breeders to tease out the effects of individual genetic loci. This makes it possible to find those rare genes with positive effects even in progenies that are phenotypically negative because of the many undesirable genes they also carry. Using this approach, genes have been found from a small-fruited wild relative of the tomato that actually increase fruit size in cultivated tomato, and genes for more intense red color due to higher production of lycopene have been found from a tomato wild relative that produces only green fruit and no lycopene.^[14] Similarly, in rice this approach has revealed genes from a low-yielding wild ancestor that actually increase yield of cultivated rice.^[14] These results not only demonstrate that there can be useful genes in non-elite and wild relative germplasm that is phenotypically undesirable, but also show that molecular markers can be used to uncover these genes.

CURRENT ISSUES AND CHALLENGES

Clearly, our germplasm collections provide a tremendous and, for many crops, largely untapped resource for plant breeders. Utilization of gene bank collections has long

been limited by lack of characterization information. With tens of thousands of collections available for many species, but usually little information describing them beyond the place and date of collection, it is difficult for a breeder to know where to begin looking for a needed trait. Resources to characterize the collections in gene banks seem perpetually inadequate, so this is likely to remain a challenge into the foreseeable future. More recently, users of gene banks have also encountered the challenge of germplasm ownership. As illustrated in the preceding discussion, collections are clearly of present and future value so it is understandable that they would be viewed as valuable intellectual property. However, their thoughtful and widespread use in many different breeding programs will be essential to providing the food supply upon which human life will depend in the future. Agreements for exchange and use of germplasm have become increasingly complex legal documents and represent another challenge to the effective utilization of germplasm collections in plant breeding programs.

Gene Expression Modulation in Plants by Sugars in Response to Environmental Changes

Barry Wobbes

Sjef C. M. Smeeckens

University of Utrecht, Utrecht, The Netherlands

INTRODUCTION

Sugars play pivotal roles in the life cycle of plants. Sugars provide energy for metabolic processes and serve as building blocks for the structural carbohydrates necessary for plant growth. A second important function of sugars is as signaling compounds that can modulate gene expression. Over the past decade it has become apparent that sugars are involved as signaling molecules in many processes important for different stages of the life cycle of the plant. The sugar-induced feedback inhibition of photosynthesis is one example of a sugar-regulated process. When carbohydrates accumulate in mature source leaves, repression of the genes involved in photosynthesis is observed, and as a consequence photosynthesis is reduced. This affects source/sink relationships on the whole plant level because sugar abundance induces storage and utilization programs, and sugar depletion results in upregulation of mobilization and export processes. But sugars are also important for regulation of genes involved in pathogen defense, storage protein accumulation, secondary metabolism, cell cycle, and germination. The type of sugar—mono- or disaccharide—can have its own specific effects. Sugars exert these effects at different levels. Next to transcription, effects on messenger RNA (mRNA) stability and posttranslational modifications have also been described. Over the past few years it has become clear that sugar signals interact with many other signaling pathways, such as light perception and signaling, N assimilation, and plant hormone-signaling cascades. This illustrates the versatile and important roles that sugars play in plants, and the complexity of the underlying signaling cascades.

HEXOSE AND DISACCHARIDE SENSING AND SIGNALING

Glucose Sensing and Signaling

The fact that sugars are able to modulate gene expression^[1] indicates the existence of specific sugar-sensing

mechanisms in plants. Since the 1980s it has been known that the baker's yeast *Saccharomyces cerevisiae* is able to sense glucose and repress genes involved in the metabolism of other carbon sources—a system known as catabolite repression.^[2] During later years, it became apparent that yeast possesses multiple glucose-sensing systems, each responsible for initiating specific signaling cascades. The two glucose transporterlike proteins, RGT2 and SNF3, sense extracellular glucose concentrations and are responsible for the subsequent induction of hexose transporter (HXT) proteins in yeast. Low amounts of glucose are sensed by SNF3 and lead to induction of high-affinity HXT, whereas RGT2 senses high glucose levels and initiates signaling, leading to induction of low-affinity HXTs. Furthermore, a G-protein-coupled receptor responsible for sensing high glucose levels was identified that operates in the cyclic Adenosine Mono Phosphate (cAMP) pathway. Both types of sensors bind glucose extracellularly and, via a conformational change, transduce the signal over the plasma membrane. In contrast, hexokinase (HXK) functions as an enzymatic and signaling factor in the carbon catabolite-repression pathway. Evidence for this dual function of hexokinase has mounted; feeding experiments with glucose analogues that are substrates for HXK and not further metabolized are able to induce the carbon catabolite-repressed state.^[2] Furthermore, *hxx2* alleles have been identified that showed uncoupling of enzymatic and signaling functions.^[2] The molecular details as to how HXK is involved in glucose repression remain to be resolved.

The evidence for the involvement of HXK in plants as sugar sensors stems from experiments with nonmetabolizable glucose analogues and transgenic plants with altered HXK levels. Overexpression of *AtHXK1* leads to a glucose hypersensitivity phenotype, whereas lower levels of the main signaling hexose kinase lead to hyposensitivity.^[3] Similarly, glucose analogues that are substrates for HXK can mimic the glucose repression of photosynthesis^[4] and glyoxylate cycle genes.^[5] These results indicate the possible role HXK could fulfill as a glucose sensor. Plants possess at least three separate glucose signaling systems, each responsible for regulating a specific set of

genes.^[6] Two HXK-dependent systems are present: a system for which glucose phosphorylation by itself is sufficient for its activation, and another system that relies on further glucose metabolism. The pathogenesis-related PR1 and PR5 genes require further glucose metabolism for induction,^[7] whereas regulation of several genes involved in photosynthesis and nitrogen metabolism depends solely on glucose phosphorylation. Furthermore, a HXK-independent glucose-sensing/-signaling pathway is present that regulated transcription of a number of genes involved in a variety of processes such as carbon and nitrogen metabolism and UV-protection.

Work with yeast on the metabolism of trehalose, a disaccharide consisting of two glucose moieties, has revealed that trehalose-6-phosphate (T6P) is a negative regulator of HXK activity and thereby interacts with glucose signaling. In plants, the trehalose-metabolizing enzymes trehalose phosphate synthase (TPS) and trehalose phosphate phosphatase (TPP) have been expressed and shown to enhance and decrease photosynthesis, respectively.^[8] This led to the hypothesis that T6P inhibits HXK activity in plants also. However, evidence for such regulation lacks experimental substantiation. Nevertheless, in plants the trehalose system serves a signaling function.

Sucrose-Specific Sensing

Specific sucrose sensors have not been identified from yeast, plants, or any other organism. Recent experimental data, however, indicate that plants possess such sensors, because expression of the basic leucine-zipper type transcription factor *ATB2* is repressed in a sucrose-specific manner.^[9] Repression operates posttranscriptionally and occurs when seedlings are exposed to elevated but physiologically relevant sucrose concentrations. Application of similar concentrations of glucose and fructose—the two products of sucrose hydrolysis—did not cause repression. Deletion of the 5'UTR resulted in loss of the sucrose response, indicating the involvement of *cis*-acting elements in transducing the signal. Feeding sucrose to detached sugar beet leaves also revealed the potential of sucrose to negatively regulate sucrose symporter activity by decreasing messenger levels.^[9] Addition of glucose or the HXK inhibitor mannoheptulose did not result in decreased transport activity, indicating that HXK-dependent signaling pathways are not involved. The fact that glucose could not substitute for sucrose indicates sensing of sucrose occurs before it is hydrolyzed. This conclusion was confirmed by results from a study on the repressive effects of (nonmetabolizable) disaccharides on GA-induced α -amylase expression in barley. Repression by sucrose and glucose was shown to be mediated by

destabilizing the transcript,^[10] whereas nonmetabolizable sucrose analogues affected α -amylase expression via repression of transcriptional induction. These results indicate the existence of different systems to sense and signal the presence of glucose and sucrose in plants.

SUGAR-SIGNALING INTERMEDIATES

The SNF1 kinase complex is an important component of sugar-signaling cascades in yeast. Activation of this protein kinase occurs under low-glucose conditions and leads to derepression of glucose-repressed genes, enabling yeast to grow in the presence of carbon sources other than glucose. SNF1 kinase homologues from a large number of plant species (SnRKs) have been isolated and shown to complement the yeast SNF1 mutation. This indicates that the complex has been evolutionarily conserved and could function in sugar sensing/signaling in plants as well. The yeast SNF1 kinase complex and plant SnRKs are related to the mammalian AMP-activated protein kinase (AMPK), suggesting they could be activated as a consequence of intracellular changes in AMP levels. Plant SnRKs have been shown to regulate expression and activity of key enzymes in carbon and nitrogen metabolism, such as sucrose phosphate synthase (SPS), sucrose synthase and nitrate reductase (NR).^[11] Interestingly, activities of phosphorylated SPS and NR are inhibited only by the binding of 14-3-3 proteins adding another layer of regulation. The activity of the SnRK complex itself is also regulated. Mutations in *PRL1*, a SnRK-interacting protein, results in derepression of glucose-repressed genes and hypersensitivity to glucose and sucrose.^[12] In the *prl* background, activity of SnRK1 is approximately 50% higher indicating *PRL1* is a negative regulator of the SnRK complex in plants.^[13] The *prl* phenotype is highly pleiotropic, showing augmentation of sensitivity to cytokinin, ethylene, abscisic acid (ABA), and auxin. Furthermore, *prl* accumulates sugars and starch in leaves and shows inhibition of cell elongation and root growth. The pleiotropic phenotype of *prl* and the variety of SnRK targets indicate this complex could function as an important cross point between hormone, nitrogen, and sugar signaling.

INTERACTION OF SUGAR WITH HORMONE SIGNALS

Over the last few years, extensive cross talk between sugar- and phytohormone-signaling cascades has been discovered, as described for the *PRL1* locus. But also

more specific interaction between sugar- and hormone-signaling cascades has also become clear;^[14,15] the interaction of ABA and ethylene with sugar signaling has been characterized in some detail. ABA and ethylene are both involved in a plethora of physiological processes in plants. ABA is best known as a stress hormone and its biosynthesis is induced (or sensitivity to ABA is enhanced under adverse growth conditions). The classical ethylene-regulated processes include fruit ripening and the triple-response. The three-way interaction of ABA, ethylene- and sugar- signaling pathways was revealed in mutational and epistatic analyses.^[16] The *abi4* locus was originally identified as an ABA-signaling mutant, but in recent years it was also isolated from various sugar-related mutant screens. In one such screen for mutants lacking the ability to repress PC expression by sucrose, *sun6* (sucrose uncoupled) was isolated and shown to be allelic to *abi4*.^[9] From another sucrose-response screen, *abi4* was isolated as the *isi3* (impaired sucrose induction) mutant and shown to lack the ability to induce the *ApL3* gene by sucrose.^[14] ABA itself is not able to induce *ApL3* but enhances the sensitivity of tissues to sugars. Furthermore, the *isi4* mutant was shown to be allelic to the ABA-deficient mutant *aba2*, confirming the ABA-sugar interaction.^[14] Ethylene signaling also interacts with sugar responses as indicated by the facts that ethylene overproduction or constitutive signaling (*eto* and *ctr1*) causes insensitivity to glucose and that ethylene-signaling mutants (*etr1* and *ein2*) are glucose-hypersensitive.^[16] Application of ethylene to wild-type seedlings phenocopies the glucose-insensitive phenotype; together with the behavior of the ethylene mutants, these results show that ethylene desensitizes seedlings for sugars. Because ABA itself is negatively affected by ethylene, the ethylene effect on sugar sensitivity may depend on ABA interaction with the sugar-signaling systems. It has thus become clear that extensive cross

talk between ABA, ethylene signalling, and sugar signaling can occur (Fig. 1). The question remains as to the physiological relevance of these interactions and to what extent stress-signaling is involved under the high-sugar conditions used.

INTERACTION OF CARBON AND NITROGEN SIGNALS

In addition to mechanisms that perceive and signal the presence of sugars, plants also sense nitrogen compounds and enhance or limit nitrogen uptake and assimilation as needed. Coordination of sugar production via photosynthesis, nitrogen uptake, and assimilation allows plants to efficiently use these compounds to optimize growth. For example, genes involved in nitrate transport and reduction are induced by sugars. On the contrary, low carbon levels have inhibiting effects on N assimilation.^[17] Furthermore, the reciprocal induction of photosynthetic gene expression and photosynthesis by high nitrate further indicates the existence of C:N balancing mechanisms. Nitrate also can repress starch production by decreasing *AGPS*, a key regulator of starch biosynthesis. These interactions result in the enhanced availability of carbohydrates to sustain production and transport of amino acids when N availability is high. The molecular details of regulation by C:N ratios are largely unknown, but the ability of SnRKs to phosphorylate such diverse targets as NR and SPS, and the subsequent inactivation by 14-3-3 protein binding show the ability of this complex to play a role in controlling internal C:N balance.

CONCLUSION

Sugar signaling is of crucial importance in many if not all stages of the plant life cycle. It is now clear that sugar-signaling pathways are tightly interwoven with other signaling systems, such as those for hormones and nitrate. The challenge remains to further explore these interactions and understand their physiological significance.

Gene Flow Between Crops and Their Wild Progenitors

Roberto Papa

Università Politecnica delle Marche, Ancona, Italy

Paul Gepts

University of California, Davis, California, U.S.A.

INTRODUCTION

Gene flow occurs when there is migration of individuals (e.g., seeds) or gametes (e.g., pollen) between populations. Along with drift, selection, and mutation, it represents one of the main evolutionary forces causing changes in gene frequencies. The main effect of gene flow is the reduction of differentiation between populations accompanied by a parallel increase in differences between individuals within a population. The life history and demographic factors are also important in the determination of the effect of gene flow on the structure of genetic diversity (e.g., domestication bottleneck). Here we will briefly illustrate the current knowledge relative to the level, causes, and consequences of gene flow in the specific context of crops and their wild progenitors.

IMPORTANCE OF GENE FLOW

Wild-to-domesticated gene flow has important implications in relation to the evolution of crop plants. After domestication, gene flow in the centers of origin can partially restore the low genetic diversity included in these first domesticated populations. For instance, the differentiation of domesticated barley from the Himalayas and India compared to the Near East germplasm is probably due to introgression from Asian populations of wild barley (*Hordeum vulgare* ssp. *spontaneum*) after domestication.^[1] Gene flow still plays an important role as a source of new alleles for domesticated crops where traditional farming continues to be practiced.^[2]

Besides this natural gene flow, we should also consider the human-driven gene flow from wild to domesticated populations due to modern plant breeding, whereby useful wild alleles are integrated into the domesticated crop species. Many sources of resistance to pathogens and parasites have been introduced from wild germplasm by breeders and, more recently, genes relating to quantitative traits, such as fruit size in tomato and grain yield in rice.^[3] Gene flow from domesticated to wild populations is also an important issue relative to the release of transgenic

varieties because of the potential effect on the genetic diversity of the wild relatives and the possible production of new aggressive weeds.

FACTORS AFFECTING GENE FLOW

Table 1 summarizes the various factors affecting gene flow. In order to exchange genes, individuals need first to be sexually compatible; in other words, gene flow occurs between populations of the same biological species, or between populations of closely related species (introgressive hybridization), among which hybrids are partially fertile and can yield fertile progeny. In most cases, crops and their wild progenitors belong to the same biological species.^[4] However, in some cases domesticated crops and their progenitors belong to different biological species, in particular when domestication has involved polyploidization and/or interspecific hybridization, such as is seen for bread wheat (*Triticum aestivum* L.), a hexaploid originated by hybridization between a domesticated tetraploid and the wild diploid *Aegilops tauschii*. In these cases, even with the reproductive barrier due to the different ploidy level between the domesticated and wild progenitors, hybridization can still occur and can produce fertile progeny.

Gene flow between wild and domesticated populations is also limited by their phenology, geographic distribution, and spatial arrangement. Gene flow can occur if plant populations have overlapping flowering periods and are at a suitable distance, depending on the seed and pollen dispersal ability and the environmental factors such as wind, humidity, and biotic factors (pollinators and other animals favoring seed dispersal). Pollen and seed dispersal rates are strictly correlated with distance, such that dispersal rapidly decreases with distance to a very low value (e.g., within 50–200 meters), although a relatively low level of dispersal may occur even over very great distances (e.g., several kilometers). Evidence of gene flow between wild progenitors and domesticated crops has been documented for almost all crop species, including allogamous, autogamous, and vegetatively propagated

Table 1 Factors related to gene flow between wild progenitors and domesticated crop populations

Factors	Key aspect(s)	General consequences
<i>Prezygotic</i>		
Reproductive barrier I	Pollen competition, sexual compatibility	Partial incompatibility will reduce gene flow. Pollen competition may reduce gene flow or increase it just in one direction.
Geographical distance	Pollen/seed dispersal ability	Gene flow occurring only within the center of origin of a crop or within the (sympatric) areas of distribution of wild populations
Phenology	Genotype x environment interaction	Gene flow occurring only if flowering period is overlapping in the areas of sympatry
Dispersal ability	Biotic and abiotic factors affecting dispersal/breeding and propagation system	Rate of gene flow higher in allogamous than autogamous or vegetative propagating species
Population size	Relative size of wild and domesticated populations	Different sizes of domesticated and wild populations may lead to one-way gene flow.
Weedy populations	Presence of uncultivated fields and disturbed areas. Weed control.	Gene flow will be limited by weed control and favored by the presence of disturbed or uncultivated fields.
<i>Postzygotic</i>		
Reproductive barrier II (Hybrid fertility)	Different ploidy, chromosomal mutation	Partial sterility will reduce gene flow.
Selection in wild populations	Level of differentiation between wild and domesticated/genetic control of the domestication syndrome	Selection will act only in the segregant progeny with a lower fitness of progeny homozygous for domesticated alleles (when wild alleles of the domestication syndrome are dominant).
Selection in domesticated populations	Farmers' conscious selection (e.g., seed)/agronomic practices/genetic control of the domestication syndrome	Selection will limit gene flow as a post-zygotic reproductive barrier by reducing the fitness of first generation hybrids (when domesticated alleles of the domestication syndrome are dominant).
Breeding system	Effective recombination (out-crossing and heterozygosity)	In allogamous species, introgression will be limited only for selected loci; in autogamous species, introgression will also be limited for loci linked to selected loci (hitchhiking).
Demography	Population size (bottleneck)	Reduced population size will increase hitchhiking and will extend the effect of selection following gene flow events.

species. One of the very few exceptions is the strict selfing species *Arachis hypogaea*.^[2,5] According to a theoretical model, the amount of gene flow needed to prevent the genetic isolation and differentiation of populations and their independent evolution has been shown to be relatively low, about one migrant per generation,^[6] suggesting that even if the rate of dispersal and out-crossing is very variable among and even within species, gene flow is expected to be an important evolutionary force for most species.

Nevertheless, the reproductive and the propagation systems of domesticated crops represent crucial factors affecting the rate of gene flow between wild and domesticated populations. Clearly in an allogamous species the higher out-crossing rate results in a much higher frequency of domesticated-to-wild hybridizations than in an autogamous species. For vegetatively propa-

gated crops, such as fruit trees, gene flow from wild to domesticated populations will not occur unless farmers/breeders use sexual reproduction to obtain new cultivars. In contrast, gene flow will be very intensive in the opposite direction (domesticated to wild) leading to unilateral gene flow (one-way migration). One-way migration may also occur in sexually propagated species. For instance, in the common bean (*Phaseolus vulgaris* L.), the gene flow from the domesticated to the wild populations has been found to be about 3–4-times higher than that in the opposite direction.^[7] In this case, one-way migration can be promoted by the presence of differences in population sizes between the wild and domesticated populations because the domesticated genes will gradually increase in the wild populations, while in the domesticated populations, the few immigrant genes will be diluted and hence have a very low effect on gene frequencies.

Farmers' fields usually contain a large number of individuals, while wild populations close to such fields will often be made up of a very small number of individuals. Consequently, hybridization events will be more frequent when wild plants are the maternal parent than when they are the paternal parent.

Farmers themselves can also affect the rate of gene flow from wild to domesticated crops. Indeed, in several cases traits related to the domestication syndrome are recessive, and, hence, first generation hybrids are usually more similar to the wild plants, and are thus easily detectable. For this reason farmers can discard first generation hybrids by choosing the seeds for the planting of the next generation, producing an effect analogous to that of a post-zygotic reproductive barrier. Gene flow is also limited by weed control and intensive cultivation (e.g., absence of uncultivated areas), which eliminate wild plants growing within and around the crop. It is likely that in the early ages of agriculture the opposite situation would have occurred, with the predominant direction of gene flow being from wild to domesticated populations because of the smaller crop populations and the lower differentiation between wild and domesticated forms.

In some cases, hybridization between wild and domesticated populations leads to the development of weedy populations^[1,7] that can be found in farmers' fields or that can colonize other disturbed environments (i.e., field borders, abandoned fields, roadsides) and present intermediate characteristics between wild and domesticated forms.^[4] These weedy forms can also originate as "escapes" from cultivation. In either case, their presence facilitates the exchange of genes between domesticated and wild populations.

GENE FLOW AND SELECTION

In the previous paragraphs we have demonstrated that gene flow between wild progenitors and domesticated populations is a significant phenomenon in almost all crop species. However, wild progenitors and domesticated crops maintain their distinct phenotypes even in sympatry. This suggests that selection has a prominent role in limiting the introgression between the wild and domesticated forms. However, even if there is little direct evidence, selection is likely to vary greatly between the wild and the domesticated environments, as among the different genes involved in the control of the domestication syndrome, and among different crop species^[8] and different agronomic systems. As previously indicated, for several key traits of the domestication syndrome, the wild alleles are dominant (i.e., shattering, dormancy, growth habit, photoperiodic sensitivity), and the first generation

hybrids are more similar to the wild than to the domesticated forms. Considering also that hybrids may show heterosis, the first generation hybrids will have a much higher reproductive success in the wild environment than in the domesticated environment, where farmers may easily eliminate them by selecting the seeds or because the progeny will not be included in the next harvest due to shattering or dormancy. Consequently, in the wild environment, selection against domesticated alleles will mainly occur in the segregating progeny following the F₁ generation, thus favoring the introgression of genes from domesticated populations because of recombination. Both selection and asymmetric gene flow will favor the introgression from domesticated to wild populations rather than in the opposite direction; this may explain why in domesticated populations low levels of introgression from the wild progenitors are often seen,^[1,7] even for allogamous species such as maize.^[8]

Asymmetric gene flow and different types of selection can be considered as possible causes of the displacement of genetic diversity in the wild progenitor populations, as has been observed in cotton and rice,^[5] and to a lesser extent in the common bean.^[7] In addition to the target loci (i.e., genes for domestication traits), selection may affect the surrounding chromosome regions because of linkage (hitchhiking). Indeed, in allogamous species, which present a high level of heterozygosity, selection will affect (by elimination of the migrant alleles) only loci under selection because of recombination. In contrast, in autogamous species, selection will indirectly reduce the introgression for neutral loci linked to those under selection (hitchhiking). The extent of hitchhiking can be very low (a few hundred base pairs) in allogamous species such as maize,^[9] but can also become very large (several cM) in autogamous species, because the reduction of the out-crossing rate drastically reduces the level of effective recombination. In addition, the extent of hitchhiking also varies according to the level of recombination in different parts of the genome, the demography of the population (e.g., the existence of bottlenecks in the evolution of the population versus the species as a whole), and other evolutionary factors such as selection.^[10-12]

CONCLUSION

Gene flow and introgression between domesticated crops and their wild progenitors occurs in most cases, although its intensity and effects are very variable in relation to any given species (of crop and its wild progenitor), its life history, the environment (space and time), genome location (in relation to domestication syndrome genes), the agro-ecosystem, and human activities. Knowledge of

this subject is currently growing rapidly because of the interest in evaluating the potential effects of transgene release into the environment and the role of wild progenitor genetic diversity in conservation and breeding.

Gene Silencing: A Defense Mechanism Against Alien Genetic Information

Peter de Haan

Phytovation B.V., Leiden, The Netherlands

INTRODUCTION

Gene expression in eukaryotic cells is tightly controlled by regulatory mechanisms acting at the transcriptional level in the nucleus or at the posttranscriptional level in the cytoplasm. The last few years it has become clear that besides proteins, noncoding RNA molecules play an important role in gene regulation. Several independent lines of research relating control of gene expression led to the discovery of a novel posttranscriptional regulatory mechanism referred to as RNA silencing. RNA silencing uses RNA instead of proteins as the signaling and target molecules.

In plants, RNA silencing appears to play an important role in morphogenesis. In addition, this cytoplasmic RNA surveillance mechanism is involved in protection against intracellular molecular parasites such as the transposable elements, viroids, and viruses.

RNA SILENCING TO CONTROL GENE EXPRESSION

RNA molecules play prominent roles as signals and targets in gene regulation. This implies that the central dogma in molecular biology (where DNA is transcribed into RNA, which is translated into proteins, which play major roles in gene regulation and development) clearly needs to be updated.

A number of observations originally made about plants—such as transgene-induced silencing of genes (e.g., flower pigmentation), RNA-mediated virus-resistance, and virus-induced gene silencing—and later on about other organisms—such as quelling in fungi and RNA interference in nematodes, insects, and mammalian cells—turned out to rely on a similar molecular process. This process, which can generally be termed RNA silencing, is induced by overexpressed and double-stranded RNA (dsRNA) molecules, and involves sequence-specific RNA degradation in the cytoplasm of cells from higher eukaryotes.^[1]

The key step in the induction of RNA silencing is the formation of dsRNA by host RNA-dependent RNA polymerases (RdRp), which is recognized and cleaved by a dsRNA-specific RNase III-type nuclease (denoted DIC-

ER) to yield small (21–25 nucleotides long), short, interfering RNAs (siRNAs). The siRNAs have the capacity to specifically bind to complementary mRNA molecules and thereby enable the host-encoded RdRps to produce a second generation of dsRNA molecules, which are again cleaved by DICER to yield secondary siRNAs. Genetic studies revealed additional genes and proteins (such as helicases) active in the RNA silencing pathway in plants and animals. All these proteins are associated with cytoplasmic nuclease complexes—denoted RNA-induced silencing complexes (RISC)—approximately 500 kD in size.^[2]

Besides siRNAs, other classes of noncoding transcripts have been found that play important roles in gene regulation. One particular class of noncoding transcripts—denoted micro-RNAs (miRNAs)—has been identified in nematodes, mammals, and recently plants, that was hitherto overlooked using standard methods for identifying genes. In plants, there are indications that miRNAs are involved in morphogenesis and in stress responses. The miRNA genes are clustered on the chromosomal DNA, suggesting they are processed from long precursors. The miRNAs have extensive duplex secondary structures that are cleaved by DICER to yield short temporal RNAs (stRNAs) resembling siRNAs. These molecules are targeted to the 3' ends of cognate mRNAs and thereby inhibit their translation. Because this process requires (some of) the same components as the RNA silencing pathway and also takes place in cytoplasmic complexes with size similar to that of RISC, it is tempting to assume that miRNAs initiate RNA silencing in RISC. It has remained unclear which host genes are precisely targeted by miRNAs and how their expression patterns are modified. It is possible that transcriptional control of certain genes by their own promoters is not stringent enough; miRNAs here serve as an extra lock to prevent accumulation of cognate proteins in specific tissues at specific points in time.^[3]

Silenced host genes are kept in a silent state either by continuous supply of stRNAs and/or siRNAs, or by transcriptional gene silencing. A number of reports, mainly dealing with transgene-induced gene silencing, show that siRNAs are able to induce methylation of homologous sequences on the chromosomal DNA. This coincides with alterations in the local chromatin structure,

rendering euchromatin into heterochromatin, which finally results in inhibition of transcription of the affected gene. A number of genes have been identified in *A. thaliana*, including one encoding a methyltransferase (MET1) and one encoding a protein involved in chromatin remodelling (DDM1), which play roles in transcriptional silencing. Hence, it appears that RNA silencing is not an exclusive posttranscriptional process but that it also has components acting at the transcriptional level.^[4]

The main question remains, how does RISC discriminate between RNAs to be degraded and RNAs to be retained? Most structural RNAs, e.g., transfer RNAs (tRNAs) and ribosomal RNAs (rRNAs), have extensive double-stranded structures, but they do not initiate RNA silencing. It is also known that these structural RNAs are closely associated with proteins to form ribosomes, and may therefore not be accessible to the RISC complex. Protein encoding mRNA molecules are covered with ribosomes in polysome complexes, immediately after translocation to the cytoplasm. Hence, all structural and coding RNAs are covered with proteins or imbedded in higher-order structures and very seldom occur as naked RNA. RISC was discovered by copurification with polysomes; it could therefore very well be that in vivo RISC is associated with ribosomes. Remarkably, one of the RISC components ARGONAUT shows sequence homology to translation initiation factor eIF2C, which

might be another indication of the tight linkage between translation and RNA silencing.

The covered or imbedded RNAs are hidden from the surveillance activity of RISC and protected from being degraded. The most plausible explanation for the selectivity of RISC is therefore that exclusively RNA molecules, which accumulate free in the cytoplasm such as noncoding (ds)RNAs, miRNAs, and overabundant mRNAs, are targeted by RISC and enter the degradation pathway. Resulting siRNAs reside in RISC and target complementary RNAs or induce transcriptional silencing (Fig. 1). In this process the dsRNA and miRNA species are direct prey for DICER, whereas the overexpressed RNAs are first copied into dsRNA by a host RdRp, most likely in a primer-independent fashion.^[5] Alternatively, it may be that RNA synthesis is randomly primed by tRNAs.

RNA SILENCING TO CONTROL INTRACELLULAR PARASITES

All living organisms are hosts for parasites. A number of them are intracellular parasites that use host components for their replication. Plants suffer from three classes of intracellular parasites: transposable DNA elements, viroids, and viruses.

Fig. 1 Schematic representation of gene regulation in eukaryotes. 1: In the nucleus, genes are transcribed to yield RNA molecules. The RNAs play regulatory roles in RNA processing in the nucleus, or they are transported to the cytoplasm. 2: The structural RNAs are imbedded in polysomes, which are responsible for translation of host and viral mRNAs. 3: RISC performs a surveillance function and targets unprotected RNAs for degradation. The resulting siRNAs in RISC bind to complementary RNAs and induce their degradation. Viral replication intermediates are always wrapped with CP or NP (or with ribosomes in the case of plus-strand RNA viruses). (View this art in color at www.dekker.com.)

Transposable elements such as retroelements and transposons are integrated in host chromosomal DNA and have the capacity to jump to other positions. They were first described in maize in the early 1950s, and turned out to be highly abundant in eukaryotes, including most crop species. Because of their mobilizing capacities, transposable elements represent mutagens and thus have the potential to destroy the genetic makeup of individuals.^[6] It has recently been shown that eukaryotes use RNA silencing to protect their genomes from jumping DNA elements. Inserted transposable elements are usually methylated and transcriptionally silent, whereas specific siRNAs can be found in the cytoplasm. These elements are most likely kept immobilized by transcriptional silencing induced either by overproduced transcripts or by dsRNAs, which are produced from multiple tightly linked copies of a particular element.^[7]

In tissues such as meristems, RNA silencing appears not to be active, so that one could imagine that during active cell division (both in mitosis and meiosis), RNA silencing is inactive and DNA methylation patterns are reset. As a result, transposable elements can become active and jump to other loci. The elements are stabilized again in the differentiated cells. Besides having negative effects, transposable elements are also beneficial to their hosts. Because mobilization creates additional variability in progeny populations, conferring a selective advantage to the host, it may be in the host's interest to retain transposable elements that are active during cell division but that are controlled by RNA silencing in vegetative tissues.

Another class of intracellular parasites are viroids, which are pathogenic small circular noncoding single-stranded RNAs folded into dumbbell structures. They replicate in the nucleus of infected cells and from there migrate to the cytoplasm.^[8] As noncoding and almost perfect dsRNA entities, they seem ideal prey for RISC. However, in the cytoplasm viroids most likely mimic small ribosomal RNAs, hide in ribosomes, and thereby escape from being massively degraded.^[5]

Most crops are hosts for viruses, the most complex intracellular parasites. Viral infections cause symptoms varying from unnoticeable to severe necrosis, and may lead to dramatic yield losses. Most of the plant-infecting viruses have RNA genomes and exclusively replicate in the cytoplasm of infected cells. Relatively few plant viruses have DNA genomes that replicate in the nucleus. However, their transcripts are normally directed to the cytoplasm where the viral proteins are produced. Also, virus replication in plants is controlled by RNA silencing.^[9] It has been suggested that double-stranded replication intermediates induce silencing, but this seems unlikely. DNA viruses also hide their replication intermediates in the nucleus and are susceptible to silencing. Moreover, if RNA viruses would expose their dsRNA replication intermediates as naked RNA in the cytoplasm, this would induce an immediate and massive RNA-

silencing response. The genomic sense and antisense RNA molecules are therefore always carefully wrapped with coat proteins (CP) or ribosomes in case of plus-strand RNA viruses or nucleocapsid proteins (NP) in case of negative-strand RNA viruses. The amount of CP or NP accumulating in the cytoplasm determines whether transcription or replication takes place by the viral RdRp. In the beginning of the infection process, with low amounts of CP/NP, transcription or translation occurs, yielding mRNAs encoding viral proteins. At a later stage, when high amounts of CP/NP accumulate, RNA replication takes place, yielding genomic RNAs assembled into progeny virus particles. Virus replication is therefore controlled by simultaneous activity of two types of RdRps: viral and host RdRps. It seems likely that threshold levels of viral mRNAs in the cytoplasm instead of double-stranded replication intermediates trigger RNA silencing (Fig. 1). In this process, a host RdRp copies the viral mRNAs, most likely in a primer-independent or tRNA-primed fashion.

One should bear in mind that RNA silencing is not capable of creating virus resistance in many if not all cases. True resistance is mediated by virus resistance genes, such as the N gene from tobacco or the Tm-2a gene from tomato, both conferring immunity against tobamovirus infections in solanaceous crops. RNA silencing is merely involved in keeping viral titres low, thereby minimizing the detrimental effects of the virus infection on the plant.

It is not surprising that as part of the ongoing battle between parasite and host, many viruses carry functions to suppress this intracellular defense mechanism. A number of plant viral RNA-silencing suppressors have recently been identified. Mutations in the viral RNA-silencing suppressor genes frequently lead to a dramatic drop in virulence. Therefore, the viral RNA-silencing suppressors can be regarded as the major virulence factors. The suppressors identified and studied so far are highly heterogeneous and appear to inhibit different components of the RNA silencing pathway. This indicates that silencing suppressors are independently acquired by viruses, and that this hence has been a relatively recent event.

One of the best studied suppressors is cucumber mosaic virus (CMV) P2b.^[10] Next to RNA silencing suppression, P2b is also indicated as being involved in long-distance movement of the virus. The protein is targeted to the nucleus and prevents silencing in newly emerging tissues. It is not able to reverse silencing, once established. Compared to other plant viral silencing suppressors, P2b is relatively weak; this might explain why CMV infections generally cause mild mosaic symptoms.

Another well studied suppressor is potato virus Y (PVY) HC-Pro. This suppressor prevents degradation of dsRNAs into siRNAs by DICER, and is able to reverse RNA silencing. The NSs gene from *Tomato spotted wilt virus* (TSWV)—a negative-strand RNA virus—seems to inhibit

the same step in the RNA silencing pathway as PVY HC-Pro. Both silencing suppressors have strong activities, which may explain why potyviruses and tospoviruses rank among the most economically detrimental groups of plant viruses, generally causing severe disease symptoms.

In contrast to HC-pro or NSs, the P19-silencing suppression protein of tombusviruses does not prevent the formation of siRNAs and directly interacts with the siRNAs or with RISC and inhibits their action. The 2b protein of CMV and the p25 protein of PVX seem to interfere with processes even further downstream. The C2 protein of tomato yellow leaf curl virus (TYLCV) is the first silencing suppressor identified from a plant DNA virus. All plant viruses most likely carry RNA-silencing suppressor genes, which are important if not essential in overcoming this general intracellular defense response.

CONCLUSION

RNA silencing is a newly discovered gene regulation mechanism, involving cytoplasmic sequence-specific RNA degradation. RNA-silencing components are clustered into a riboprotein complex called RISC that seems associated with polysomes. RISC has a surveillance function and targets free uncovered RNAs, such as over-expressed RNA and dsRNAs for degradation. The central molecules are the degradation products of the DICER enzyme—siRNAs—that serve as a sequence-specific memory for the recognition of complementary RNAs to be degraded, and as a signal for transcriptional gene silencing in the nucleus. RNA silencing plays a dual function in eukaryotic organisms. First, it is involved in morphogenesis and possibly other developmental processes. Second, it counteracts alien intracellular genetic information: It is responsible for keeping transposable elements latent and for suppression of virus disease development. RNA silencing has been analyzed in detail in plants. Although many questions await an answer, this led to an enormous body of information on this newly discovered regulatory mechanism. This knowledge has already led to a number of applications. Engineered virus-resistant crops based on RNA-silencing principles have recently reached the market. Gene silencing is employed to produce crops resistant to other pathogens. This is achieved by blocking the expression of recessive dispensable genes such as powdery mildew resistance in cereals. Plant viral RNA-silencing suppressors can be used as gene expression enhancers to produce recombinant proteins in plants.

Current genomics efforts will reveal additional information on RNA-silencing machinery, especially on the biological functions of noncoding RNAs. With detailed knowledge of this intriguing process, many more applications will undoubtedly become available in the near future.

ACKNOWLEDGMENTS

I would like to thank Dr. M. W. Prins for critically reading the manuscript. I apologize to a crowd of researchers who have contributed to the increase in knowledge of RNA silencing, whose work I was unable to mention here.

Genetic and Epigenetic Variation Released Upon Polyploidization

Avraham A. Levy

Moshe Feldman

Weizmann Institute of Science, Rehovot, Israel

INTRODUCTION

The discovery of polyploidy was followed by the quantification of its prominence and the contemplation of the reasons for its success as a driving force in plant evolution. The paradigm was that polyploid species are successful because of the increased range of gene dosage; the new heterotic interactions between alleles, homeoalleles, or genes; and the buffering of the mutation load as a result of gene duplication, facilitating the formation of novel genes and recombinant genomes. Although this long-held view is still valid, there are now new twists to the paradigm. Recent studies have emphasized the importance of non-Mendelian processes and have described their time course. These studies show that new variation, not previously present in diploid progenitors, can be induced rapidly upon polyploidization rather than on an evolutionary scale. The basis of this new variation is both genetic and epigenetic.

ADDITIVE AND HETEROTIC INTERACTIONS

Despite substantial evidence for genetic and epigenetic rearrangements in polyploids, most genes and gene expression patterns are unchanged compared with the diploid progenitors. Yet, the new gene dosage levels and the combination of different alleles or genes also provide new genetic variation.

Dose Response

Accumulating evidence in plants supports a genomewide scale sensitivity of transcription levels to gene dosage. For example, expression of several loci was shown to be affected by genome dosage (ploidy level) in a series of maize lines containing between one and four copies of the same genome.^[1] This type of positive dosage is likely to contribute to the additive variation of many genes, in particular for genes that affect quantitative traits. One gene whose variation in dosage and expression is associated with variation in flowering time in *Brassica*

and *Arabidopsis* is the MADS box gene *FLC*.^[2] This gene may be a good example that links gene dosage variation in polyploids and phenotypic variation not existing in the diploid progenitors.

The Heterotic Effect

Polyploidization generates new genetic variation by coexpressing divergent alleles, homeoalleles, or genes in the same genome. This merger can have a complementary or heterotic effect. For example, the merger of tetraploid emmer wheat (genome BBAA) and the genome of *Aegilops tauschii* (genome DD) provided a mechanism to combine the desirable large grains and productivity of emmer wheat (used for pasta and flat bread) with the elasticity of gluten proteins from the wild *A. tauschii* to produce the hexaploid wheat, *Triticum aestivum* (genome BBAADD), which is used to make rising bread. Similarly, the cold hardiness of *A. tauschii* allowed wheat to expand its area of adaptation from the Near Eastern and Mediterranean areas to the worldwide area occupied by bread wheat today. In allopolyploids that are predominantly self-pollinators, a new successful combination of different homeoalleles can be fixed (permanent heterozygosity) because pairing is mostly restricted to homologs (disomic inheritance). Disomic inheritance also facilitates the fixation of positive interactions between nonallelic genes of different genomes. In autopolyploids, which are predominantly cross-pollinators, the heterozygotic condition is not fixed because multivalent pairing results in polysomic inheritance. However, the multiplicity of alleles at a locus still increases the chances for new heterotic intralocus interactions, resulting in a new level of variation relative to diploids.

GENETIC ALTERATIONS

Gene duplication arising from polyploidy provides new templates that allow substantial changes on an evolutionary scale. Exciting recent studies indicate that genomic variation is also induced very rapidly, occurring in as early

as the first generation of the polyploid state. In this section, we describe how polyploidy can stimulate alterations in the DNA blueprint itself, both on an evolutionary scale and as a rapid response.

Acquisition of Novel Genes

It has often been proposed that gene duplication causes a relaxation in selection on one gene copy, thus facilitating the acquisition of a new function by the second copy. A series of works supports this hypothesis.^[3] Gene decay in polyploids is less rapid than expected, suggesting that the duplicated genes are not completely redundant and that functional differentiation, or dosage effect, does provide some increased fitness.^[3] Possible examples for new function acquisition are the maize transcription factors R and B, which map to homeologous chromosomal segments and regulate anthocyanin biosynthesis. These genes were not only maintained after ~12 million years since the duplication of the ancestral gene, but underwent accelerated evolution in protein sequence and diverged in developmental gene expression.^[3] This suggests that accelerated functional diversification might affect gene-coding regions, noncoding cis-regulatory elements, and/or trans-acting regulatory factors, thus contributing to long-term retention of duplicated genes.

Intergenic Interactions

Some types of DNA rearrangements, such as intergenomic horizontal transfer of chromosomal segments, transposons, or genes, between the constituent genomes can occur almost exclusively in an allopolyploid background. For example, intergenomic translocations were found by genomic in situ hybridization (GISH) or gene mapping in several allopolyploids, including oat, tobacco, *Brassica*, and wheat.^[2,4,5] These translocations might have been brought about either by recombination between homeologous chromosomes, between dispersed repeats, or by illegitimate recombination.

Transposons, a significant part of the repetitive DNA fraction, can insert into both linked and unlinked sites, thus contributing to intergenomic horizontal transfer. The analysis of a series of cotton (*Gossypium hirsutum*; genome AADD) repetitive DNA sequences showed that sequences that are specific to the A genome at the diploid level are present in both A and D genomes at the tetraploid level. Most of these repetitive families have homology to known classes of transposons.^[3] Another type of repeat frequently associated with intergenomic interactions is the ribosomal DNA (rDNA) repeat array. The comparison of the parental arrays to those of the polyploid suggests that

homogenization of the repeats may occur as a result of homologous recombination (e.g., through gene conversion and unequal crossover). This type of concerted evolution was found in several species.^[3] However, in other species, the parental arrays are unchanged, or, alternatively, one of the parental arrays is eliminated.

Genetic Rearrangements in Nascent Polyploids

The lack of knowledge on the precise progenitors of natural polyploids, together with the usually long period after polyploidization make it difficult to determine the type of genetic alterations that are directly caused by the process of polyploidization. Fortunately, it is possible to artificially produce polyploids (synthetic polyploids) that are analogous to natural ones. The analysis of synthetic polyploids in *Brassica* and wheat has shown that DNA rearrangements can occur in the first generation(s) upon polyploidization.^[2,5] DNA rearrangements in wheat were mostly elimination of coding or noncoding sequences, reproducible in independent crosses, and similar to events present in natural polyploids.^[5] In contrast, the types of rearrangements in *Brassica* were more varied and unpredictable.^[2] Sequence elimination in wheat allopolyploids occurs immediately in the F1 hybrid, or after chromosome doubling. It may occur as soon as zygote formation, and it involves both low-copy DNA as well as repetitive DNA.^[5] In contrast, there is an apparent homeostasis of the genome in cotton synthetic polyploids and no DNA rearrangements were found.^[3] In *Arabidopsis*, there are preliminary reports of transposon-mediated genetic rearrangements in synthetic polyploids.^[6]

EPIGENETIC VARIATION

Heritable alterations in gene expression, namely silencing or activation in the absence of genetic changes, were found in several synthetic polyploids.^[7] Silencing of rDNA genes (nucleolar dominance), as well as a broad range of other genes, has been reported. Polyploidy in *Arabidopsis* was also shown to induce the silencing of transgenes and to generate stable epialleles.^[8] Epigenetic alterations can also lead to the transcriptional activation of genes, including transposons. The underlying mechanisms for these epigenetic changes include alterations in patterns of cytosine methylation and histone modifications, both of which are related to chromatin structure. Transposon activation not only results in transposon movement, but can also affect the expression of adjacent genes via readout synthesis of sense or antisense RNA.^[9] Unlike

Fig. 1 New variation released upon polyploidization. Hybridization between two diploid progenitors (e.g., genomes AA and BB) followed by chromosome doubling gives rise to a new polyploid (e.g., genome AABB). If genomes A and B are from different species, an allopolyploid is formed; if they are from the same species, an autopolyploid is formed. The chromosomal complement of genomes AA and BB is shown schematically as two vertical grey bars and two vertical white bars, respectively. A new variation can be released in the polyploid as a result of the new combination of genotypes, through gene dosage effects or through new interactions between alleles, homeoalleles, or genes. Genetic alterations not present in the diploid progenitors can occur upon polyploidization. This includes intergenomic translocations of chromosomal segments; accelerated gene evolution, presumably because of a relaxation in selective pressure, and thus diversification of gene structure and function; conversion between homeologous alleles that can affect whole gene arrays such as the rDNA genes; elimination of both coding and noncoding sequences from one of the diploid constituent genomes; and transposon activation leading to genetic alterations via intragenomic or intergenomic transposition. Transposons can also affect gene expression in the absence of transposition: they can cause activation or silencing of adjacent genes via sense or antisense readout transcription; they can also undergo methylation or demethylation; and they can affect chromatin structure and the activity of genes in cis or in trans. Epigenetic alterations can lead to gene silencing or activation, or to differential expression of genes via alterations in methylation or chromatin structure.

genetic alterations, epigenetic alterations are reversible. Moreover, epigenetic alterations, triggered by allopolyploidy, can lead to the rapid and stable functional divergence of homeoalleles.^[10]

CONCLUSION

Polyploidy represents a considerable genomic stress. The genome has to deal with redundancy, imbalanced and antagonistic gene expression, orchestration of DNA replication, and the pattern of chromosomal pairing. The evolutionary success of polyploidy suggests that mechanisms allowing the organism to survive these challenges and to take advantage of the potential benefits of polyploidy exist. We have described the diversity of strategies and responses that have been reported both at the genetic and epigenetic levels (Fig. 1). Some species

have a precise genomic response, whereas other species seem to respond to polyploidy via random DNA rearrangements or show genomic homeostasis. Epigenetic alterations are emerging as a fascinating mechanism that can rapidly generate a heritable yet flexible variation in expression patterns, contributing not only to the on/off activity of genes but also to the establishment of more subtle developmentally regulated patterns of expression. Transposons seem to play a very unique role beyond their mutagenic effect. They can be activated upon polyploidization and subsequently affect the expression of adjacent genes.^[9] Transposons may also affect gene expression in trans via dsRNA and chromatin remodeling, as recently proposed.^[6] Despite the abovementioned findings, our understanding of the variation-inducing mechanisms in polyploids is quite limited. Few concrete examples that describe the link between the alteration of a particular gene and the effect on the phenotype and fitness of the plant exist.

Genetic Conservation Ex Situ: Botanical Gardens, Arboreta, and Herbaria

Mary T. Burke

UC Davis Arboretum, University of California, Davis, California, U.S.A.

INTRODUCTION

Botanical gardens and arboreta are collections of living plants used for research, study, and education. Arboreta traditionally focus on collections of large trees and shrubs (woody plants) while botanical gardens include research and display collections of both herbaceous (bulbs, biennials, perennials) and woody (trees and shrubs) plants. In actual practice, the boundaries between these two collection types have become less clear during the past century; for instance, many arboreta have expanded their collections to include herbaceous plants but retain their historical names. Both botanical gardens and arboreta are distinguished from public parks and other recreational landscapes by collection policies that emphasize wild-collected plants, by collections organized for scientific and educational purposes, and by extensive documentation; that is, a plant record system that includes information on provenance, nomenclature, and other taxonomic and cultural information of interest to researchers. A herbarium (herbaria, pl.) is a collection of dried, pressed, or preserved plant specimens with associated relevant collection information. Many herbaria are associated with botanical gardens and arboreta; others are associated with universities and other plant science research facilities. Some botanical gardens also maintain or are closely associated with seed banks, facilities where seeds are stored under cold and dry conditions in order to preserve the seed viability for future use.^[1] As extinction rates for plant species have increased, these institutions have begun to play important roles in ex situ conservation, or conservation outside the native habitat.

CENTERS FOR EDUCATION

Botanical gardens and arboreta are “living museums”; in addition to their scientific mission, these plant collections are important and popular centers of informal science education. In the last 20 yr, botanical gardens and arboreta have begun to switch their focus away from simply displaying and identifying plants, and more toward conveying critical scientific ideas and

significant issues. Exhibits and labels are being redesigned to teach not only about plants as beautiful or interesting organisms, but about the role plants play in the real world: their ecosystem functions, the dependence of all life upon them, information about invasive species and their threats, the need to survey and understand unknown areas, and how people can manage native plant ecosystems. Effective conservation exhibits give visitors more of the fascinating and complex story of which plants are a critical part, rather than just a little information about a particular plant.

Globally, botanical gardens and arboreta are visited by more than 150 million people a year.^[2] Recognizing the opportunity this represents, botanical gardens have assumed a new responsibility to educate people in a way that will help local citizens go on to influence policy makers and create a locally active group of people that have global concerns.

Examples of gardens and displays organized around conservation themes include the two-acre New England Garden of Rare and Endangered Plants at the New England Wild Flower Society’s Garden in the Woods; the large display of rare and endangered California native plants, as well as 210 rare taxa from around the world, at the University of California Botanical Garden at UC Berkeley; and the exhibits highlighting the impact of invasive plants in Australia at the Botanic Gardens of Adelaide. Even the work of tissue culture as a method for preserving genetic resources has been showcased as a public exhibit at the Center for Research of Endangered Wildlife, the research program of the Cincinnati Zoo and Botanical Gardens. Here, tour groups can walk through the scientific facility and look through glass-lined walls at tissue culture incubators, a working greenhouse, and into a laboratory with liquid nitrogen storage tanks—The Frozen Garden. These exhibits introduce the general public to some aspects of science and technology currently focused on the preservation of rare and endangered species.^[3]

CENTERS FOR RESEARCH AND DISCOVERY

As scientific institutions, botanical gardens and arboreta serve another important conservation role

by conducting research or plant surveys on critical habitats, endangered plants, and invasive species. Collaborating with universities and other centers for plant studies, botanical gardens and arboreta are a place where people come together to study species of special concern. In many countries, public gardens are among the leading, and sometimes the only, institutions capable of undertaking the extensive work needed in plant research and conservation.^[2]

There are about 2200 botanical gardens and arboreta in the world; it is estimated that about one-fourth of the world's flowering plants and ferns are included within their collections.^[4] The extensive ex situ taxonomic and geographic collections that botanical gardens have amassed also play a critical role in botanical research, as they gather together in one place a wide variety of plants that would be difficult to study in the wild. These documented collections provide scientists with accurately identified plants of known provenance. Information about the locality in which the plant was originally collected is maintained by the scientific staff to enhance the value of the collection for researchers. The genetic resource collections in botanical gardens are often supplemented at major plant research centers by ancillary collections, including extensive herbarium collections of preserved plant specimens and seed and tissue banks. Herbaria deserve special mention as repositories of plant genetic resources: these museum specimens serve as a permanent global reference on the plant diversity of the world.

Efforts are currently underway to consolidate the inventories of ex situ plant genetic resource collections around the world, held in seed banks, field collections, herbaria, and other collections. These efforts have been hampered to some extent by not simply the scale of the undertaking, but the wide variety of ways in which collection managers have independently tracked information about their scientific holdings. Protocols for information management in natural history collections are gradually evolving in the scientific community (Darwin protocol,^[5] Dublin metadata core^[6]). Currently, some botanical gardens and arboreta that use a common database standard (BG-Base) list their holdings on the web in a common format that can be searched in all the consolidated inventories through a single search query.

Traditionally, botanical gardens, arboreta, and herbaria have provided open access to their collections and holdings for research or conservation purposes. In the spirit of willing compliance with the Convention on Biological Diversity (1993) on the issue of ownership of genetic resources,^[7] many gardens have begun to implement policies and procedures to address obligations regarding access to their collections and sharing the benefits of research based on them with the

nations of origin. An estimated 90% of all living plant collections in botanical gardens predate the Convention on Biological Diversity (CBC). Although, technically, such collections are not covered by its provisions,^[2] most scientific collections attempt to meet the CBC's goals and comply with the spirit of the convention.

CENTERS FOR PLANT PROTECTION

In addition to education and research, botanical gardens have another critical role to play in plant conservation: they often serve as the sole source of horticultural expertise for specialty plant groups, particularly for wild plants that are rarely used for display or ornamental purposes.^[2] Highly accomplished nursery staff at botanical gardens often are experienced in the propagation of unusual plants. The value of this highly specialized skill to global plant conservation cannot be overemphasized, for knowing how to grow a plant may be a key to its survival or its return from the brink of extinction. In Hawaii, tissue culture and micropropagation have also been critical tools in the attempt to reestablish plants from in situ populations with less than 10 or 20 individuals.

Working within national or local consortiums or with state or federal agencies, botanical gardens may grow large collections of endangered plants, sometimes receiving them in the wake of new development or urbanization of former wildlands, holding them safely in cultivation or in seed banks, and occasionally reintroducing them back into the wild as part of species-recovery programs. Other endangered plants are featured in display gardens as part of the educational program of the garden. These displays vividly illustrate the disappearing flora to visitors and educate them about their own disappearing local ecosystems. For example, the Coco De Mer Gardens Reserve on Praslin Island and the National Botanic Garden on Mahe in the Seychelles both feature the unusual rare and endemic plants native to these islands.

Many botanic gardens are also involved in in situ conservation efforts, as they manage natural reserves or work with associated scientists and activists to study, monitor, and conserve plants in the wild. Restoration ecology and its practical applications is an important area of study and application for many botanical gardens in the United States.

The Royal Botanical Garden in Hamilton, Ontario, Canada, has been working for 10 yr on Project Paradise, the largest habitat restoration project in North America, to restore the wetlands and fisheries included within the 2200 acres of natural land the garden manages on the shores of Lake Ontario.^[8] Staff of botanical gardens often work as champions of

natural reserve systems that protect the flora of their region. Examples include the work of Dr. Charles Lamoureux, Director of the University of Hawaii Lyon Arboretum, in establishing the 19 reserves, encompassing more than 109,000 acres, of the State of Hawaii Natural Reserves System, and the work of Dr Mildred Mathias, Director of the UC Irvine Botanical Garden (now named in her honor), in establishing the University of California Natural Reserve System that protects 130,000 acres.

A NEW ERA OF INTERNATIONAL AND NATIONAL COLLABORATION

During the last 20 yr, botanical gardens, arboreta, and public gardens worldwide have begun to link together in a highly focused effort to safeguard the world's genetic resources. Clearly, in an era of declining habitats and disappearing plant species, intensive and deliberate collaboration on an international scale is needed to identify plants most in need of protection in ex situ collections. In 1987, Botanical Gardens Conservation International (BGCI) was founded as a network of cooperating botanical gardens dedicated to effective plant conservation.

At present, with over 450 member gardens in 100 countries, BGCI works to establish clear and effective plant conservation goals for a worldwide community of scientists and professions and to assist gardens in working collaboratively to meet these goals. In its first 15 yr, BCGI has supported a wide range of activities for the international community: it provides technical guidance and support for botanical gardens engaged in plant conservation efforts; assists in the development and implementation of the worldwide Botanical Gardens Conservation Strategy for plant conservation (the "International Agenda for Botanic Gardens in Conservation," June 2000); helps to create and strengthen national and regional networks of gardens in many parts of the world; and organizes major meetings, workshops, and training courses. Recognizing the primary role public gardens play in conservation education, BCGI also publishes a newsletter, *Roots*, to share experience and information about plant conservation specifically written for educators.

Just as importantly, BGCI has a support group, the Plant Charter Group, to reach out to the business community to educate them about the importance of plants and help develop partnerships for plant conservation projects. These efforts have led to establishment of a unique \$50 million "eco-partnership" between HSBC, an investment bank, and BCGI, Earthwatch, and the World Wildlife Federation to assist botanical gardens internationally in conserving and managing plant genetic resources.^[9]

In addition to working tirelessly to increase communication and collaboration between the botanical gardens and arboreta internationally, BGCI also conducts inventories and surveys on issues in plant conservation, supplying much needed data for good decision making. A critical first step was the 2001 survey of botanical gardens of the world and their ex situ plant collections. This survey documented the status of 2178 botanical gardens in 153 countries. These research and teaching gardens include approximately 6.13 million accessions in their living collections and another 42 million herbarium specimens in botanical garden herbaria. The majority of these botanical gardens are in the developed countries in Europe and North America (850), while another 200 are found in East and Southeast Asia. There are relatively few botanical gardens or centers of plant conservation in North and Southern Africa, the Caribbean islands, South West Asia, and the Middle East. In some tropical countries, new gardens have been created in conjunction with national parks and are designed to play roles in conservation, sustainable development, and public education.^[4]

Similar collaborative efforts are underway in the United States. The American Association of Botanical Gardens and Arboreta has an active Plant Conservation Committee and regularly publishes articles on the plant conservation activities of its member gardens in its journal, *The Public Garden*. The North American Plant Collections Consortium is a voluntary association of botanical gardens and arboreta in North America that focuses each participating garden's collection development in way that will ensure effective conservation of genetic resources.^[10] National collections of important genera are protected in a coordinated and complementary network of public gardens across North America, where each garden is encouraged to enrich its collection with a targeted list of plants that have been identified as top priority for conservation and are appropriate to that garden's climate and site. The Center for Plant Conservation conducts similar collaborative efforts, enjoining its participant gardens to step forward and assume coordinated ex situ protection of the rare, endangered, and threatened plants in its local flora.

CONCLUSIONS

Botanical gardens, arboreta, and herbaria hold nearly 50 million documented ex situ plant specimens in scientific collections. As educators, scientists, and conservationists, the staff of these institutions are in a special position to reach the public with ideas, sound information, and inspiration. In addition to their considerable scientific merit, these collections help

educate a community of people worldwide and engage with them to preserve and restore the damaged ecosystems of the world.

Genetic Conservation of Genomic Resources

David A. Kudrna

Rod A. Wing

The University of Arizona, Tucson, Arizona, U.S.A.

INTRODUCTION

Conservation of plant genetic resources for food and agriculture is an important undertaking for future generations. The advent of biotechnology in crop science has produced an explosion of genetic data and molecular clone resources from all major crop and model plants as well as many minor and orphan crop species. Molecular resources are produced from genomic DNA and maintained as large insert clones [bacterial artificial chromosomes (BACs)] or from transcribed mRNA in the form of complementary DNA (cDNA) clones, representing expressed genes. The millions of clones available as resources are used as substrates to sequence entire genomes, to clone agriculturally important genes, and to investigate global gene expression patterns with the goals of preventing crop failures, pathogenic outbreaks, and famine. Importantly, these genomic gene-bank resources also provide powerful tools to work in concert with established germ plasm conservation methods for the necessary evaluation and preservation of biological diversity.

CONSERVATION AND BIOTECHNOLOGY

In 1996, the Food and Agriculture Organization (FAO) of the United Nations established a global plan of action for the conservation and sustainable utilization of plant genetic resources for food and agriculture. Beginning in 1998, and at frequent intervals thereafter, FAO publishes (www.fao.org, Ref. [1]) updates on various aspects of genetic conservation of foods and related agricultural materials. This surge of awareness for genetic conservation of foods has moved to aquaculture, to domesticated animals, and to all organisms used for fiber, shelter, medicine, and raw materials. Multinational centers involved with research and in situ and ex situ gene banking of germ plasm were established for the purpose of preserving biological diversity for future generations.^[2]

With the development of molecular biological tools,^[3] the usefulness of biotechnology in agriculture appears a

perfect match.^[4–6] As scientific teams unravel the genetic basis of many physiological systems, likewise, other teams discover the genetic reasons for specific crop failures, poor yields, and pathogenic outbreaks. Biotechnology is the mix of genetics from multiple systems applied to the utility of a living organism. What began as small gene cloning and sequencing experiments in the 1980s has now exploded with thousands of molecular projects aimed at discovering cures for disease, famine, scientific understanding, and product development. Such projects involve living organisms at all phylogenetic branches of life. These far-reaching efforts, to be feasible, have created millions of clones that, when put together, represent the genomes of those organisms from which they came. These genome clone libraries are an ex situ genetic conservation of the organism at the molecular level.

The framework of genetics rests on the four nucleotide bases of DNA and how they are ordered, expressed, regulated, and coordinated. These DNA sequences, either in the form of cloned genes or as whole organisms, are the sources of genes needed for both basic research and plant breeding. For many plant species, it is common to introduce (transform) genes, add regulatory sequences, and measure protein or gene products. Transformation offers a very exact use of genetic conservation of genomic resources and may avoid genetic disruption of a host genome and allow the use of genes from foreign organisms.^[7]

GENOMIC RESOURCES

Genomic resource clones produced in laboratories can be classified into two types: genomic (whole genome) and expressed. Genomic, whole-genome, clones are currently the backbone of genome studies because they contain an organism's complete genetic makeup, every chromosome from telomere to telomere. These clones are produced from a particular organism's whole-genome DNA that is extracted from tissue or purified nuclei, precisely cut and selected for uniform size, and ligated

into a predetermined plasmid vector capable of successful replication of the cloned DNA followed by introduction into the bacterial host, *Escherichia coli*, by transformation. These cloned DNA fragments are quite large (100–300 kb), exist as single copy clones in bacterial host cells, and are referred to as bacterial artificial chromosomes or BACs. Each BAC clone contains a single fragment of the source DNA such that a specified number of these clones represent the source organism's genome in what is called a BAC library. The statistical representation of the source organism's genome may be determined by analyzing the size of the inserted DNA fragments, the number of clones in the library, and the size of the source organism's genome.

Expressed clones use a source organism's mRNA as the starting point for the purpose of obtaining complementary DNA (cDNA) only from expressed genes. The transcribed DNA is cloned into a high-copy replicating vector and transformed into *E. coli*. DNA pieces of expressed genes are called expressed sequence tags (ESTs), while full-length complementary DNA (FLcDNA) clones have the complete nucleotide sequence of a gene. Tremendous efforts have been undertaken to identify hundreds of thousands of ESTs from major plant species from mRNA extracted from several tissues of plants grown under constricting growth conditions. Complete genome representation FLcDNA libraries for most major crop species are under development. The DNA sequences of BAC and EST clones are deposited into public databases. Three principal databases that contain all publicly available sequence information from around the world are National Center for Biotechnology Information (NCBI, www.ncbi.nlm.nih.gov), European Bioinformatics Institute (EMBL-EBI, www.ebi.ac.uk/embl), and DNA Database of Japan (DDBJ, www.ddbj.nig.ac.jp). As huge amounts of additional data are generated (genetic and physical maps, DNA and protein sequences, discoveries, tools and methods, collaborators, etc.), centers for compiling, and more importantly displaying in an informative manner, data for major plant projects have been developed. A concise list of major plant databases for the most popular species is listed in Table 1, while a more comprehensive list identifying germ plasm, clone resources, sequence information, collaborators, bioinformatics, genetic conservation, crop improvement, links, etc. is available.^[8]

GENE BANKING OF GENOMIC RESOURCES

Bacterial artificial chromosome and expressed sequence tag clone resource centers (Table 1) have been created to

handle the vast amounts of molecular resources available today. For example, the Arizona Genomics Institute (AGI, www.genome.arizona.edu) and Clemson University Genomics Institute (CUGI, www.genome.clemson.edu) collaborate to maintain and construct the largest collection of plant agriculture BAC and EST libraries in the world. Researchers worldwide have also donated large numbers of libraries created by their labs for the purpose of archiving and distributing these resources to the scientific community. Libraries are named based on genus, species, specific plant variety or accession, and library type, and individual clone addresses are based upon a standard 384-well microtiter dish. Once these libraries are produced or obtained, robotic manipulations and computerized bar code databases are used to assemble, archive, handle, and distribute the large numbers of clones. Efficient handling of libraries for fast, accurate, and collaborative resource distribution is facilitated with laser-reading-equipped robots (Fig. 1). Long-term storage of the libraries in storage freezing media (buffered growth broth and glycerol) is used for banking clones in bar-coded, databased ultracold freezers at -80°C . A standard 20 ft.³ ultracold freezer houses more than 1 million clones. Although this storage technology has been known for decades, the exact biological life of stored *E. coli* cultures is unknown; thus bacterial cultures are replicated and refreshed every 5 years. Library copies are maintained in triplicate at either AGI or CUGI with backup copies at the opposite location.

Fig. 1 Laser-equipped robots, such as the “Q-bot” (Genetix LTD, Hampshire UK) shown here, provide fast and accurate handling of the huge numbers of biological samples. (View this art in color at www.dekker.com.)

Resources are distributed via ordering from Web sites allowing for quick and accurate distribution of the clones. Because *E. coli* is the organism containing the source DNA, worldwide movement of resources presents no concerns for the transfer of agricultural pathogens or deleterious germ plasm and is easily performed by overnight shipping with dry ice. In the past year, AGI and CUGI distributed over 175,000 individual clones, 80 whole libraries, and 1750 screening filters; produced 46 BAC libraries containing over 3 million clones, 10 cDNA libraries (over 250,000 clones), and 20 subclone libraries; accepted donated libraries for archiving and distribution (15 BAC and 49 EST) comprising nearly 3 million clones. Distribution for all resources is on a cost-recovery basis.

Additional valuable resources and tools are accessible with utilization of molecular genomic resources. Macroarray, high-density, hybridization screening filters can be produced from all BAC and cDNA libraries to identify clones containing desirable nucleotide sequences. Each filter contains up to 23,000 duplicate spotted clones and is reusable multiple times. Subclone libraries can be produced by a variety of methods and are used for sorting specific sequences within larger clones. High-throughput sequencing can be performed on BACs and cDNAs for in silico (via computer) screening of deposited orthologs or chromosome assembly. Deposited sequence data may be used for cross-species comparisons and a multitude of organism research projects. DNA fingerprinting and physical map assembly by Finger Print Contig (FPC, Ref. [9]) software can be used to develop physical maps of a genome. Molecular genetic (linkage) maps may be assembled using a variety of methods (such as restriction fragment length polymorphism, RFLP; amplified fragment length polymorphism, AFLP; simple sequence repeat, SSR) involving both genomic or cDNA clones. Microarray screening of cDNAs can be used to identify a specific gene(s) (clone DNA) expressed under strict experimental conditions such as pathogen infection, salt stress, temperature or light alteration, growth development, etc.

Publicly generated genomic resources must be maintained and made available to the scientific community to avoid unnecessary re-creation of resources. As example, to reap the enormous U.S. federal investment in the generation of these (and future) genomic resources, the National Science Foundation (NSF) is requiring investigators to include a 5-year plan (including funds) for maintenance and distribution of resources. The majority of investigators deposit their resources in facilities designed to handle such large projects. Caution should be noted that several "for profit" companies have attempted to provide services for clone archiving and

distribution; however, the majority have stopped providing such services because of profitability or business plan issues.

CONCLUSION

Conservation of genomic resources offers considerable value to the overall goal of preserving biological diversity. However, efforts of this magnitude do require careful consideration because costs for operation and maintenance of a resource facility are not trivial. Expenses for freezers, robots, incubators, buildings, personnel, and electricity are expensive, but when strategically incorporated into a functioning molecular research institution, the utility of the resources for the various applications quickly becomes necessary to the operation. Other considerations are clone storage life, biological consequences as a result of human errors, mechanical dependence, and intellectual property issues. Future developments in ambient temperature storage and full robotic handling (see www.genvault.com) are promising for decreasing expenses, improving efficiency, and extending culture life.

These current and expanding genomic gene-bank resources and sequencing databases represent a significant economic and scientific investment. With the usefulness of these resources impacting today's research, agriculture, and ecology communities and advancing knowledge and practical agriculture more dramatically in the future, long-term availability issues must be considered. Sufficient attention by the global scientific community to management, preservation, and availability must occur for these technology tools to be beneficial for our future.

Genetic Conservation of Nonseed Materials

Charles J. Simon

United States Department of Agriculture—Agricultural Research Service, Geneva, New York, U.S.A.

INTRODUCTION

The preponderance of the literature regarding germplasm preservation is concerned with seed collections.^[1] However, some genetic resources are appropriately preserved as specific genotypes, rather than as seed stocks. Principal examples of such resources include most of the fruit and nut crop varieties, although some vegetable crops such as potatoes and garlic, and many ornamental crops are also most appropriately preserved clonally. There are a range of reasons for this, spanning from the desire to maintain the genetic intactness of modern or heirloom fruit varieties to the loss of sexual reproduction ability in something such as garlic. The form of clonal preservation varies with the crop. Fruit and nut tree crops are typically preserved as live trees that are propagated by rooting cuttings or by grafting. Tuber crops, such as potato, and some of the ornamentals are periodically regenerated in the field and stored as tubers. Garlic and other bulb crops are likewise routinely regenerated and stored as bulbs or cloves. Tissue culture and cryopreservation are technologies that have augmented the way that some collections are maintained. These techniques will not likely serve as a primary means of preservation, but they do offer a good measure of security in backing up collections.

WHY NOT JUST SAVE EVERYTHING AS SEEDS?

This question has many answers. In some cases such as garlic, plants have lost their ability to reproduce by seed. Other crops, such as many of the tropical crops, produce seeds that have an extremely short life span, and if they are not planted right away, they lose their viability almost immediately. In other cases, it is a matter of preference to preserve specific gene combinations. This method preserves specific varieties that have their own precise and unique characteristics. In the case of fruit and nut tree species, much of the material in repositories is heirloom or landrace variety. Trees have very long life cycles compared with vegetable and agronomic crops, and because of the extended time required to breed new tree varieties, it is essential that breeders select parents for their crosses very carefully.

It is essential that tree breeders work with well-characterized material for parents, and the only timely way to do that is to work with clonal material that has already been well characterized.

TRADITIONAL CLONAL PRESERVATION METHODS

Because of the variation in the types of plants that are clonally preserved, it is impossible to generalize traditional methodology. The bulb/tuber/division types of crops are often regenerated annually in the field or in potted culture, and then their reproductive organ is stored in an appropriately controlled environment until the following year. For the long-lived perennial crops such as the fruit and nut trees, genebanks typically maintain at least two trees as living trees in the orchard and/or in potted culture. The rationale for having at least two plants is fairly obvious, in that if one of the trees were to die, it could be replaced by propagating from the remaining tree. It is desirable in the genebank setting to have at least one tree in an orchard, so that characterization of the accession for horticultural traits in the most natural setting is possible.

ALTERNATIVE CLONAL PRESERVATION METHODS

Tissue culture of genetic resource collections is an especially advantageous approach.^[2] Propagules can be stored on slow growth medium for years before they require reculturing. The cultures are generally pest-free, and if they can be tested for disease before going into culture, a clean culture will result, which avoids the problems associated with germplasm movement discussed below. The plants in culture require little space, and so are usually maintained in multiple, which offers secure backup to the collection. Aside from potential technical difficulties, such as contamination or recalcitrant rooting of the cultures, the most important downside to incorporating tissue culture in a genebank is that it does require a technically able staff to make and maintain the cultures.

Fig. 1 Diversity in apples. (View this art in color at www.dekker.com.)

Cryopreservation of vegetative tissues is another relatively new approach to genetic resource preservation. It is the long-term storage of living propagules at ultra-low temperatures, such as that of liquid nitrogen. This approach is nearly always used as a backup to traditional preservation methods, rather than as a primary method. One common variation using this approach is to freeze intact bud segments.^[3] This method works especially well in cold hardy crops such as apple, where intact budstick segments can be stored in the vapor phase of liquid nitrogen, and, when needed, taken out of the tank and simply chip-budded onto rootstock. In fact, in the United States Department of Agriculture (USDA) genebank system, nearly the entire apple collection is stored in this way, and a few years ago, the said genebank suffered 2 years of heavy fireblight disease infection that killed many of the trees in the repository's orchard. A considerable number of apple accessions would have been lost to the fireblight during that outbreak had the collection not been suitably backed up in nitrogen (Fig. 1).

SPECIAL PROBLEMS WITH CLONAL PRESERVATION

The two areas that are most problematic when working with clonally propagated genetic resources are the areas of maintenance of the resources and their exchange, either as acquisition or distribution. Short life cycle clonal resources such as potatoes, garlic, or many ornamentals must be regenerated frequently to preserve the viability of

the propagules. Long-lived species, such as the tree and vine crops, must be kept alive indefinitely in the orchard or vineyard. As these materials age and potentially suffer disease or other decline, they must be promptly repropagated to keep the accession alive. If disease is the issue, then steps must be taken, when possible, to eliminate the disease. This can be a difficult, if not impossible, challenge at times.

The other problematic area that affects clonal preservation of genetic resources is the movement of the germplasm, both in its acquisition and its distribution.^[4] Compared with clonal material, seeds retain relatively few harmful diseases or other pests. Only a fraction of virus diseases, for example, is seed-borne. That is in great contrast to clonal stocks, which are capable of harboring anything that has ever infected an accession. Because of this, nearly all nations and/or states or districts have strict provisions for at least inspection, if not full quarantine, of clonal material as it is moved.

NONCLONAL NONSEED GENETIC RESOURCE PRESERVATION

In addition to the preservation of vegetative plant parts, there has been interest shown in the preservation of plant gametes and also DNA, either in pure form or as intact nuclei. Pollen is especially amenable to long-term storage, and is readily used by most members of the genetic resource user community.^[5] This is especially convenient when one considers that the pollen of an accession is what plant breeders really want in the first place. Pollen is an even better filter for disease problems than is seed, which is a further benefit. DNA is an even more benign substance than pollen, although some countries still require a permit for its importation. The obvious limitation with DNA is that the applications of what one can do with it are quite limited.^[6] Nevertheless, as molecular biology continues to advance, the interest in researchers receiving simply DNA, rather than plant propagules, is increasing.

CONCLUSION

It is likely that more and more clonal germplasms will be backed up by cryopreservation and/or tissue culture in the future. Certainly, it is one of the priorities of the USDA National Plant Germplasm System to develop a much more complete backup of the clonal collections. This will entail considerable research into this matter, as the physical requirements and protocols vary considerably in the very diverse taxa this includes. Another

area that will receive more research attention for the clonal collections is the inclusion of more thorough genetic analysis of the collections. This will involve the use of genomics to sort out issues of authenticity, diversity, and redundancy in the collections.^[7] With this information, genebank managers can better refine and manage their collections. This will grow increasingly important as the collections continue to grow, in a world of limited resources.

The website of the USDA germplasm system is www.ars-grin.gov. This is a huge site and it contains a great number of interesting links that will inform you much further about germplasm and the principal repositories that make up the USDA National Plant Germplasm System.

Genetic Diversity Among Weeds

Michael J. Christoffers

North Dakota State University, Fargo, North Dakota, U.S.A.

INTRODUCTION

Weeds are plants that grow where they are not desired, often in areas disturbed by humans. Genetic diversity is considered an important component of plant adaptability and is therefore important to the ability of weeds to establish and proliferate in areas and/or environments to which they are not native. Tools for genetic diversity research are expanding from heritable phenotypic traits to DNA-based molecular markers. Genetic diversity among weeds is influenced by breeding system, population history, gene flow, selection, and genetic features such as ploidy. Weed genetic diversity can be used to investigate the history of weedy populations and may also help predict the likelihood of survival and spread of weed populations.

RESEARCH TOOLS

Phenotype is the expression of genotype as influenced by environment. However, phenotype is often a poor indicator of genotype because of environmental effects. Weeds often have high phenotypic plasticity that masks underlying genetic components. Selection also may encourage divergence among genetically related weeds or select for similarities among genetically unrelated weeds. Thus, the study of weed genetic diversity using genetic markers that are selectively neutral and stable in dynamic environments is desirable.

Isozymes

Isozymes are enzyme variants that are separable on electrophoretic gels. Isozymes may be encoded by genes at different loci or by alleles of a single locus. The latter are often termed allozymes. Isozyme markers are advantageous for genetic diversity studies because of their ease of use and low cost. Allelic isozymes are codominant, which allows heterozygotes and homozygotes to be distinguished and facilitates estimates of allele frequency. However, the number of isozymes available for use is limited, so genetic diversity is sometimes underestimated. Also, isozymes are expressed proteins, so their selective neutrality cannot always be ensured.

Restriction Fragment Length Polymorphisms (RFLPs) and Amplified Fragment Length Polymorphisms (AFLPs)

Tools to directly assess variation at the molecular DNA level have been successfully used to study weed genetic diversity.^[1] One technique is based on the presence/absence or distance between DNA sequences, typically four to six base pairs, recognized and cut by restriction enzymes. Variations are observed as fragment length polymorphisms and are usually considered selectively neutral. Nuclear RFLPs involve detection of specific fragments through hybridization to labeled probes and are usually codominant. RFLPs are highly reliable but require relatively large DNA samples and the availability of probes with homology to the sequences being investigated. Analyses involving large numbers of RFLPs can be expensive and time-consuming.

RFLPs are also commonly used to assess organellar genome variation, especially using chloroplast DNA (cpDNA). The relative abundance of cpDNA decreases the amount of plant tissue needed for RFLP analysis and may also eliminate the need for probes. Organellar genomes are typically but not always maternally inherited.

AFLPs involve the attachment of oligonucleotide adapters to fragments generated by restriction enzyme digestion followed by fragment amplification using the polymerase chain reaction (PCR). AFLPs require little prior sequence knowledge and more easily detect genome-wide diversity compared with RFLPs. AFLPs can also be used with small samples and, like RFLPs, are highly reproducible. However, AFLPs are dominant markers and do not allow classification of individuals as heterozygous or homozygous.

Randomly Amplified Polymorphic DNAs (RAPDs)

RAPDs are one of the most popular DNA markers for weed genetic diversity studies. Markers for RAPD analyses are generated using single, typically 10-base-pair PCR primers of arbitrary sequence to randomly amplify sequences in a genome. RAPDs require little prior sequence knowledge and do not require large DNA samples. A single RAPD primer may generate several bands, but

RAPDs are dominant and provide less information than markers that distinguish between homozygotes and heterozygotes. RAPDs are considered selectively neutral but are subject to concerns about reproducibility.

Simple Sequence Repeats (SSRs) and Inter-Simple Sequence Repeats (ISSRs)

A selectively neutral PCR-based system that can generate codominant marker data involves the analysis of SSRs, a.k.a., microsatellites. SSRs most useful for genetic diversity studies are those with tandem repetition of two to four base pairs. Repeat numbers are often highly variable among allelic SSRs, providing ample variability for genetic diversity studies. SSR analyses involve PCR primers anchored to SSR flanks, allowing amplification of intervening repeats, and discrimination of repeat number using high-resolution electrophoresis. Since sequences surrounding SSRs often vary among species that are not closely related, development of SSR primers may be necessary prior to new weed diversity studies.

A second tool for weed genetic diversity studies based on SSRs is the PCR amplification of ISSRs. In this technique, a single primer based on SSR sequence is used to amplify regions between adjacent SSR loci. ISSRs are considered relatively easy to use, reliable, readily adaptable to divergent weed species, and selectively neutral. ISSR markers are usually scored as dominant without identification of heterozygotes, but some ISSRs are codominant.

DNA Sequencing

DNA sequence data provides the most definitive and accurate analysis of genetic variation. However, sequencing is expensive and labor-intensive and is not practical for most weed diversity studies. The most popular sequencing application for weed research has been characterization of genes known to be important for weedy traits, such as those that confer herbicide resistance. However, the diversity among such genes is often not selectively neutral.

APPLICATIONS

Weed genetic diversity studies are used to address many aspects of weed ecology and biology. Studies may involve the analysis of individual, population, or species relatedness to trace historical influences on weed evolution. Molecular data derived from cpDNA RFLPs has been used to investigate relatedness among populations of leafy

spurge, revealing similarities between several North American populations and those from Russia.^[2] Isozyme diversity among tall and common waterhemp has been used to support grouping the two species into one,^[3] while RAPD markers have supported the possibility of different barnyardgrass species in Arkansas.^[4]

The origin and spread of herbicide resistance is an important area of weed research and has been studied in wild oat using ISSR and RAPD markers.^[5] Gene flow among weed species^[5] and relationships among wild, weedy, and cultivated forms of plant species^[6] have also been investigated using molecular genetic markers.

Genetic diversity is considered critical to the adaptability of species.^[7] Weed adaptability facilitates the establishment of populations in new areas and survival of weeds in dynamic environments. Comparisons of inter- and intra-population genetic diversity can help predict weed population adaptability. For example, high intra-population genetic diversity based on SSRs suggests that barren brome on English farms may also be diverse for traits such as herbicide resistance or seed dormancy.^[8]

FACTORS THAT INFLUENCE GENETIC DIVERSITY

Weed genetic diversity is important for population establishment and survival, but diversity is also influenced by varied factors. Weed biology components and environment are major factors influencing genetic diversity among weeds.

Breeding Systems and Gene Flow

Self-pollination and/or asexual reproduction are considered advantageous for establishment of new weed populations due to reproductive assurance. Lack of sexual recombination among individuals also helps maintain adapted genotypes. As a general rule, plant species that tend toward self-pollination or asexual reproduction have lower intra-population but higher inter-population genetic diversity compared with predominantly outcrossing species.^[9] High inter-population diversity is due to minimal pollen exchange leading to increased genetic drift among populations of self-pollinating or asexual species. However, gene flow among populations via seed or other propagules can maintain intra-population diversity without sexual recombination. Many weeds are especially adapted to dispersal through movement of seed or whole plants via wind or animals. Agricultural activity also promotes exchange of weed propagules among populations through movement by farm implements, crop seed, or irrigation water.

Ploidy

Genetic diversity of individuals is also important to weed adaptability. Polyploids are found with increased frequency among weeds compared with other plant species.^[10] Polyploids, especially allopolyploids, often display high genetic diversity due to fixed heterozygosity among their genomic copies. Maintenance of this diversity in self-pollinating species minimizes potential inbreeding depression. The potential diversity carried by an individual weed, however, is limited. Large genomes are correlated with characteristics detrimental to weeds including relatively slow growth and development.^[10]

Environment

Environment may select for specific genotypes within populations and reduce overall genetic diversity. However, weeds with newly selected traits such as herbicide resistance often have higher-than-expected intra-population diversity. Genetic diversity may be maintained by hybridization, multiple genes or multiple gene origins for traits, or phenotypic plasticity. Dynamic environments may also favor different genotypes at different times, which maintains overall genetic diversity.

CONCLUSION

Genetic diversity is considered critical for weed population adaptability. Weeds have diverse means of maintaining genetic diversity based on their biology and responses to environment. Selectively neutral genetic markers have been successfully used to investigate relationships among weed populations, but their neutrality may make them poor predictors of weed adaptability. Continued research of genetic diversity underlying selectable weed traits is necessary to optimize weed management.

Genetic Engineering Experiments: Design and Selection of Candidate Genes

David A. Somers

University of Minnesota, St. Paul, Minnesota, U.S.A.

INTRODUCTION

Genetic engineering technologies have been developed for most crop plant species. The numerous cases of commercially approved genetically engineered vegetable and field crops document the increasing application of genetic engineering for crop improvement. However, further improvements in genetic engineering technologies and careful consideration of selecting candidate genes are required to fully integrate genetic engineering into crop improvement programs. The aim of this section is to describe from beginning to end how one goes about designing a genetic engineering project with consideration of food safety and ecological risk issues.

DESIGNING A GENETIC ENGINEERING EXPERIMENT

Plant genetic engineering was first achieved in 1983 using *Agrobacterium tumefaciens* strains carrying disarmed Ti plasmids as vectors for DNA delivery (for review see Ref. [1]). *Agrobacterium*-based methods are now widely used for both dicotyledonous and monocotyledonous species. Plant transformation via using protoplasts as the target cells and polyethylene glycol- and electroporation-mediated direct delivery of DNA was achieved soon after the success with *A. tumefaciens* (for review see Ref. [2]). In 1987, Klein et al.^[3] reported the development of microprojectile bombardment technology for delivery of biologically active materials into intact plant cells. Since then microprojectile bombardment has also been used to transform a wide array of plants (for reviews see Refs. [4,5]).

Several factors must be considered in the early stages of designing a genetic engineering experiment. The goal of the project, i.e., whether it is for scientific inquiry or crop improvement, is crucial because it dictates numerous experimental design issues including the decision to use elite vs. experimental genotypes, the stringency required in producing or identifying events with simple transgene loci, requirement for regulatory approval, and consideration of food and feed safety, and ecological risk

issues. Factors such as target genotype, genetic engineering approach, and characterization of transgenic lines will be discussed in more detail within each section covered below. For consideration of regulatory approval and risk issues, it is suggested that federal regulatory guidelines and permitting requirements at <http://www.aphis.usda.gov> and its links to the EPA and FDA biotechnology regulatory sites are consulted early in the planning process.

COMPONENTS OF GENETIC ENGINEERING SYSTEMS

Plant genetic engineering systems are composed of three major components: 1) a source of target cells that are totipotent or are germline cells that give rise to gametes; 2) a means of delivering DNA into the target cells; and 3) methods for selection of or identifying transgenic cells or plants. Designing a successful crop genetic engineering experiment must take into account the availability of technologies within these three components for the target species and the inherent constraints they impose.

Sources of Totipotent Target Cells

Tissue cultures are currently the main sources of totipotent target cells. Initiation of plant regenerating tissue cultures is affected by the choice, physiological state, and genotype of the explant, culture medium composition, and culture environment. In many species, tissue culture response is strongly determined by the genetic background of the explant. Media formulations may minimize the genotype effect in some species but more often media are more optimal for specific genotypes. For many seed-propagated crops that suffer from a major genotype effect such as sweet corn, the current strategy involves genetically engineering an amenable genotype and transferring the transgenic trait via hybridization and backcrossing into elite germplasm. The genotype effect may be the main limitation to applying genetic engineering to crop improvement in species that are asexually propagated.

The effort then would be focused on discovering media formulations that improve the tissue culture response of the target genotype. Developing nontissue culture plant transformation systems should alleviate problems associated with tissue cultures as sources of totipotent cells. While an excellent example exists in the floral dip method for transformation of *Arabidopsis*,^[6] this method and other nontissue culture methods have not yet been widely translated to crop plants.

Tissue culture is highly mutagenic, producing both visible phenotypic and chromosomal changes called “somaclonal variation” in regenerated plants and their progeny. For example, variant frequencies ranged from 0.15 to 1.32 per regenerated corn plant (reviewed in Ref. [7]). Somaclonal variation is a major problem for genetic engineering applications in which recovery of the parent plant with the novel transgenic trait is required. This is especially true of asexually propagated species in which there is little chance to “clean up” these somaclonal mutations by backcrossing. The only means of minimizing the problem of somaclonal variation in a genetically engineered asexually propagated crop is to generate large numbers of transgenic plants and extensively screen them to identify useful plants. This becomes difficult in species that are long-lived or produce crop after an extended juvenile period.

DNA Delivery Methods

The choice of direct DNA delivery methods vs. *Agrobacterium*-mediated systems is influenced by factors ranging from whether a specific method exists for the plant species of interest to proprietary rights issues. There is currently a major shift toward using *Agrobacterium*-mediated transformation because it results in a higher proportion of transgene loci that are simpler in structure than those produced via direct delivery methods. However, not all crops can be transformed using *Agrobacterium*. The different DNA delivery methods impose specific requirements on the recombinant plasmid(s) designed for delivery of the transgenes of interest.

Transformation Constructs

Direct DNA delivery methods, such as microprojectile bombardment, usually employ transgene cassettes carried on common *Escherichia coli* plasmids. In many experimental studies, the entire plasmid carrying the transgene is delivered.^[4] In most applications, the transgene of interest must be codelivered with a plant selectable marker gene for selection of transgenic cell cultures and regenerated plants. Either the transgene of interest and the plant

selectable marker are incorporated into the same plasmid or the two genes are placed on separate plasmids, which are mixed together and codelivered. Codelivered transgenes are most frequently integrated into the same transgene locus and coexpression of the delivered genes occurs at about the same frequency as when both transgenes are incorporated into the same plasmid.^[8] For commercial applications, only the transgene cassette with minimal extra DNA should be delivered. This strategy results in a higher proportion of transformation events with simpler transgene loci^[9] that can be easily characterized for regulatory approval. Other methods for removal of unwanted delivered DNA, such as the selectable marker gene, have been reported.^[10]

Agrobacterium delivers T-DNA delineated by left and right border sequences in the Ti plasmid.^[11] Thus in T-DNA constructs, the transgene cassette must be placed between the left and right borders of the T-DNA. Accordingly, a range of binary vectors carrying plant selectable marker genes and multiple cloning sites are available that allow for plasmid construction in *E. coli*, followed by transfer into *Agrobacterium* for T-DNA delivery. In *Agrobacterium*-mediated cotransformation, incorporation of both genes within the same T-DNA results in a high frequency of cotransformation and cointegration into the same transgene locus. Incorporation of the two genes on separate binary plasmids or in separate T-DNAs on the same plasmid results in some proportion of the resultant transgene containing both genes and some as unlinked genes. The production of unlinked transgene loci provides a simple means of producing marker-free transgenic plants via selection in segregating generations. As in direct DNA delivery constructs, methods exist for excising unwanted DNA sequences from the T-DNA following genomic integration.

Selection Systems for Transgenic Tissue Cultures and Plants

A method to select or identify transgenic cells, tissue cultures, or plants is required for recovery of transgenic plants carrying the trait of interest. In only a few cases, such as transgenic herbicide resistance, can the transgene be directly selected. Selection is usually conducted using a combination of selectable marker gene and selective agent. Selectable marker genes code for enzymes that confer plant cell resistance to metabolic inhibitors such as antibiotics and herbicides. A list of selectable marker genes and their corresponding selective agents is presented in Ref. [12]. A few more selectable marker genes have been developed since then, but overall the choices are somewhat limited. Determination of the appropriate selectable marker and selection regime is usually

determined empirically. Screenable markers or reporter genes allow visible selection of transgenics. Enzymes such as *E. coli* *b*-glucuronidase and firefly luciferase convert substrates to readily detectable colored or luminescent products. Other reporter genes such as the green fluorescent protein (GFP) enable detection in the absence of applied substrate.

SELECTION OF CANDIDATE GENES

Risk Issues Regarding Candidate Genes

Consideration of risk issues must be foremost in designing a genetic engineering experiment. Several aspects of such risks are discussed in the following sections. Careful planning and trait selection can mitigate risk associated with a transgenic crop. Food and feed safety of the transgenic trait and any other expressed transgene product must be considered. Avoidance of transgenes coding known allergens and toxins is obvious. Expression of the selectable marker gene in the transgenic plant is currently regarded as undesirable. The main concern relates to the potential for horizontal transfer of bacterial antibiotic resistance genes used either for plant selection or bacterial selection to soil or human and animal gut microbes rendering the antibiotics useless in animal and human medicine. While the potential for this outcome is regarded as very low, the removal of such antibiotic resistance genes from the plant genome by methods described above certainly obviates the concern. Knowledge of metabolic pathways that are the target of the transgenic manipulation will assist in anticipating and avoiding unanticipated changes in the composition of the transgenic crop.

Ecological risk issues including the weedy potential of the target species, its pollination behavior and sexual compatibility and presence of its wild relatives, and characteristics of the transgene trait must also be taken into account. Cross-pollinated species may “contaminate” adjacent crops with transgenes precluding their designation as certified organic, thereby resulting in monetary loss by the producer. Transgenic traits may confer a competitive advantage to the recipient plant. For example, selectable markers such as herbicide resistance genes and some transgenes may pose ecological risk if the crop itself is weedy or is grown in regions where sexually compatible weedy relatives exist. Transfer of transgenes via pollen flow to weedy relatives as well as cross pollination-mediated transgene stacking of transgenic herbicide resistance has been documented in transgenic crop systems. The resultant transgenic weeds may be less controllable or disruptive of managed and unmanaged

ecosystems. Avoidance of these scenarios must be considered upfront in experimental design considerations.

Transgene Expression

Molecular manipulations of the transgene and choice of appropriate regulatory sequences are required to insure appropriate expression of a transgene designed to confer a trait of interest. Bacterial, viral, and animal transgene coding sequences may be used as sources of candidate genes in transgene constructs. These sequences may be either used directly or may require extensive modification. It is essential that appropriate eukaryotic transcription and translation signals are either present or added to genes from prokaryotic sources. Although the genetic code is universal, organisms vary in nucleotide composition of their DNA and specifically in codon usage. Thus, to assure efficient translation of the transgene, host codon usage must be taken into account. Modifications of transgene codon usage to achieve efficient translation may simply involve attachment of host-preferred leader sequences, such as signal peptides, or may require resynthesis of the transgene to match host codon usage. In addition, appropriate subcellular localization of the transgene product is usually essential for proper function. Most plant genes have transit peptides or signal sequences that likely will function properly in their new host cell. However, prokaryotic transgenes do not have such sequences and therefore must be so modified. Finally, cDNAs of eukaryotic genes are most frequently used as transgenes, in some cases it may be desirable to add plant introns and/or leader sequences to these cDNAs and to prokaryotic transgenes to boost transgene expression.

Direction of transgene expression in the correct plant organ at the right time of development is required for the optimum use of genetic engineering. Transcriptional control of transgene expression is regulated by promoter sequences fused 5' to the transgene coding sequence. While numerous seed-, fruit-, and organ-specific promoters have been characterized, only a few are being used in transgenic applications. Likewise, there are less than a dozen constitutive promoters available for use in specific crops. Most useful inducible promoters respond to xenobiotics such as copper, estrogen, or ethanol and therefore have limited use in commercial scale applications. Thus, there is a substantial need for more well-characterized constitutive, tissue and developmental specific, and inducible promoters.

Avoiding Transgene Expression Problems

Suppression of transgene expression via silencing is frequently associated with duplication of components

of the transgene DNA. This applies to both coding sequences and promoters of transgenes, thus multiple promoters are required to insure the expression of stacked transgenes. This same need for multiple different DNA sequences for transgene construction also pertains to 3' untranslated termination sequences and the transforming DNA backbone.

CHARACTERIZATION OF TRANSGENIC LINES

Genotypic Characterization

Both direct DNA delivery and *Agrobacterium*-mediated transformation produce transgenic plants with variable numbers of transgene loci that may contain multiple copies of intact and rearranged delivered DNAs. In plants, genomic integration of delivered DNA mostly occurs via illegitimate recombination and the resultant loci can range from quite simple to extremely complex structures.^[13–15]

Moreover, genomic sequences flanking transgene loci may also be rearranged, deleted, or duplicated. The primary goal in genotypic characterization is to identify individual transgenic plants that have a simple transgene locus containing only the delivered DNA of interest with minimal rearrangements to the delivered and flanking genomic DNAs and that is transmitted to progeny in a Mendelian manner. Depending on the goal for the genetic engineering experiment, the requisite level of genotypic characterization may vary widely. In crop improvement for eventual commercial release, a combination of comprehensive Southern analyses, transgene locus sequencing, and progeny analysis should be conducted to determine the stability of the transgene locus structure and the absence of small nonexpressing loci and spurious open reading frames created by rearrangements of the delivered and flanking genomic DNA sequences. As previously mentioned, the absence of the selectable marker genes and other DNAs associated with the transgene construct should be demonstrated.

Phenotypic Analysis

The transgenic phenotype should be evaluated to identify transgenic individuals that reproducibly express the phenotype in the desired tissue-specific or constitutive manner over multiple generations. A continuum of transgene expression levels is frequently observed. While this variation may appear at first glance to be useful for plant improvement, it forces the production of multiple transgenic plants to increase the probability of recovering

one “good” event. Stability of the transgenic phenotype must be evaluated using standard agronomic tests over multiple years and locations to identify an individual line for further variety development.

CONCLUSION

Plant transformation has advanced substantially since it was first developed in 1983 such that most crop plants can now be transformed. Understanding of the mechanism(s) of transgene locus formation and factors affecting transgene locus structure and expression has also advanced, leading to a range of strategies and technologies that can maximize the success of a crop genetic engineering experiment. Careful consideration of these strategies and technologies may also streamline regulatory approval requirements for developing a commercial transgenic crop.

Genetic Loads

Ohmi Ohnishi

Kyoto University, Mukoh City, Japan

INTRODUCTION

The genetic load in a population has been defined as the reduced amount of population fitness as compared with the maximum value of fitness (w_{\max}) that can be obtained by a population. That is, the genetic load $L = (w_{\max} - w) / w_{\max}$, where w is the fitness of a population. There are several reasons why a population cannot achieve its maximum fitness. However, several indicate that genetic load is an important factor. Mutational loads are due to recurrent deleterious mutations, segregational loads are caused by segregation of deleterious genotypes from the adapted optimal genotype, and evolutionary loads (substitutional loads) are due to segregation of previously well-adapted but now inferior genotypes during the course of substitution of an allele by another.

MUTATIONAL LOAD

The mutational load was first discussed by Haldane,^[1] although the word “mutational load” itself was first coined by Muller.^[2] This is the load the population carries due to the reduction of fitness by the existence of deleterious mutant alleles in the population.^[3–5] The frequency of the deleterious mutant alleles is maintained by the balance between selection against the genotypes with a deleterious mutant allele and newly arising mutations. Theoretically, the frequency of such detrimental alleles in a population should be u/h at each locus at equilibrium, where u is the mutation rate of the deleterious mutants and h is the selective value of heterozygous individuals carrying the mutant allele, i.e., $1 - h$ is the fitness of heterozygotes. The estimated value of u/h , the frequency of detrimental alleles in a population, is well documented in human and *Drosophila* populations: it ranges from 0.001–0.005.^[6,7]

Crumpacker^[8] first reviewed the frequency of detrimental genes in plant populations and showed that many outbreeding plant populations, mostly forage grasses and legumes, maintain chlorophyll-deficient alleles in their populations. In many plant species, the frequency of a detrimental mutant allele at a locus is in the range of 0.001–0.005, as expected from theoretical studies of outbreeding populations. Sprague and Shuller^[9] in maize,

Ohnishi^[10] and Ohnishi and Nagakubo^[11] in buckwheat supported this conclusion by directly estimating the frequency of recessive deleterious alleles.

Concealed detrimental alleles in populations are usually recessive or partially dominant, but occasionally dominant or overdominant. These alleles have been revealed by inbreeding (full sib mating or selfing in plant species). The reduced fitness by inbreeding is called inbreeding depression (ID). This phenomenon is especially common in predominantly outcrossing plant species. Many studies on inbreeding depression have been carried out in gymnosperms as well as angiosperms (see a review in Ref. [12]) and more sophisticated studies in homosporous ferns by Klekowski.^[13] Two genetic models have been proposed to account for inbreeding depression: 1) a model in which recessive or partially dominant deleterious alleles are held in equilibrium by a selection–mutation balance, and 2) an overdominance model. Both dominance and overdominance predict a decline in fitness in an inbred population in proportion to the inbreeding coefficient F . If the loci affecting fitness act independently, then the logarithm of fitness should decline linearly with increased inbreeding, with a slope that measures the extent of the mutational load in terms of lethal equivalents.^[4]

Controversy over whether inbreeding depression primarily reflects dominance or overdominance has persisted for much of the last century.^[14] This controversy comes from so-called associative (pseudo) overdominance which is caused by pairs of detrimental mutations. The linked beneficial and detrimental alleles mimic a single overdominant locus.^[15]

Associations between heterozygosity and fitness in *Drosophila* and pines appear attributable to associative overdominance.^[16,17] A recent study of two species of *Mimulus* concluded that the inbreeding depression was attributable to greater expression of recessive alleles.^[18] At present, it seems clear that mutational load is of sufficient magnitude to account for a substantial part of observed inbreeding depression, and it is unnecessary to assume a large contribution from overdominant loci.^[12]

The total amount of mutational loads is $2u$,^[1,2] which is not large when compared with other loads. The increase of mutational loads caused by an increase in the mutation rate caused by environmental mutagens such as X-ray,

UV, and chemical mutagens was an issue that was seriously discussed for human welfare by Muller.^[2]

SEGREGATIONAL LOAD

When mutant alleles are maintained in a population by overdominance (heterozygote advantage over homozygotes), deleterious homozygotes are segregating in the populations and lead to a loss of population fitness. The amount of segregational load due to a locus, where the homozygotes have a minimum fitness of $1-s_1$ and $1-s_2$ as compared with the heterozygote with the maximum fitness of 1, is $s_1s_2/(s_1+s_2)$, which is a fair amount larger than the mutational load. The case of the sickle cell anemia gene *HgS* is a well-known example of overdominance in human populations where malaria is still a serious disease. In plants, only a few cases of overdominance are known. An allele that behaves beneficially and detrimentally at different developmental stages is known to be overdominant in some cases.^[19] However, as mentioned above, most of the cases are associative (pseudo) overdominance.

EVOLUTIONARY LOAD

Evolutionary load is the decrease of fitness during the process of allelic substitution. When a previously advantageous allele becomes disadvantageous due to a change of environmental factors, then the segregation of disadvantageous genotypes continues to appear throughout the process of substitution of the allele by the advantageous allele. This leads to a decrease of fitness of the population. The amount of evolutionary genetic load is $L = -2\log_e p_o$ for partial dominant alleles, where p_o is the gene frequency of the disadvantageous allele at the start of the substitution process. The idea of evolutionary load was first discussed by Haldane^[20] under the term of "cost of natural selection," where he found that the evolutionary load was not dependent on the degree of selective value of the allele. The well-known case of allele substitution in natural populations is industrial melanism found in English populations of moth *Biston betularia*. In this case, the estimated advantage of the black type over the disadvantageous white type was more than 0.5. In plants, no reports similar to the detailed analysis of industrial melanism have been available in any population.

We can consider other kinds of genetic load than that mentioned above.^[3] However, the concept of genetic loads is no longer considered important in understanding the evolutionary process of population or the maintenance of genetic polymorphisms in a population. Nevertheless, it is worth noting that the concept of genetic loads led to

the neutral theory of evolution or non-Darwinian evolution of genetic variation,^[21,22] which is now the well-understood theory of evolution, particularly at the molecular level.

During the course of allozyme studies in *Drosophila* and man, it was revealed that about 20% of randomly selected loci are polymorphic in a population.^[23,24] If these polymorphic loci are maintained by overdominance or other selective forces, then the population cannot survive due to the heavy genetic load it contains. If most of the polymorphic loci are maintained accidentally by chance, that is to say, the alleles are selectively neutral and are maintained by random drift, then the populations are free from the heavy genetic loads. This is the main idea of Kimura's neutral theory of evolution.^[21] When this theory was first proposed in 1968, various controversial opinions appeared. However, later experimental studies, conducted mostly at the molecular level, have supported this neutral theory of evolution.

CONCLUSION

The concept of genetic load and many experimental studies on genetic loads have greatly contributed to the development of classical population genetics, in particular to the issue of maintenance of genetic variation in populations. This is highlighted by Kimura's neutral theory of evolution,^[21] which is the main historical contribution of the concept of genetic loads to evolutionary theory and to population genetics theory. Today, in the age of molecular population genetics, the concept of genetic loads becomes less important, but still plays an important role in the issues such as maintenance of slightly deleterious genes in populations, and heterosis and inbreeding depression in plant breeding.

Genetic Resource Conservation of Seeds

Florent Engelmann

*Centre de Coopération Internationale en Recherche Agronomique pour le Développement,
Montpellier, France*

INTRODUCTION

In the 1950s and 1960s, major advances in plant breeding brought about the “green revolution,” which resulted in wide-scale adoption of high-yielding varieties and genetically uniform cultivars of staple crops, particularly wheat and rice. Consequently, global concern about the loss of genetic diversity in these crops increased, as farmers abandoned their locally adapted landraces and traditional varieties, replacing them with improved, yet genetically uniform modern ones. The International Agricultural Research Centers (IARC) of the Consultative Group on International Agricultural Research (CGIAR) started to assemble germplasm collections of the major crop species within their respective mandates. The International Board for Plant Genetic Resources (IBPGR) was established in 1974 in this context to coordinate the global effort to systematically collect and conserve the world’s threatened plant genetic diversity. Today, as a result of this effort, over 1300 genebanks and germplasm collections exist around the world, maintaining approximately 6,100,000 accessions, largely of major food crops including cereals and some legumes, i.e., species that can be conserved easily as seed.

This article reviews the current storage technologies and management procedures developed for seeds, describes the problems and achievements with seed storage, and identifies priorities for improving the efficiency of seed conservation.

CONSERVATION OF ORTHODOX SEEDS

Many of the world’s major food plants produce so-called orthodox seeds, which tolerate extensive desiccation and can be stored dry at low temperature. Storage of orthodox seeds is the most widely practiced method of *ex situ* conservation of plant genetic resources (FAO 1996), since 90% of the accessions stored in genebanks are maintained as seed. Following drying to low moisture content (3–7% fresh weight basis, depending on the species), such seeds can be conserved in hermetically sealed containers at low temperature, preferably at -18°C or cooler, for several decades.^[1] All relevant techniques are well established,

and practical documents covering the main aspects of seed conservation, are available, including design of seed storage facilities for genetic conservation, principles of seed testing for monitoring viability of seed accessions maintained in genebanks, methods for removing dormancy and germinating seeds, and suitable methods for processing and handling seeds in genebanks.^[2]

In addition to being the most convenient material for genetic resource conservation, seeds are also a convenient form for distributing germplasm to farmers, breeders, scientists, and other users. Moreover, since seeds are less likely to carry diseases than other plant material, their use for exchange of plant germplasm can facilitate quarantine procedures.

CONSERVATION OF NONORTHODOX SEEDS

In contrast to orthodox seeds, a considerable number of species, predominantly from tropical or subtropical origin, such as coconut, cacao, and many forest and fruit tree species, produce so-called nonorthodox seeds, which are unable to withstand much desiccation and are often sensitive to chilling. Nonorthodox seeds have been further subdivided in recalcitrant and intermediate seeds based on their desiccation sensitivity, which is high for the former and lower for the latter group. Nonorthodox seeds cannot be maintained under the storage conditions described above, i.e., low moisture content and temperature, and have to be kept in moist, relatively warm conditions to maintain viability. Even when stored in optimal conditions, their lifespan is limited to weeks, occasionally months. Of over 7000 species for which published information on seed storage behavior exists,^[3] approximately 10% are recorded as nonorthodox or possibly nonorthodox.

Genetic resources of nonorthodox species are traditionally conserved as whole plants in field collections. This mode of conservation is faced with various problems and limitations, and cryopreservation (liquid nitrogen, -196°C) currently offers the only safe and cost-effective option for the long-term conservation of genetic resources of problem species. However, cryopreservation research is still at a preliminary stage for nonorthodox species.^[4]

MANAGEMENT OF SEED COLLECTIONS

Only a limited number of genebanks operate at very high standards, whereas many others are facing difficulties due to inadequate infrastructures, lack of adequate seed processing and storage equipment, unreliable electricity supply, funding and staffing constraints, and inadequate management practices. Therefore, seeds are often stored under suboptimal conditions and require more frequent regeneration, thus bearing additional costs on often already insufficient operating budgets of genebanks. Great difficulties are faced in particular by many countries with regeneration of seed collections.^[5] Seed storage technologies are relatively easy to apply. The problems relate more to resource constraints that impact the performance of essential operations. Efficient and cost-effective genebank management procedures have now become key elements for long-term *ex situ* conservation of plant genetic resources.

Other important aspects of genebank operations concern germplasm characterization and documentation. The extent to which germplasm collections are characterized varies widely between genebanks and species^[5] but is far from complete in many instances. Concerning documentation, the situation is highly contrasted.^[5] Some, mainly developed, countries have fully computerized documentation systems and relatively complete accession data, while many others lack information on the accessions in their collections, including the so-called passport data.

MAIN CHALLENGES AND PRIORITIES FOR IMPROVING SEED CONSERVATION

Various priority areas have been identified for orthodox and nonorthodox seed conservation research and for improving seed genebank management procedures.

Research Priorities for Orthodox Seed Species

Determining critical seed moisture content

The preferred conditions recommended for long-term seed storage are 3–7% moisture content, depending on the species, at –18°C or lower.^[1] However, it has been shown that drying seeds beyond a critical moisture content provides no additional benefit to longevity and may even accelerate seed aging rates, and that interactions exist between the critical relative humidity and storage temperature. Research should be pursued on this topic of high importance.

Developing low-input storage techniques

Various research projects have focused on the development of the ultra-dry seed technology, which allows storing seeds desiccated to very low moisture contents at room temperature, thereby suppressing the need for refrigeration equipment. Although drying seed to very low moisture prior to storage seems to have fewer advantages than was initially expected, ultra-dry storage is still considered to be a useful, practical, low-cost technique in those circumstances where no adequate refrigeration can be provided.^[6] Research on various aspects of the ultra-dry seed storage technology and on its applicability to a broader number of species should therefore be continued.

Improving and monitoring viability

The viability of conserved accessions depends on their initial quality and how they have been processed for storage, as well as on the actual storage conditions. There is evidence that a very small decrease in initial seed viability can result in substantial reduction in storage life. This needs further investigation, and research should be performed notably on the effect of germplasm handling in the field during regeneration and during subsequent processing stages prior to its arrival at the genebank, as well as on growing conditions, disease status, and time of harvest of the plants.

Research Priorities for Nonorthodox Seed Species

Understanding seed recalcitrance

A number of physical and metabolic processes or mechanisms have been suggested to confer, or contribute to, desiccation tolerance.^[7] Different processes may confer protection against the consequences of loss of water at different hydration levels, and the absence, or ineffective expression, of one or more of these could determine the relative degree of desiccation sensitivity of seeds of individual species. Additional research is needed to improve our understanding of the mechanisms involved in seed recalcitrance.

Developing improved conservation techniques

Various technical options exist for improving storage of nonorthodox species. Especially with species for which no or only little information is available, it is advisable, before undertaking any “high-tech” research, to examine the development pattern of seeds and to run preliminary experiments to determine their desiccation sensitivity as well as to define germination and storage conditions.

IPGRI, in collaboration with numerous institutions worldwide, has developed a protocol for screening tropical forest tree seeds for their desiccation sensitivity and storage behavior,^[8] which might be applicable to seeds of other species after required modification and adaptation. For long-term storage of nonorthodox species, cryopreservation represents the only option. Numerous technical approaches exist, including freezing of seeds, embryonic axes, shoot apices sampled from embryos, adventitious buds, or somatic embryos, depending on the sensitivity of the species studied.^[4]

Germplasm Management Procedures

The objective of any genebank management procedure is to maintain genetic integrity and viability of accessions during conservation and to ensure their accessibility for use in adequate quantity and quality at the lowest possible cost. As mentioned previously, many genebanks face financial constraints that hamper their efficient operation. It is therefore very important to improve genebank management procedures to make them more efficient and cost-effective. In this aim, the use of molecular markers should be increased to improve characterization and evaluation, improved seed regeneration and accession management procedures should be established, the use of collections should be enhanced through the development of core collections, germplasm health aspects including new biotechnological tools for detection, indexing, and eradication of pathogens should be better integrated in routine genebank operations, and improved documentation tools should be developed. Special attention should be given to developing appropriate techniques for genebanks in developing countries, where specialized equipment is frequently lacking and resources are usually limited.

CONCLUSION

The improvements in the seed storage techniques and genebank management procedures resulting from the research performed on the priority areas identified above will further increase the key role of seeds in the ex situ conservation of genetic resources of many species. However, it is now well recognized that an appropriate conservation strategy for a particular plant gene pool requires a holistic approach, combining the different ex situ and in situ conservation techniques available in a complementary manner.^[9] Selection of the appropriate methods should be based on a range of criteria, including the biological nature of the species in question, practicality and feasibility of the particular methods chosen (which depends on the availability of the necessary infrastruc-

tures), their efficiency, and the cost-effectiveness and security afforded by their application. An important area in this is the linkage between in situ and ex situ components of the strategy, especially with respect to the dynamic nature of the former and the static, but potentially more secure, approach of the latter.

Genetic Resources of Medicinal and Aromatic Plants from Brazil

Roberto Fontes Vieira

Embrapa Recursos Genéticos e Biotecnologia, Brasília, Brazil

INTRODUCTION

Approximately two-thirds of the biological diversity of the world is found in tropical zones, mainly in developing countries. Brazil is considered the country with the greatest biodiversity on the planet, with nearly 55,000 native species distributed over six major biomes: Amazon Forest, Cerrado, Caatinga, Atlantic Forest, Pantanal, and Meridional Forest and Grassland.

Embrapa (Brazilian Agricultural Research Corporation), through its Genetic Resources and Biotechnology Research Center and in collaboration with several universities and other Embrapa research centers, has been developing efforts to establish germplasm banks for medicinal and aromatic species. Twenty germplasm collections of medicinal and aromatic plants have been established in Brazil, and 70 species recently were defined as priority for germplasm conservation. The main challenge now is to develop strategies for the conservation, cultivation, and sustainable management of each of these species.

GERMPLASM CONSERVATION

The Brazilian Amazon Forest covers nearly 40% of all national territory. This ecosystem is rather fragile, and its productivity and stability depend on the recycling of nutrients whose efficiency is directly related to the biological diversity and the structural complexity of the forest.^[1]

The Cerrado is the second largest ecological dominion of Brazil, covering approximately 23% of Brazilian territory, where a continuous herbaceous stratum is joined to an arboreal stratum, with variable density of woody species. The Caatinga extends over areas of the states of the Brazilian Northeast and is characterized by the xerophitic vegetation typical of a semiarid climate. The soils that are fertile, due to the nature of their original materials and the low level of rainfall, experience minor runoff.^[1]

The Atlantic Forest extends over nearly the whole Brazilian coastline and is one of the most endangered ecosystems of the world, with less than 10% of the original vegetation remaining. The climate is predominantly hot and tropical, and annual precipitation ranges

from 1000 to 1750 mm. The territory of the Meridional Forests and Grasslands includes the mesophytic tropical forests, the subtropical forests, and the meridional grasslands of the states of southern Brazil. The climate is humid, tropical and subtropical, with some areas of temperate climate. Pantanal is a geologically lowered area filled with sediments that have settled in the basin of the Paraguay River. Pantanal flora is formed by species from both Cerrado and Amazon vegetation.^[1]

Ex situ conservation of threatened germplasm includes seed banks, field preservation, tissue culture, and cryopreservation. Seed storage is considered the ideal method. Seeds considered orthodox can be dried and preserved at subzero temperatures (-20°C), whereas recalcitrant seeds, including most tropical species, lose their seed viability when subjected to the same conditions.^[2] Seeds of maize (*Zea mays* L.) have been maintained at Embrapa for more than 12 years in a long-term cold chamber at -20°C . Maintenance of the germplasm in field collections is costly, requires large areas, and can be affected by adverse environmental conditions. Tissue culture or cryopreservation techniques also can be considered in some cases. In an ex situ procedure, the germplasm is collected from fields, markets, small farms, and other sites in the form of seeds, cuttings, underground systems, and sprouts. The collected samples should represent the original population with passport data and herbarium vouchers.

The following species have been recognized as priority for germplasm conservation.^[3]

Psychotria ipecacuanha (Brot.) Stokes, Rubiaceae (Ipecac)

Ipecac (*P. ipecacuanha*) (Fig. 1A) is a shrub whose medicinal value relates to the production of emetine in the roots. Ipecac is found in the humid forests of the southern part of the Amazon Forest in the states of Rondônia and Mato Grosso, and in the Atlantic Forest in the states of Bahia, Espírito Santo, Minas Gerais, and Rio de Janeiro.^[4]

Ipecac is a powerful emetic used to treat gastrointestinal diseases, diarrhea, and intermitent fevers. It is employed as an expectorant in bronchitis, bronchopneumonia, asthma, and mumps, and also as a vasoconstrictor.

Fig. 1 Medicinal plants from Brazil: (A) *Psychotria ipecacuanha*, (B) *Pilocarpus microphyllus*, (C) *Maytenus ilicifolia*, and (D) *Puffia glomerata*. (View this art in color at www.dekker.com.)

In 1988, Embrapa began a project for the recollecting and conservation of Ipecac genetic variability. Five collecting expeditions covering seven states were undertaken, collecting a total of 86 accessions^[4] that are now maintained in field germplasm banks at Embrapa Ocidental Amazon, PA. Recently, more germplasm accessions were collected by the North Fluminense University, including 10 accessions that originated in the Atlantic Forest.

***Pilocarpus microphyllus* Stapf., Rutaceae (Jaborandi)**

Jaborandi (*ia-mbor-end*) (Fig. 1B) is an indigenous name of the species *P. microphyllus*, which contains the highest pilocarpine content in the leaves. This plant is an

understory species of the Amazonian rainforest that reaches six to eight meters in height.

Pilocarpine is an imidazolic alkaloid that stimulates secretions of the respiratory tract and the salivary, lachrymal, gastric, and other glands.^[5] In the treatment of glaucoma, the alkaloid pilocarpine acts directly on cholinergic receptor sites, thus mimicking the action of acetylcholine. Intraocular pressure is thereby reduced, and despite its short-term action, pilocarpine is the standard drug used for initial and maintenance therapy in certain types of primary glaucoma.^[6]

In 1991, Embrapa initiated a project for recollecting and conservation of the genetic variability of *P. microphyllus* and its closely related species. From 1991 to 1993, two collection expeditions were undertaken, collecting a total of 27 accessions in the form of seeds and seedlings.

A Jaborandi germplasm bank was established at Maranhão State University, São Luis, MA and at Embrapa Ocidental Amazon, Belém, PA.

Pilocarpus microphyllus seeds are considered orthodox. Seeds can be dried down to 6–8% moisture content and can be conserved for a long period at -18°C and 5% relative humidity.^[7] The wild harvest of leaves from wild *P. microphyllus* has been carried out to such an extent that it has significantly reduced the natural populations. Currently, this species can be found only in indigenous areas and on private lands, and is included in the official list of endangered plants from Brazilian flora.

***Phyllanthus niruri* L., Euphorbiaceae (Quebra Pedra)**

Quebra Pedra is a small, erect annual herb growing up to 30–40 cm in height. Although several species are recognized by this common name, *P. niruri* and *P. sellovianus* are the most scientifically studied. The antispasmodic activity of alkaloids in *P. sellovianus* explains the popular use of the plant to treat kidney and bladder stones. The alkaloid extract demonstrates smooth muscle relaxation specific to the urinary and biliary tracts, which facilitates the expulsion of kidney or bladder calculi.^[8,9]

Quebra Pedra has gained worldwide attention due to its effects against Hepatitis B.^[10] There have been no side effects or toxicity reported in any of the clinical studies or in its many years of reported use in herbal medicine.

Several species are called Quebra Pedra and contain the same or similar active compounds. A germplasm collection to study the genetic and chemical variation of this species, as well as its seed physiology, is necessary and warranted.

***Maytenus ilicifolia* Martius ex. Reiss., Celastraceae (Espinheira Santa)**

Espinheira Santa (Fig. 1C) is a small, shrublike evergreen tree reaching up to 5 m in height. It is native to many parts of southern Brazil, mainly in the Paraná and Santa Catarina states.

Leaves of *Maytenus* species are used in the popular medicine of Brazil for their reported antiacid and antiulcerogenic activity. Attempts to detect general depressant, hypnotic, anticonvulsant, and analgesic effects were reported by Oliveira et al.^[11] The potent antiulcerogenic effect of Espinheira Santa leaves was demonstrated to be effective compared to two leading antiulcer drugs, Ranitidine and Cimetidine.^[12] Toxicological studies have demonstrated the plant's safety.

Seeds of *Maytenus ilicifolia* can be classified as orthodox and can be stored in long-term cold chambers at -20°C . In 1995, the Forestry Department of the University of Paraná began a project to study the genetic variability of natural populations of *M. ilicifolia*, and 78 accessions were collected in the states of Paraná, Santa Catarina, and Rio Grande do Sul. Field collections are maintained at an Embrapa center in Ponta Grossa, PR.

***Pfaffia glomerata* (Spreng.) Pedersen, Amaranthaceae (Brazilian Ginseng)**

Pfaffia glomerata (Fig. 1D) is a large, shrubby ground vine, which has a deep root system. It grows mainly in the borders of the Paraná River, and predatory collection has greatly reduced its natural populations. *Pfaffia* is known as “Brazilian ginseng” because it is widely used as an adaptogen for many ailments and to overcome weakness, much like American and Asian ginseng (*Panax* spp.).

This action is attributed to the anabolic agent—ecdysterone and three novel ecdysteroid glycosides, which are found in high amounts in *Pfaffia* roots. The root of *Pfaffia* also contains about 11% saponins. These saponins include a group of novel chemicals called pfaffosides as well as pfaffic acids, glycosides, and nortriperpenes. These saponins have clinically demonstrated the ability to inhibit cultured tumor cell melanomas and to help regulate blood sugar levels.^[13]

In 2001, Embrapa Genetic Resources, in collaboration with Paraná State Rural Assistance Corporation and São Paulo State University (Unesp), Botucatu, launched a field expedition that collected 15 accessions, including more than 200 hundred individuals from all along the borders of the Paraná River. This material has been evaluated for chemical and molecular markers and has been deposited in both filed and in vitro collections.

Genetic Resources: Access, Benefit-Sharing, and Bioprospecting Issues

Santiago Carrizosa

University of California, Davis, California, U.S.A.

INTRODUCTION

Accessing and sharing genetic resources and knowledge among nations having rich biodiversity resources will continue to provide the means to improve the quality of life of humankind for generations to come. Genetic resources form the basis for the improvement of agricultural crops and for the development of key medicines and pharmaceutical, crop protection, and other biotechnology products that are fundamental for the welfare of industrialized and developing countries. Many developing countries are within centers of origin and diversity of crops such as maize (Mexico), potato (Peru and Bolivia), rice (Philippines), and soybean (China). The agricultural productivity of countries that grow these crops such as Australia and the United States is heavily dependent on a supply of genetic resources from these countries.^[1]

There is demand for new raw material, chemical compounds, and genes in the agricultural, pharmaceutical, botanical medicine, and biotechnology industries. Most of the contributions of biological diversity to the pharmaceutical industry come from plants, but only between 0.1% and 0.5% of the 250,000 species of known flowering plants have been intensively examined for possible medicinal value.^[2] Living organisms are being used and modified to clean up polluted sites, to provide energy, and to separate valuable minerals from ore, among other uses. This article provides a brief overview of access frameworks, benefit-sharing strategies, and bioprospecting strategies that facilitate the exchange of genetic resources.

BINDING ACCESS FRAMEWORKS

Since the 1992 Convention on Biological Diversity (CBD), the international community of countries envisioned the beginning of a new era in the development of nature-based products for humanity. While indigenous communities were concerned about a potential new wave of colonialism and biopiracy, scientists anticipated a new green revolution fostered by novel technologies designed to harness products from biological samples. Multinationals also anticipated the potential of big profits derived from biological diversity, and biodiversity-rich countries pre-

pared to develop new access legislation to obtain a share of the profits. Expectations were raised at all levels.

Before 1992, individuals and organizations collected, conserved, used, and exchanged genetic resources under an open-access regime. These resources were made freely available under the common heritage principle.^[3] In 1992, the CBD recognized the sovereign rights of countries to control the use of their resources. The CBD encouraged countries to develop policies to regulate access to and benefit sharing of genetic resources.^[4] However, in the years since the CBD was signed and ratified, countries still struggled to develop and implement national access and benefit-sharing (ABS) policies. In 2002, the sixth Conference of the Parties of the CBD adopted the Bonn Guidelines on "Access to Genetic Resources and the Fair and Equitable Sharing of Benefits Arising Out of their Utilization" designed to help countries develop their ABS policies. In addition to this effort, in 2002, the plan of implementation of the World Summit on Sustainable Development held in Johannesburg (South Africa) called for an international regime on access and benefit sharing. The CBD's second Ad Hoc Open-Ended Working Group on Access and Benefit Sharing continued the discussions on the process, nature, scope, elements, and modalities of the proposed regime. No consensus definitions for these terms have been reached, and the process will continue at the seventh meeting of the Conference of the Parties to the CBD.

While in 1992 the CBD indicated that genetic resources were no longer the common heritage of humankind, this was not the case for an important percentage of plant genetic resources used for food and agricultural purposes that had been assembled in gene banks before the CBD came into force. In 1994, the international collections of the gene banks of the Consultative Group for International Agricultural Research (CGIAR) centers were placed under the aegis of the Food and Agriculture Organization (FAO) of the United Nations. Under the FAO sponsorship, these resources remain freely available in principle to crop breeders.^[1] In addition, 7 years later, the 2001 FAO International Treaty on Plant Genetic Resources for Food and Agriculture (hereafter Treaty) placed 36 genera of crops and 29 genera of forages in the public domain and

guaranteed access to these resources for research and breeding purposes.^[5] The scope of the treaty covers all plant genetic resources for food and agriculture, so the number of crop and forage genera placed in the public domain will likely increase in the future. The Treaty also endorsed one of the most important principles of the CBD, i.e., the sovereign rights of countries to control the use of their genetic resources. These two agreements also stressed that the authority to determine access to genetic resources rests with national governments and is subject to national policies. The objectives of the CBD called for the conservation of biological diversity, its sustainable use, and the fair and equitable sharing of benefits derived from the use of genetic resources. Similarly, the objectives of the Treaty promoted the conservation, sustainable use, and equitable sharing of the benefits derived from plant genetic resources for food and agriculture. The Treaty also stressed that these objectives should be accomplished by “linking this Treaty to the Food and Agriculture Organization of the United Nations and to the Convention on Biological Diversity.”^[5]

BENEFIT SHARING AND BIOPROSPECTING

Access to genetic resources for food and agriculture will be granted through material transfer agreements (MTAs) under a multilateral system of exchange of genetic resources as soon as the Treaty enters into force. Under this system, participants will place genetic resources in a common pool and agree on a common set of rules to use and exchange these resources. If resources are transferred to users outside the multilateral system, MTAs^[6] may be used to facilitate the negotiation of economic benefits in both bilateral and multilateral arrangements.

Economic benefits derived from genetic resources put in the multilateral system will be channeled to a trust fund to compensate countries that provided these resources. All participants of the system will have equal access to these benefits independent of individual contributions. This, however, may be a disincentive for providers of large quantities of genetic resources who are eager to optimize their economic benefits. In this case, providers may decide to follow a bilateral approach to negotiate economic benefits. This approach, however, usually results in high transaction costs. The advantage of the multilateral approach is that because exchange rules are commonly agreed upon among participants, transaction costs can be minimized.

The CBD endorses the bilateral approach to facilitate access and benefit-sharing goals. Sharing of genetic resources is negotiated on mutually agreed terms and subject to prior informed consent procedures. Bilateral agreements or contracts have been the main vehicle to facilitate access and benefit-sharing goals under national

ABS policies that include the objectives and principles of the CBD.^[7] Three years after the signing of the CBD, a handful of biodiversity-rich countries pioneered novel examples of access legislation. On 18 May 1995, the Philippine government adopted Executive Order 247 “Prescribing Guidelines and Establishing a Regulatory Framework for the Prospecting of Biological and Genetic Resources in the Philippines, their By-Products and Derivatives for Scientific and Commercial Purposes and for other Purposes.” One year later, the Andean Pact countries adopted the regional regime on ABS known as Decision 391. Some of the similarities among these and other access policies developed under the aegis of the CBD include: 1) the establishment of agreements between bioprospecting groups and the national governments; 2) the recognition of national sovereignty over biological and genetic resources within national borders; 3) the establishment of procedures for obtaining prior informed consent not only from government authorities, but also from the providers of biological resources including local communities; and 4) the equitable sharing of benefits derived from the use of biological diversity.^[8] Thus scientists who are collecting organisms with useful properties had to modify their bioprospecting approaches. Today, bioprospecting groups must take into account not only the principles stated by the CBD, but also the obligations of national laws that regulate access to genetic resources.

Before the CBD entered into force, access and benefit-sharing contracts were also used by bioprospectors. In 1991, Merck and the National Biodiversity Institute (INBio) of Costa Rica announced the negotiation of a contract in this area. Merck paid INBio an advance amount of \$1.1 million and negotiated an undisclosed percentage of potential royalties in exchange for access to Costa Rica’s genetic resources as part of the bioprospecting agreement between these two organizations.^[9] In the following years, this trend was emulated by several bioprospecting groups and still continues. For example, the International Cooperative Biodiversity Groups (ICBGs) negotiated contracts in several countries that lack ABS policies.^[10] The ICBGs endorsed the conservation and benefit-sharing objectives of the CBD and, in some cases, provided incentives for the government to develop their own access and benefit-sharing policies.

Contracts signed by these and many other groups have been the heart of bioprospecting initiatives. They are not only a set of promises involving the sale of genetic resources and information in exchange for compensation, but also a reflection of a relationship or transaction between technology-rich and biodiversity-rich parties from developed and developing countries. Contracts formalize this relationship and attempt to ensure that pharmaceutical, agricultural, and biotechnological companies compensate researchers, collectors, and collaborators from countries

with great biological, genetic, and cultural diversity. Their fairness depends in large part on the skills of the parties to negotiate adequate benefit-sharing and compensation provisions. In the past, negotiators from developing countries may not have been as qualified as their counterparts from industrialized countries, but this is changing. The actors involved in the business of bioprospecting have increased in diversity, number, and expertise. Information about the rights and obligations of bioprospecting parties and their collaborators has proliferated, and it is reaching scientists and indigenous groups from developing countries.

NONLEGALLY BINDING INSTRUMENTS: CODES OF CONDUCT

In the absence of clear access and benefit-sharing policies, codes of conduct have provided guidance to facilitate access to and exchange of genetic resources. In 1993, for example, the Commission on Plant Genetic Resources and the FAO conference adopted an International Code of Conduct for Plant Germplasm Collecting and Transfer as a voluntary instrument pending the adoption of the Treaty. The code also proposes minimum guidelines for sponsors, curators, collectors, and other users of genetic resources covering the collection and transfer of these resources.

In practice, it is often necessary to obtain access permits when collecting genetic resources in nature, but most samples are obtained by exchange among institutions. Many countries allow for relatively unrestricted access to their gene banks and encourage the use of MTAs to facilitate the exchange of germplasm. Under MTAs, germplasm can only be used for research purposes and they may oblige the recipient not to seek intellectual property protection over the material transferred or its derivatives. This contractual mechanism has been used by organizations worldwide to provide important benefits to the agriculture of many nations. Equally effective has been the "standard order form" used by the International Agriculture Research Centers (IARCs) for the transfer of "designated germplasm" from ex situ collections maintained in international centers before the CBD came into force. Under this form, participants agree not to seek intellectual property protection over germplasm transferred and to ensure that future recipients are bound by the same obligation.^[1]

CONCLUSION

It has been more than 10 years since the signing of the CBD and no significant sharing of economic benefits has been documented from the use of genetic resources identified in this period. For example, the pharmaceutical

industry has not developed any moneymaking drug from native genetic resources and has not been able to share with local communities the millions of dollars that analysts predicted in the 1980s and early 1990s. It is unlikely that such an amount of money will ever flow to local communities. However, some pharmaceutical companies have identified potentially useful chemical substances and molecular structures,^[10] and since drug development usually takes between 10 and 15 years, there is still hope that some products will be developed in the near future. In the meantime, universities, pharmaceutical, and biotechnology companies continue to test many biological samples, most of them aware of the regulatory power of the CBD and national access laws that limit their access to new genetic resources, but not many have a good understanding of the scope of these laws. There is also great concern about the lack of clarity of government provisions to implement these access laws. In addition, many companies complain about high transaction costs, bureaucracy, and corruption. Representatives of the pharmaceutical, biotechnology, and seed industry also believe that this relatively new legal environment will force their organizations to stop collecting in nature. Instead, they will go back to ex situ conservation collections maintained in developed countries where access is free.^[11] However, native germplasm of some taxa in such collections is quite limited in diversity and eventually a return to the natural environment for more samples will be necessary.

Scientists perceive that access laws have imposed barriers to academic, scientific, and commercial research.^[12] Many developing countries lack the capacity and expertise to negotiate access contracts and prefer to close their borders to bioprospecting initiatives to keep the option of future value of species with potential medicinal and industrial applications. The International Center for Tropical Agriculture (CIAT), for example, has stopped collecting native germplasm in several Andean countries until existing access and benefit-sharing policies and procedures are clarified and streamlined. Other source countries such as Mexico face great pressure to restrict access from indigenous groups that oppose bioprospecting initiatives because of the lack of transparency of these initiatives.

Genetically Engineered Crops with Resistance Against Insects

Johnie N. Jenkins

USDA—ARS, Mississippi State, Mississippi, U.S.A.

INTRODUCTION

Many insect pests reduce yield and quality of agricultural crops, and a large worldwide market exists for insecticides for their control. Even though insecticides are used for their control, insects in the order Lepidoptera and Coleoptera remain major worldwide pests of important food and fiber crops. The common soil bacterium, *Bacillus thuringiensis* (Berliner), produces a crystalline protein that is toxic when consumed by certain larvae in those orders. Insecticides based on crystalline proteins from *B. thuringiensis* have been useful in the control of Lepidopterous caterpillars. These *B. thuringiensis* pesticides have been used successfully and safely for over 50 years. They are not toxic to humans, to other mammals, or to other higher animals.

Host plant resistance to insects has been developed for several crops using conventional breeding of genes within the plant species.^[1] Genetic transformation technology offers a means of moving genes across the species barrier. With the advent of this technology in the early 1980s, scientists began attempts to transform plants using genes from *B. thuringiensis*, thereby providing control of selected insects using a bacterial gene genetically engineered into a plant. The first reported use of a toxin gene from *B. thuringiensis* expressed in plants occurred in 1987 when tobacco plants, *Nicotianatabacum* L., were developed that produced enough of the toxin to kill first instar larvae of tobacco hornworm, *Manduca sexta* L., placed on leaves of transformed plants.^[2-4]

GENETICALLY ENGINEERED CROPS

Transformation of plants by the bacterium *Agrobacterium tumifacens* became routinely possible in the early 1980s. In 1987, cotton plants, *Gossypium hirsutum* L., were first regenerated from cells into complete plants via tissue culture. Scientists had previously attempted to transform cotton plants with DNA sequences of the delta endotoxin gene from *B. thurgiensis* var *kurstaki*. Scientists at Monsanto Co. first transformed tomato, *Lycopersicon esculentum*, to express the Bt toxin gene and field tested these plants.^[5] Scientists at Agracetus were the first to

produce cotton plants for field testing that expressed the *B. thuringiensis* gene.^[6] However, when Agracetus cotton plants were grown in field plots they did not express the toxin at a level sufficient to control targeted insects.^[7] Monsanto was the first company to produce transformed cotton, corn, *Zea maize*, and potato, *Solanum tuberosum*, plants that expressed toxin(s) from *B. thuringiensis* at levels needed for commercial control of targeted insect pests.^[8,9] This increased toxin expression in transformed plants resulted from modifications by Monsanto scientists^[8] to the DNA sequence of a specific toxin gene of *B. thuringiensis*.

All the transgenic, insect-resistant crop species that have been commercialized to date express one of the various crystalline proteins from *B. thuringiensis*. Three transgenic crop species are currently approved by the U.S. Environmental Protection Agency (EPA) for growing in the United States.^[10] The Cry1Ac protein in cotton was registered by Monsanto as Bollgard[®] and targeted to tobacco budworm, *Heliothis virescens* (Fab.), bollworm, *Helicoverpa zea* (Boddie), and pink bollworm, *Pectinophora gossypiella* (Saunders). The Cry3A protein in potato was registered by Monsanto as NewLeaf[®] and targeted against the Colorado potato beetle, *Leptinotarsa decemlineata* Say. The Cry1Ab protein in corn was registered by Monsanto as YieldGard[®] for full commercial use in field corn. The Cry1Ab protein in corn was registered by Syngenta Seeds, Inc. as YieldGard[®] and Attribute[™] for full commercial use in field and sweet corn, respectively.

Transgenic Bollgard cotton was first grown commercially in the United States in 1996. In 2000, cotton with a gene from *B. thuringiensis* was grown on 1.5 million hectares (ha) and cotton with this gene plus a herbicide resistance gene was grown on 1.7 million ha in the world, primarily in the United States, China, Australia, Argentina, Mexico, and South Africa.^[11] The United States is the largest user of Bollgard cotton with 39% of the U.S. crop in 2000 planted to Bollgard or Bollgard plus herbicide resistant cotton.^[11] In China, cotton with a *B. thuringiensis* gene was grown for the first time in 1997 on 63,000 ha and in 2000 it was grown on 500,000 ha.^[11] In 2000, growers of Bollgard cotton accrued \$168 million in economic benefit from lower production costs and increased yield.^[12] They applied 1.04 million fewer pounds

of insecticide. Additional benefits were reduced pesticide exposure risks, improved preservation of beneficial insects, and increased wildlife benefits.^[12] In China, the Chinese Academy of Agricultural Sciences (CAAS) and Monsanto/DeltaPine each have versions of Bt cotton grown by an estimated 3 million small farmers in 2000.^[11] Transgenic Bt cotton offers the small farmers of China a significant increase in income and a significant decrease in pesticide usage and associated pesticide problems.

Corn is another major crop with a significant area planted to transgenic hybrids. Corn with a gene from *B. thuringiensis* was first planted in the United States in 1996. In 2000, 6.8 million ha were planted on a global basis, with 92% planted in the United States.^[11]

HOW PLANTS WITH GENES FROM *B. thuringiensis* KILL INSECTS

The toxin produced by transgenic plants transformed to express the toxin gene from *B. thuringiensis* affects susceptible insects as the protein^[13] is solubilized and proteolytically processed into polypeptide molecules that bind with specific affinity to receptor sites in the insect's midgut epithelial cells. This causes pores or ion channels to develop in the cell membranes, thus disturbing cellular osmotic balance and causing cells to swell and lyse and causing paralysis in the insect's midgut and mandibles. Death then occurs through a combination of starvation and septicemia.

MANAGING OR DELAYING DEVELOPMENT OF INSECT RESISTANCE TO Bt IN GM CROPS

Management of the development of resistance to *B. thuringiensis* insecticidal toxins in transgenic plants is of great concern to many people.^[13] The U.S. EPA requires a unique resistance management plan as part of its approval of transgenic Bt cotton and corn. This resistance management plan requires delayed development of populations of pest insects that are resistant to the toxin. The plan was developed around a high-toxin dosage and a concept of refuge in which susceptible insects are produced in sufficient numbers to mate with the low numbers of resistant insects that may survive on the transgenic crops. Because no actual data had ever been developed to test this strategy, insect population models were developed and used to define refuge sizes and a strategy for use. General conclusions from population models were that 1) the level of toxic protein should be very high relative to the target pests LD₉₀; 2) these crops should be planted in a manner that allows high levels of mating among susceptible and

resistant pest insects; and 3) movement of larvae between transgenic and nontransgenic plants must be avoided.^[14]

CURRENT STATUS OF *B. thuringiensis* GENES IN PLANTS

Approximately 40 different insect resistance genes have been introduced into crop plants.^[15] At least 10 Bt genes encoding different Bt toxins (cry1Aa, cry1Ab, cry1Ac, cry1Ba, cry1Ca, cry1H, cry2Aa, cry3A, cry6A, and cry9c) have been genetically engineered into 26 species of plants; however, codon-optimized genes have been transformed into only cotton, corn, potato, broccoli, *Brassica oleracea italica*, cabbage, *B. oleracea capitata*, and alfalfa, *Medicago* sp.^[15]

CONCLUSION

In the future many types of genes will be used to genetically engineer insect resistant plants. Some of the promising non-cry genes from *B. thuringiensis* and *B. cereus* are the vegetative phase insecticidal proteins VIP 1, VIP 2, and VIP 3A.^[15] Candidate genes, other than those from *B. thuringiensis*, are plant protease inhibitors, plant amylase inhibitors, plant lectins, and chitinases. From animals, serine protease inhibitors and chitinase genes are being investigated. At present, only plants with *B. thuringiensis* cry genes have been commercialized.^[15] Over 240 insecticidal cry proteins produced by the various strains of *B. thuringiensis* have been classified.^[16] In addition to these other genes, there seems to be ample genetic variability among *B. thuringiensis* strains to allow scientists to use these cry genes to develop many different versions of crop resistance.

Genetically Modified Oil Crops

Denis J. Murphy

University of Glamorgan, Cardiff, U.K.

INTRODUCTION

For over five thousand years, oil crops have been sources of many useful nonfood products ranging from lubricants to lamp fuels. Since the late 19th century, such nonfood uses of plant oils have declined due to the twin pressures of relatively cheap petroleum-based alternatives and the need to feed the ever-increasing human population of our planet. By the late 20th century, less than 15% of plant-derived oils were used for industrial purposes. The vast bulk of vegetable oils are currently traded as commodities destined for human consumption in such products as margarines, cooking oils, and processed foods. More recently, however, interest has revived in the possible exploitation of oil crops for a wide spectrum of nonedible products including cosmetics, biodegradable plastics, and even high-value pharmaceuticals.

MARKETS AND CROPS

Global vegetable oil markets are dominated by the “big four” crops—soybean, oil palm, rapeseed, and sunflower—which together make up over 86% of the total global traded production of almost 90 million tonnes. The major aim of oil crop engineering has been to alter the fatty acid profiles of the major oil crops. As shown in [Table 1](#), these crops have relatively narrow fatty acid profiles dominated by C16 and C18 groups that are not optimal for many industrial uses. On the other hand, there are many examples of minor crops and noncrop plants that accumulate very high levels of a diverse range of novel fatty acids with chain lengths from C8 to C24, and with useful chemical functionalities such as hydroxyl, epoxy, and acetylenic groups. Such oils can be used for the manufacture of products such as adhesives, paints, detergents, lubricants, and nylons, to name but a few. In [Table 2](#), some examples of oil-bearing seeds that already produce some of these novel and potentially useful fatty acids are shown. Over the past decade, many of these plants have been used as sources of genes encoding fatty acid biosynthetic enzymes for transfer into mainstream oil crops in the hope that those crops would then accumulate the novel oils on a scale of up to millions of tonnes

per year. This concept has been termed “designer oil crops.”^[1]

Rapeseed was successfully transformed as early as 1984, followed by sunflower and soybean in the 1990s. More recently, marker transgenes have been inserted into oil palm^[2] and lipid biosynthetic genes will doubtless soon follow, although it will probably be another decade before alteration of the oil composition of this important tree crop has been achieved. Most of the genes related to fatty acid biosynthesis were isolated during the 1990s, either from the various exotic oilseeds or from model plants such as *Arabidopsis thaliana*, which as well as being an important research plant is also an oilseed that accumulates storage lipid as almost half of its seed weight. Therefore, in principle, it should now be possible to engineer transgenic oil crops to produce the desired range of novel fatty acids for a variety of industrial applications.

PROBLEMS AND PROSPECTS

Unfortunately, it appears that the accumulation of high levels of a single desired fatty acid in the storage oil, although fairly common in nature, is not readily achievable by simply inserting a few lipid biosynthetic genes into a given transgenic plant. There is increasing evidence that fatty acid modifications may behave as quantitative traits that are controlled to a greater or lesser extent by numerous genes.^[3] It may be the case that in order to achieve levels of 90% of a particular fatty acid in a crop plant, the insertion of at least four and as many as ten transgenes may be required. This will add considerably to the cost and timescale of such manipulations.

Another problem in oil crops such as rapeseed is that exotic fatty acids designed for sequestration in the storage oils may sometimes also accumulate in membrane lipids, with possible deleterious consequences. Plants that naturally accumulate exotic fatty acids such as lauric acid (C12), which is a powerful membrane-destabilizing detergent, have evolved mechanisms to “channel” these deleterious fatty acids into the storage lipid pool. This mechanism, which probably involves specific phospholipases and acyltransferases, is found in lauric-accumulating seeds such as *Cuphea spp* and *Umbelluria californica*,

Table 1 Percentage fatty acid composition of the “big four” oil crops

Fatty acid ^a	Soybean	Oil palm ^b	Rapeseed	Sunflower
16:0	11	45	5	6
18:0	4	5	1	5
18:1	22	38	61	20
18:2	53	11	22	69
18:3	8	0.2	10	0.1

^aFatty acids are denoted by their carbon chain length followed by the number of double bonds.

^bMesocarp.

but does not appear to be particularly active in rapeseed.^[4] A further potential technical challenge to the engineering of designer oil crops is the finding that some of the gene promoters most commonly used to achieve the seed-specific expression of transgenes may also direct gene expression in other tissues, including roots.^[5,6] While it is possible that in many cases the accumulation of exotic fatty acids in nonseed tissues may not be problematic, this may not always be true, and it underlines the need for the thorough metabolic profiling of all transgenic varieties before their general release.

The consequence of these and other complexities of plant molecular genetics and metabolism is that, despite many impressive achievements in isolating oil-related genes and producing transgenic plants with modified seed oil compositions, it has not been possible yet to achieve the kind of high levels (80–90%) of novel fatty acids that will make possible their widespread commercial exploitation. In the case of the high-lauric transgenic rapeseed (canola) crop, difficulties in its commercialization are also due to the existence of a competing source of lauric oil, namely palm kernel oil from the Far East. Palm oil is both cheaper to produce than rapeseed oil and in much more plentiful supply. The lauric-oil variety of rapeseed was improved from 40% to 60% lauric content by the insertion of several additional transgenes,^[3] but it still remains far from being a commercial success and is no longer under development as a crop variety in the United States.

The availability of many genes involved in fatty acid modification and the good progress in transforming the main oil crop species will doubtless encourage further efforts to resolve the challenge of low levels of novel fatty acid production. But even if such efforts are successful, the commercial success of transgenic oil crops will remain problematic. It will be necessary to identify and develop robust markets for transgenic oil products; simply substituting for low-cost petroleum-derived products is unlikely to be economical for many decades. The additional costs of identity preservation will probably preclude the use of such transgenic oils as large-scale, low-value commo-

ties in competition with conventional plant oils, even for industrial applications. In summary, transgenic oil crops producing novel fatty acids may have promise for the long-term future, but their commercial prospects over the next few years remain decidedly uncertain.

An attractive alternative to novel fatty acid production in oil crops is to engineer them to accumulate biopolymers instead. Virtually all of our conventional plastics are made from nonrenewable petroleum-derived products

Table 2 Accumulation of novel fatty acids by some oil-producing plants

Fatty acid ^a	Amount ^b	Plant species	Uses
8:0	94%	<i>Cuphea avigera</i>	Fuel, food

^aFatty acids are denoted by their carbon chain length followed by the number of double bonds or the nature of other functionalities.

^bPercentage of total fatty acids; data are taken from Ref. 10.

such as adipic acid and vinyl chloride. Some soil bacteria such as *Ralstonia eutrophus* are able to accumulate up to 80% of their mass in the form of nontoxic biodegradable polymers called polyhydroxyalkanoates (PHAs). The PHAs are made up of β -hydroxyalkanoate subunits that are synthesized from acetyl-CoA via a relatively short pathway involving as few as three enzymes for the most common PHA, polyhydroxybutyrate.^[7] The cost of PHAs could be considerably reduced if they were produced on an agricultural scale in transgenic crops. This prospect has led several companies, including Monsanto and MetaboliX, to attempt to develop transgenic rapeseed plants containing the bacterial genes responsible for PHA biosynthesis. Provided the PHAs accumulate in the plastids, and not in the cytosol, it is possible to obtain modest yields of the polymer from either leaves or seeds.^[8] A major and as yet unresolved technical hurdle is how to extract biopolymers from plant tissues in an efficient and cost-effective manner. Another complexity is that polyhydroxybutyrate, which is the most widespread PHA, is a rather brittle plastic and is not suitable for most applications. The best-performing plastics are copolymers of polyhydroxybutyrate with other PHAs, such as polyhydroxyvalerate. Although the production of such copolymers in transgenic plants is considerably more difficult than the production of single-subunit polymers, progress has recently been made in this area.^[9] While there are several companies and academic labs attempting to make commercially extractable PHAs in plants (including one in oil palm), it seems unlikely that these environmentally friendly products will be commercially available for quite a few years to come.

Apart from these scientific and technical challenges, engineered oil crops also face considerable challenges regarding their management and economics. The major managerial problem concerns the need to segregate a transgenic crop variety producing a novel product from nontransgenic commodity crops and from other transgenic varieties of the same species that accumulate different products. This is a formidable task, given the intricacy of the supply chain from breeder to grower to crusher to processor and so on, all the way to the retailer and, ultimately, to the consumer. The difficulties in ensuring strict segregation of otherwise indistinguishable transgenic crops have consistently been underestimated by many in the industry. Several well-publicized failures in the segregation of transgenic rapeseed and maize crops in recent years (e.g., the STARLink affair, although note that this did not involve genes modified for oil composition)^[10] have thrown this issue into much sharper focus. The contamination of a batch of seeds containing, for example, a hydroxy oil designed for industrial use with another batch of seeds containing a high-oleic oil for edible consumption (or vice versa) would result in a mixture that would be useless for both purposes. Efficient

segregation is likely to be both difficult to control and expensive to implement. This may limit the cultivation of transgenic crops producing novel oils to geographically remote areas and/or to relatively high-value niche markets, where the additional costs of identity preservation can be met by the added value of the product.

CONCLUSION

The conclusion that engineered oil crops may be best suited to relatively low-volume, high-value markets allows the possible expansion of the target oilseed species beyond the “big four” oil crops to include minor oil crops like safflower or linseed, or even noncrop species like *Cuphea*. Use of such oil crops to produce novel products would have the advantage that segregation from sexually compatible food crop varieties would be fairly straightforward. Another innovative development of transgenic oil crops is the use of the oil as a carrier for recombinant high-value proteins such as pharmaceutical peptides and industrial enzymes.^[11] Therefore, the prospects for oil crop biotechnology are now significantly different from the 1990s vision of large-scale “designer oil crops,” but the prospects remain positive, albeit rather more long-term than was originally envisaged. For this new vision to be realized, more investment in research must be coupled with a better appreciation of the economic, managerial, and public acceptability challenges that will confront the new crops.

Genome Rearrangements and Survival of Plant Populations to Changes in Environmental Conditions

G

Pier Giorgio Cionini

Università di Perugia, Perugia, Italy

INTRODUCTION

The capability of plants to develop plastic response reactions to adapt to changes in environmental conditions is unique in the biological world. However, the idea that the effect of the environment on an organism is, as a rule, physiological—with the genome remaining unchanged—has been a corollary of the biological tenet that a genome must be constant—apart from changes in chromosome number and type—on account of the absolute primacy of DNA over all biological phenomena and of its function as the basis of heredity. The concept that the nuclear genome may be intrinsically plastic due to its content of independent replicative units still meets with incredulity.^[1] However, there is a growing consensus of opinion at the present time that changes in genome size and organization may be not restricted to species divergence, and that fluid domains do exist in the nuclear DNA in addition to more stable portions, particularly in plants.

Genomic rearrangements occurring in plant populations have been revealed by changes of genome size, confirmed and specified by molecular investigation, and shown to be related to alterations of plant developmental dynamics and phenotypic characteristics. The following sections show that changes in the nuclear DNA, which as a rule consist of redundancy modulations of repeated DNA sequences and which hence alter the organization of the genome: 1) may differentiate both populations and plants within one and the same population; 2) may have a role in overcoming both changes and changeability of the environment; and 3) may represent either the results of selection processes or direct responses of plant genomes to environmental stimuli.

GENOMIC VARIATION BETWEEN POPULATIONS

Broad bean (*Vicia faba*) is a good example of genomic rearrangements which may differentiate plant populations. Local populations of this species scattered all along the Mediterranean Basin differ 1.35-fold in genome size. Molecular analyses show that the copy

number of both tandemly arranged and interspersed DNA repeats differs between populations and correlates significantly with the genome size.^[2] Similar observations have been made in other species. A highly significant, positive correlation was found to exist between the mean genome size of *Dasypyrum villosum* populations and the altitudes of the stations where they grow.^[3] The amounts of DNA and heterochromatin vary according to latitude and altitude in North American lines of maize (*Zea mays*).^[4] The genome sizes of populations of wild barley (*Hordeum spontaneum*) differ significantly and correlate positively with January temperature at the stations, and *BARE-1* retrotransposons have been shown to vary in redundancy in the nuclear DNA of wild barley plants from stations having microclimates sharply differing in solar irradiation and aridity.^[5] The amount of nuclear DNA may vary up to 1.32-fold in Italian populations of fescue (*Festuca arundinacea*) due to variations in the amount of heterochromatin and to changes in the redundancy of DNA sequences which belong largely to a particular fraction of repetitive DNA and are, at least in part, transposable elements or their remnants. The genome sizes of the fescue populations correlate positively with the mean temperature for the year and for the coldest month at the stations and correlate negatively with their latitudes.^[6]

The adaptive significance of these genomic changes—their role in buffering environmental pressure and allowing a species to grow in a range of ecogeographical conditions and climates—is clearly shown by their effects on the developmental dynamics of the plants. Cell proliferation and enlargement are affected by the genomic alterations occurring in broad bean populations, and the interactions between these two developmental factors cause the germination power of the seeds and the growth rate of plant organs to differ significantly between populations (compare Ref. 2). In *F. arundinacea*, the germination power of the seeds and the growth rates of roots and leaves, which are developmental events taking place during winter and early spring, are correlated negatively with the genome size, whereas the height of culms and other quantitative characteristics of plant organs developing later in the warmer season are correlated positively.^[7]

GENOMIC VARIATION WITHIN POPULATIONS

Changes in the redundancy of repeated DNA sequences, which result in genome size alterations, may also differentiate plants within populations. An intriguing example of intrapopulation variability of genome size and organization is found in sunflower (*Helianthus annuus*). In this species, genomic changes are continuously produced during reproduction, even with selfing and homozygosity. Embryos developing in different portions of the flowering head acquire different genome sizes, with a gradient, based on the genome size of the mother plant, that decreases from the periphery to the middle of the head. These genomic rearrangements are due to complex, specific changes in the redundancy and methylation of DNA repeats belonging to different sequence families.^[8] Another example is *D. villosum*. Up to a 1.66-fold difference was shown to occur between the genome size of individual plants belonging to given populations of this species, and variability of DNA contents was found to be greater, as a rule, in populations from mountain sites, where the environment is expected to be particularly limiting and/or variable.^[3]

It was shown, in both *D. villosum* and sunflower, that plants differing in genome size also differ in given aspects of their development and, remarkably, in their flowering interval. It is demonstrated in the following section that genomic rearrangements can represent direct responses of the plant genome to environmental stimuli. Therefore, changes of genome size and organization between individual plants of a population may be due to the diversity of environmental (or microenvironmental in the case of sunflower) conditions occurring during the reproduction and/or development of each of them. Intrapopulation variability of genome size and organization may be seen as an evolutionary factor allowing plant populations to withstand the variability of conditions in a given environment.^[3,9]

DIRECT RESPONSES OF THE PLANT GENOME TO ENVIRONMENTAL STIMULI

Genomic rearrangements in plant populations may be the result of selection processes after the occurrence of uncontrolled events in the genome. However, adaptive changes in nuclear DNA also may represent direct responses of the plant genome to environmental variation. The case with flax (*Linum usitatissimum*) is now classic. When plants carrying given genotypes are germinated and grown under different temperatures and/or in unbalanced mineral nutrients, small and large plants are obtained

(genotrophs). These phenotypic characters remain heritable, and genotrophs differ 1.16-fold in genome size. The changes occurring in the nuclear DNA were extensively characterized at the molecular level and shown to be due to copy number variations in given repeated sequence families.^[10]

Redundancy modulation of DNA repeats may be specifically controlled. The copy number of certain interspersed repeats increases in plantlets of *F. arundinacea* obtained by germinating seeds at 30°C, while that of different repeats increases at 10°C.^[6] In *H. annuus*, several repetitive sequence families are more represented in large-size genomes, but there are DNA repeats whose redundancy is greater in the relatively small-size genomes.^[8] This specificity suggests that given DNA domains are plastic, not simply instable, with changes occurring under plant-level control and not independently of the genome as a whole.

CONCLUSION

Genomic rearrangements may be the paramount factors, together with the processes of development and reproduction, that allow the adaptive responses of plants to environmental pressure made particularly stringent by immobility. Nucleotypic effects—which can modulate cell proliferation and enlargement and, consequently, developmental dynamics—and/or more specific controls of the nuclear activity may represent the way(s) by which genome rearrangements, determined by quantitative changes of repeated sequences having different origin and chromosomal organization, achieve environmental adaptation. These rearrangements may help to explain the extraordinary plasticity at the morphological and physiological level that is a common feature of plants and may constitute an answer to the debated question about the functional role(s) of repeated sequences in eukaryotic genomes, where they represent the DNA fraction that is by far the largest, especially in plants.

Genome Size

Michael D. Bennett

Royal Botanic Gardens Kew, Surrey, U.K.

INTRODUCTION

The DNA amount in the unreplicated gametic nucleus is referred to as its C-value. Estimates for nearly 4000 species are accessible in the Plant DNA C-values database. C-values differ more than 1000-fold for plants of similar organismic complexity reflecting differences in ploidy level or amounts of repeated DNA sequences. Genome size is evolutionarily labile and molecular mechanisms responsible for DNA gain or loss are beginning to be understood. C-value and genome size are key diversity characters with important consequences and uses.

DEFINING GENOME SIZE AND DNA C-VALUE

Plants contain DNA in nuclear and organellar (e.g., chloroplast) genomes. This article concerns only the former. Today the term genome may refer to either all the nuclear DNA or only some of it. Thus, a paper on hexaploid *Triticum aestivum* can say that “loci are triplicated in the wheat genome” but also talk of “the three genomes of hexaploid bread wheat.” Genome originally defined a basic (monoploid) chromosome set (x), and the term is restricted to this cytogenetic definition below.

To avoid confusion with chromosome number, Swift introduced the term “C-value” (“C” standing for “Constant”) in 1951. 1C refers to the DNA amount in an unreplicated gametic chromosome set (n) of an organism. This usage applies irrespective of ploidy level, so it is important to understand that whereas genome size equals the 1C DNA amount in a diploid species, genome size is always less than the 1C DNA amount in polyploid species (Table 1). DNA amounts are usually expressed in picograms (pg) or in megabase pairs of nucleotides (Mb) (NB 1 pg = 10^{-12} g; 1 Mb = 10^6 nucleotide base pairs; 1 pg = 980 Mb).

METHODS USED TO ESTIMATE DNA AMOUNTS

Since 1950 DNA amounts have been measured by various techniques. Chemical methods using extracted DNA were

little used after the 1960s, while reassociation kinetics was hardly used after the 1970s as faster and simpler techniques were developed that estimate the amount of DNA in single cells or nuclei using microdensitometry, flow cytometry, or video-based image analysis. C-values obtained by these methods are estimates due to inherent technical errors, but complete genome sequencing offers the chance of measuring genome size more exactly.

WHOLE GENOME SEQUENCING

In 2000 the Arabidopsis Genome Initiative published the first “complete genome sequence” in a flowering plant (*Arabidopsis thaliana*). Its genome size was given as 125 Mb, comprising 115.4 Mb in sequenced regions plus a rough estimate of 10 Mb in unsequenced regions.^[1] This is an underestimate, as the estimate for unsequenced gaps was too low. 125 Mb disagrees with many estimates made by other methods that placed 1C in *Arabidopsis* in the range 147–172 Mb. Moreover, comparison with *Caenorhabditis elegans* (whose 1C-value is known from complete genome sequencing to be 100.25 Mb) gave a 1C DNA amount of approximately 157 Mb for *Arabidopsis*.

In 2002 draft sequences for the first crop species were published. The 1C-value for indian rice *Oryza sativa* ssp. *indica* was given as 466 Mb^[2] with a total scaffold length of 362 Mb plus 104 Mb of masked reads. This value agrees closely with estimates made previously using nonmolecular methods (Table 2).

PLANT DNA C-VALUE REFERENCE SOURCES

DNA C-values for plants come from more than 500 widely scattered original sources. Estimates for angiosperms have been listed for easy reference since 1976^[3] and combined in an electronic database since 1997. C-values for angiosperms, gymnosperms, pteridophytes, and bryophytes were pooled in the Plant DNA C-values database,^[4] and in 2002, nuclear DNA amounts for almost 4000 plant species (excluding algae) were listed.

Table 1 DNA C-value and genome size in a hexaploid triticale and its parents

Species	Ploidy level	Chromosome number (2n)	Genomic constitution	1C DNA amount (pg)	Genome size (pg)
<i>Secale cereale</i>	2x	14	RR	8.28	8.28
<i>Triticum turgidum</i>	4x	28	AABB	12.28 ^a	6.14 ^a
<i>Triticale</i>	6x	42	AABBRR	19.80 ^a	6.60 ^a

^aMean for 2 or 3 genomes = 1C DNA amount/half ploidal level.

INTERSPECIFIC VARIATION IN DNA AMOUNT

Comparison shows large differences in numbers of estimates and representation between major plant groups (Table 3), and striking variation in C-value within some but not all groups. C-values differ more than 1000-fold in angiosperms (Table 4, Fig. 1), and 450-fold from 0.16 pg in *Selaginella kraussiana* to 72.7 pg in *Psilotum nudum* in pteridophytes. However, C-values vary only 12-fold, from 0.17 pg in *Holomitium arboretum* to 2.05 pg in *Mnium marginatum* in bryophytes, and only 14-fold in gymnosperms from 2.25 pg in *Gnetum ula* to 32.2 pg in *Pinus nelsonii*.

INTRASPECIFIC VARIATION

DNA amount is relatively constant within species and characteristic of taxa, but limited intraspecific variation is known. Such variation can reflect differences in both type and number of chromosomes (e.g., sex and B-chromosomes) and in repeated DNA sequences. A well studied example concerns corn (*Zea mays*), where C-values for different lines can vary by up to 35%. Much of this variation correlates with the presence and size of heterochromatic “knobs” in the genome. Knob number is also related to geographical distribution and may reflect environmental adaptation.^[5] However, such examples are few, and recent comparisons of onion (*Allium cepa*) cultivars from widely different regions detected no differences in genome size.

Table 2 1C-values (Mb) in *Arabidopsis thaliana* cv. Columbia and *Oryza sativa* ssp. *indica* line 93-11 based on complete genome sequencing or non-molecular methods

Method	Arabidopsis	Oryza
Whole genome sequencing	125 (3)	466 (4)
Feulgen microdensitometry	167 (2)	490 (2)
Flow cytometry	147–172 (2)	441–468 (2)

The relative constancy of genome size within species is controversial. Reinvestigation of several claimed examples shows them to be technical artifacts.^[6] Variation at the DNA-sequence level may be triggered by events such as wide hybridization. Yet the relative constancy seen in many species suggests that DNA amount may normally be subject to innate controls by counting mechanisms that detect and regulate genome size characters in tightly defined limits. If so, the mechanisms responsible are unknown.

GENOME SIZE EVOLUTION—MECHANISMS OF DNA GAIN AND LOSS

The existence of major differences in C-value raises questions concerning its origin and significance. Huge variation in genome size unrelated to organismal complexity was epitomised as “the C-value paradox” by Thomas in 1971. Such differences are now largely attributed to changes in the proportion of noncoding, repetitive DNA sequences (e.g., transposable elements) and the extent of genome duplication. The puzzle now is to understand the molecular mechanisms and evolutionary pressures that determine the amounts of repetitive DNA in species genomes and thus their genome sizes.^[7]

Evolutionary studies were long flawed by the lack of a rigorous phylogenetic framework, but new phylogenetic data recently facilitated meaningful comparisons. Superimposing genome size data onto a robust phylogenetic tree^[8] showed that ancestral angiosperms had small genomes (i.e., 1C ≤ 1.4 pg) that are retained in most extant taxa. Possession of large (≥ 14 pg) and very large (≥ 35 pg) genomes is a derived condition that arose independently at least six times during angiosperm evolution. A similar analysis for grasses suggested that plants may have a “one way ticket to genome obesity,”^[9] as only mechanisms capable of generating rapid genome expansion (such as transposable element amplification) were known. Perhaps plants with small genomes have effective mechanisms to suppress retrotransposition activity, whereas large genomes arose from the release of retrotransposition suppression. More recent studies have

Table 3 Minimum, maximum, and range (max./min.) of 1C DNA estimates in major groups of land plants and their representation in the Plant DNA C-values database

Group	Minimum (pg)	Maximum (pg)	Range	No. of species with C-values	No. of species recognized	Representation (%)
Bryophytes	0.17	2.05	12.1	171	c. 18,000	1.0
Pteridophytes	0.16	72.68	450	82	c. 9000	0.9
Gymnosperms	2.25	32.20	14.3	181	730	24.8
Angiosperms	c. 0.1	127.40	1274	3493	250,000	1.4

(From Ref. 2.)

begun to shed light on several mechanisms involving recombination that can bring about a decrease in genome size.^[10] These are poorly understood, but mounting evidence suggests that genome contraction is a widespread phenomenon operating more extensively than once recognised. Plant genome size is evolutionarily labile and the particular genome size of a plant species reflects the dynamic balance between the opposing evolutionary forces of expansion and contraction.^[11]

USES OF GENOME SIZE DATA

DNA C-values have many uses. C-value reference lists provided data for comparative studies at levels ranging from the biosphere to genome organization, and in diverse disciplines including phylogeny, ecology, genomics, cell biology, conservation, physiology, and development.^[12]

NUCLEOTYPIC EFFECTS

DNA affects the phenotype in two ways: first by its genic content, and second by the physical consequences of its

Table 4 The range of 1C DNA estimates in angiosperms

Species	Chromosome number (2n)	Ploidy level (x)	1C DNA Amount	
			(pg)	(Mb)
<i>Aesculus hippocastanum</i>	40	2	0.13	123
<i>Oryza sativa</i>	24	2	0.50	490
<i>Zea mays</i>	20	2	2.73	2670

mass and volume, independently of its encoded information (i.e., nucleotypic effects). Nuclear DNA amount shows strikingly close nucleotypic correlations with many widely different phenotypic and phenological characters at cell, tissue, and organismic levels, e.g., chromosome size, chloroplast number, pollen volume, duration of meiosis (Fig. 2), seed weight, and minimum generation time. Thus, C-value is a key factor in scaling the size and rate of development of living systems.

The closer the correlation, the more useful C-value data are as predictors. Interest in C-values as predictors extends to a broad range of ecological and environmental factors, including invasiveness, crop distribution and biomass, and predicting responses of vegetation to global warming or a nuclear winter.^[12]

CONCLUSION

Future work on plant DNA amounts offers exciting prospects. New C-value estimates for plant species will soon give complete representation for angiosperm families and for several island floras, and meaningful representation for African, Asian and South-American floras. The availability of genome sequences for several species and of databases linking species C-values with

environmental information will allow tests at sequence level of theories about molecular mechanisms responsible for DNA gain and loss, and of possible links between plant ecology, extinction rates, and genome size.

Genome Structure and Gene Content in Plant and Protist Mitochondrial DNAs

Michael W. Gray

Dalhousie University, Halifax, Canada

INTRODUCTION

Complete sequencing of mitochondrial DNA (mtDNA) has provided much information about the size, gene content, and architecture of this organellar genome. One of the striking features of mtDNA is its exceptional physical and organizational plasticity, which stands in marked contrast to its conserved genetic function (i.e., specification of a limited number of components of the mitochondrial electron transport and translation systems). This structural variability is especially pronounced within the plant and protist lineages of eukaryotes; at the same time, these two groups are distinguished in having a generally similar—and larger—gene content than either animal or fungal mtDNAs. Although we are beginning to unravel the pathways of mitochondrial genome restructuring, as yet we have gained only limited understanding of how (and particularly why) the mitochondrial genome has evolved so differently in the various eukaryotic lineages.

MITOCHONDRIAL GENOMES IN PROTISTS

Protists (protozoa and algae) are defined on the basis of exclusion: They are not animals, plants, or fungi. Most protists are single-celled, but multicellular groups do exist (e.g., among the red, brown, and green algae). To date, complete mitochondrial genome sequences have been published for more than 30 different protists (with at least 20 additional sequences in progress), covering a phylogenetically broad range.^[1] Protist mtDNAs include the most gene-poor (*Plasmodium falciparum*) and most gene-rich (*Reclinomonas americana*) mitochondrial genomes known (Table 1). Most protist mtDNA sequences assemble as single circular molecules, but linear protist mtDNAs are also found (e.g., in the ciliate protozoon, *Tetrahymena pyriformis*, and the green alga, *Chlamydomonas reinhardtii* (Table 1)).

Protist mitochondrial genomes divide roughly into two basic groups, which have been termed “ancestral” and “reduced derived.”^[2] Ancestral mtDNAs are those that

most closely resemble, in gene content and organization, the α -Proteobacteria-like genome from which contemporary mitochondrial genomes originated.^[3] Ancestral mitochondrial genomes are tightly packed, comprising mostly coding sequence. Compared to animal and fungal mtDNAs, they contain extra genes, especially ones specifying ribosomal proteins; they encode strikingly eubacterially like large subunit (LSU, 23S-like) and small subunit (SSU, 16S-like) rRNAs, as well as 5S rRNA; they carry a complete or almost complete set of tRNA genes whose tRNA products have conventional, bacterial-like secondary structures; with few exceptions, they are mostly intron-poor; they often display eubacterially like gene clusters (e.g., *rps* and *rpl* genes); and they use the standard genetic code for translation.

Ancestral mtDNAs are exemplified in Table 1 by *R. americana* and *Prototheca wickerhamii*, with the former protist (a jakobid flagellate) having the most eubacterially like mitochondrial genome yet described.^[4] While not the largest mtDNA in size (those of land plants are considerably larger; see below), *R. americana* mtDNA contains a greater number of genes of known function than any other mitochondrial genome, including some 18 protein-coding genes not previously found in any other characterized mtDNA.

Reduced derived mitochondrial genomes (such as those of *P. falciparum* and *C. reinhardtii*; Table 1) are characterized by extensive loss of genes (tRNA as well as protein-coding); loss of the 5S rRNA gene; aberrant rRNA and tRNA secondary structures; radical divergence in rDNA structure (in both *P. falciparum* and *C. reinhardtii*, the mitochondrial rRNA genes are fragmented into modules that are rearranged and dispersed throughout the genome); an accelerated rate of sequence divergence (in both protein-coding and rRNA genes); a highly biased codon usage, including complete absence of certain codons; and (often) a nonstandard genetic code. Mitochondrial genome reduction has proceeded to an extreme in *P. falciparum*. Not only is its mtDNA the smallest known (a mere 6000 bp), it encodes the fewest genes: only three protein-coding (*cob*, *cox1*, and *cox3*) and two rRNA (*rnl* and *rns*). In fact, with the exception of *cox3*, these genes are

Table 1 Genome size and form and gene content in protist and plant mitochondrial DNAs

^jA single ORF encodes both subunits 1 and 2 (*cox1* and *cox2*) of cytochrome *c* oxidase.

^kTranscripts of most *A. castellanii* mitochondrial tRNA genes (12 of 15) undergo substitutional editing at one or more of the first three positions of the acceptor stem.

^lGenome also encodes the RNA component (*mpB*) of a mitochondrial RNase P.

^mCircular-mapping genome, but biochemical data indicate a linear genome (see Ref. [6]).

ⁿGenome also contains a *nad7* pseudogene.

the only ones that are universally contained in all characterized mtDNAs. In a number of cases, tRNA genes are completely (e.g., *P. falciparum*) or almost completely (e.g., *C. reinhardtii*) absent from reduced derived mtDNAs, with nucleus-encoded tRNA species being imported into mitochondria to make up the deficit of tRNAs required for mitochondrial translation.

The division into ancestral and reduced derived groupings serves to emphasize that reduced derived genomes are (in an evolutionary sense) a degenerate form of mtDNA. However, the division into these two categories is not absolute. For example, the *A. castellanii* mitochondrial genome (Table 1), which has many of the characteristics of an ancestral mtDNA, also displays a few “degenerate” features, such as fusion of the *cox1* and *cox2* genes into a single ORF; use of TGA to specify an amino acid (tryptophan) rather than translation termination; and loss of many tRNA genes, with transcripts of most of the remaining ones undergoing a novel form of RNA editing. Likewise, the *Chondrus crispus* (a red algal) mitochondrial genome is mostly ancestral in character but has lost almost all of the ribosomal protein genes that are typically found in ancestral protist mtDNAs (Table 1).

MITOCHONDRIAL GENOMES IN PLANTS

Land plant mtDNA exemplifies a third type of mitochondrial genome organization, designated expanded ancestral.^[2] In this type, gene content approximates that of ancestral protist mtDNAs, a 5S rRNA gene is present, rRNA and tRNA secondary structures are conventional, and the standard genetic code is employed during mitochondrial translation (Table 1). However, the genome is large (180 to 2400 kb in different plants) and spacious, consisting mostly of noncoding sequence. Spacers are long, numerous repeats are present, and the genome contains many introns and intron ORFs.^[5]

Because the plant mitochondrial genome is so large, few complete sequences have been determined, although these do span the range from primitive bryophytes (e.g., *Marchantia polymorpha*) to advanced angiosperms (the dicots, *Arabidopsis thaliana* and *Beta vulgaris*, and the monocot, rice (*Oryza sativa*)).^[1] As well, partial sequences have been published for many other land plant mtDNAs. These data indicate that the expanded ancestral pattern must have emerged in the earliest stages of land plant evolution. Mapped and/or sequenced plant mtDNAs can be assembled into a “master circle” that contains all of the identified genes as well as various repeated sequences.^[5] Whether the master circle, a conceptual

model, is an accurate description of the physical state of the plant mitochondrial genome has been questioned by studies designed to examine the actual form of isolated plant mtDNA.^[6]

A hallmark of plant mtDNA is the presence of numerous repeated sequences that are recombinationally active; when such repeats are directly oriented in a circular chromosome, they promote the formation of subcircular products, each of which contains a portion of the master circle.^[5] At the sequence level, plant mtDNA is one of the most slowly evolving genomes known; in contrast, on an evolutionary timescale, it undergoes extraordinarily rapid rearrangement, undoubtedly facilitated by the genome’s high proportion of noncoding sequence.

Because it is mostly noncoding, plant mtDNA is likely predisposed to accept foreign DNA. Indeed, sequences evidently derived from both nuclear and chloroplast DNA have been found as part of the mitochondrial genome of many angiosperms;^[5] in some cases, the incorporated chloroplast DNA contributes functional tRNAs that supplement a limited set of mtDNA-encoded (“native”) tRNA species.^[7] Excluding mobile introns, sequences from nuclear or chloroplast genomes have not been found in the mitochondrial genome outside of the land plant lineage.

CONCLUSIONS

We may expect that further insights into the organization, function, and evolution of plant and protist mtDNAs will come from continued sequencing and comparative analysis of mitochondrial genomes from these two major eukaryotic groups. Particularly interesting is the question of how reduced derived and expanded ancestral forms of mtDNA arose from ancestral forms, and when these transitions occurred in various lineages. A case in point concerns streptophytes (land plants and charophyte algae) and chlorophytes (all other green algae), two monophyletic lineages of green plants that share a common ancestor to the exclusion of other eukaryotes. Although, as noted above, land plants exhibit the expanded ancestral type of mtDNA, primitive chlorophytes (prasinophytes) contain the ancestral mitochondrial genome type typical of many nongreen protists. At what point the evolutionary transition from compact to expanded genome occurred is a question that could readily be explored by judicious sequencing of mtDNA within additional primitive prasinophytes and within the charophyte algae. Comparative mitochondrial genome analysis will not only establish

pathways but may also suggest mechanisms by which mtDNA evolves.^[8,9]

Genomic Approaches to Understanding Plant Pathogenic Bacteria

João C. Setubal

Ana C. R. da Silva

Alellyx Applied Genomics, Campinas, São Paulo, Brazil

INTRODUCTION

Nowadays, a genomic approach to understanding any bacterium usually requires a detailed description of the organism's complete genome, which means the entire nucleotide sequence and a list of all potential genes and their known or predicted functions. In the case of pathogenic bacteria, we can then concentrate further study on the genes directly involved in or related to pathogenicity. This approach tries to relate the genome information to what is known about disease symptoms, ideally also including genomic data from host plants. The ultimate goal is to understand the molecular mechanisms of plant-pathogen interactions and their evolutionary history.

BACTERIAL GENOME SEQUENCING

In the whole genome approach, the aim is to determine the DNA sequence of all chromosomes and plasmids present in the organism. The process starts with purification of DNA from a pure culture of bacteria. Using the shotgun technique, bacterial DNA is randomly cut into small (between 1000 and 5000 base pairs (bp) long) pieces that are then ligated into plasmid vectors forming a genomic library of inserts. The sequence of both ends of each insert is determined (each end resulting in a read) by machines called automatic DNA sequencers, each of which is currently capable of delivering about 700 reads per day. Reads must then be assembled into a consensus sequence by computer programs. Because DNA fragmentation is never entirely random, and because of experimental errors as well as the presence of repetitive sequences in the genome, it is necessary to sequence as many as 10 times more base pairs in reads than are in the actual genome. This multiplicative factor is known as the genome coverage. Assembly is not yet an entirely automated process. A few genomic regions will require special care, and some gaps take much longer to close than others. Special software is used to determine the error probability, which can also be expressed as a quality value of each assembled base. The desired result is a gapless sequence with an estimated error of less than one base per 10,000 bp. The process of gap

closure and improvement of consensus base qualities is called finishing. Bacterial genomes vary from about one million to 10 million bp. With today's technology, and using just one sequencing machine, a five-million-bp genome can be completely sequenced, assembled, and finished in about six months by a team of about 10 people.

GENOME ANNOTATION

Once the sequence is available, it should be annotated. This means, at a minimum, finding the potential genes and assigning functions to them when possible. Most, if not all, of this is done in silico, that is, with the aid of computer programs (studied and developed in the field of bioinformatics^[1]). Function assignment relies extensively on sequence similarity. This means that we assign a function to a gene in a newly sequenced genome based on its similarity to already available gene sequences in sequence databases such as GenBank (<http://www.ncbi.nlm.nih.gov>). The most widely used similarity-detection tool is the BLAST program,^[2] although many others exist. After being given a new sequence (which can be in nucleotides or already translated into amino acids), BLAST will search a sequence database and possibly return "hits," that is, database sequences that have similarity to the given sequence above a statistical threshold. If the significant hits found by BLAST come from sequences for which a function has been assigned, then this function can be assigned to the new gene. Genes must then be classified according to their assigned function. Each genome project usually develops its own classification scheme, but most are based on one originally developed for *Escherichia coli* by M. Riley.^[3] For plant pathogenic bacteria, genome annotation requires special attention to genes associated with pathogenicity, and the classification scheme should include categories such as avirulence, hypersensitive response, exopolysaccharides, surface proteins, toxin production and detoxification, and host cell wall degradation. Genes related to flagellar and chemotaxis systems are also important for pathogenicity.^[4]

After function assignment, genome annotation can proceed to more specialized analyses. One of these is pathway

analysis, where an attempt is made to map the genes onto known gene networks. The best-studied of these networks are the metabolic pathways. This mapping can show that one or more pathways are missing or that certain pathways are almost complete, suggesting that the role of missing enzymes is played by genes not recognized as having that function. This can happen because up to 40% of the potential genes in most bacterial genomes do not resemble known genes and thus are not assigned a likely function.

More-sophisticated analyses are required to find genes that are associated with pathogenicity but that are not similar to known genes. One approach makes use of regulatory sequences that are present in the DNA region upstream of genes and that play a part in their transcription and regulation. It is known that in certain cases genes that play similar roles in an organism will have similar regulatory sequences even if the genes themselves are not similar to each other (but similarity of regulatory sequence does not always imply similar function). If the regulatory sequence, *R*, of certain pathogenicity genes is known, then one can search for additional co-regulated genes by searching for a sequence similar to *R*. The similarity may be subtle and may therefore require the use of sophisticated techniques such as hidden Markov models. On the other hand, the conservation of *R* may happen even across species, such that an *R* sequence identified in one organism can be used to help identify genes in the same family in another species.^[5]

Another approach to gain a deeper understanding of pathogenicity genes comes from careful and detailed comparison of the genomes of two or more related species. If both species are pathogenic, one may try to understand the similarities or differences they have in terms of symptoms or host range, or both, through the study of their shared or dissimilar genes. Such studies show the importance of having the complete genome of each organism so that conclusions about the absence of genes can be drawn more reliably. Complete genomes also make it possible to build gene/protein sequence databases. When including several organisms, such databases allow multiorganism comparisons that can yield important insights. For example, van Sluys et al.^[9] used this approach to obtain a list of genes shared by eight plant-associated bacteria; such genes are good candidates to be fundamental in plant-bacteria interactions. The inclusion of genomic information from plants (such as *Arabidopsis thaliana* and rice, whose genomes have been sequenced) in these databases will turn them into even more powerful resources.

The topic of horizontally transferred genes is also of particular relevance for pathogenicity studies.^[7] Genes are horizontally (or laterally) transferred when they enter the organism not through inheritance but through invasion by phages or mobile genetic elements. If such genes do not kill the organism but are instead kept in its genome, this

means that they confer some selective advantage. Lateral transfer between bacteria is well documented in the literature. One example is from Da Silva et al.,^[12] who present strong evidence that many pathogenicity genes found in *Xanthomonas axonopodis* pv. *citri* have been laterally transferred. Conversely, sometimes genes are lost because they no longer are important for the organism's survival, and their presence in a related species may suggest their continued importance in the environment of the other organism.

FUNCTIONAL STUDIES

Genome annotation forms the foundation for follow-up functional analyses in the laboratory, which will confirm or refute the hypothesis raised in silico. One technique is targeted gene disruption or knock out. This is commonly done using a special plasmid vector that does not replicate inside the bacteria under study and which has been engineered to carry part of the gene to be knocked out. After insertion of the vector, which also carries an antibiotic resistance gene, into the bacteria, it will either insert into the genome by homologous, site-specific recombination or be lost. Selection of bacteria for those expressing the vector-encoded antibiotic resistance yields cells with the vector inserted into the target gene.

Another laboratory technique is the gene expression microarray. A DNA microarray (a gene chip) is made by depositing short DNA sequences of many or all genes from a genome on a glass slide in high densities (more than 2000 spots in 2 cm²). Similar to the traditional Northern blot technique, microarrays are probed with labeled mRNA from cells so that it hybridizes to immobilized, homologous target DNAs. If the RNA was labeled with a fluorescent tag, then the intensity of fluorescence in each spot is proportional to the amount of RNA retained by the target DNA. When RNA has been isolated from bacteria exposed to two different environmental or cultural conditions, the preparations can be labeled with different fluorescent tags. Hybridization of these probes to identical microarrays, followed by suitable image and data processing, reveals genes that are differentially expressed under those conditions.

CONCLUSION

As of this writing, five plant-pathogen bacterial genomes have been completed and published:

- *Xylella fastidiosa*, strain 9a5c^[10]
- *Agrobacterium tumefaciens* C58^[6,11]
- *Ralstonia solanacearum*^[8]

- *Xanthomonas axonopodis* pv. *citri*^[12]
- *Xanthomonas campestris* pv. *campestris*^[12]

These projects have yielded a wealth of genomic information and have placed phytopathology at a new level. For a detailed review of these projects, see Van Sluys et al.^[9] No concrete and effective new ways to deal with the diseases caused by the plant pathogens have yet resulted from these projects. However, most researchers have no doubt that these genomic approaches will eventually yield disease management benefits. This may still take a great deal of time and effort; genomics is only the first step.

Genomic Imprinting in Plants

Daphné Autran

Jean-Philippe Vielle-Calzada

CINVESTAV—Unidad Irapuato, Irapuato, Mexico

INTRODUCTION

The differentiation and fusion of male and female gametes to initiate the formation of a new organism is a common feature in the life cycle of higher eukaryotes. In the ovule of flowering plants, the embryo develops following fertilization of the haploid egg cell by one of the sperm cells delivered by the pollen tube, giving rise to a diploid zygote. A second sperm cell fuses with the binucleated (homodiploid) central cell to give rise to the triploid endosperm having a 2:1 maternal to paternal genomic ratio. The embryo and the endosperm, each with different ploidy and parental gene dosage, coordinately develop inside diploid maternal tissues.

Plant gametes carry distinct haploid genetic constitutions that are usually considered to be functionally equivalent, both contributing active alleles that will influence the phenotype of the newly formed individual. For some traits, the activity of an allele is influenced by the parent from which it came. Parent-of-origin effects can be the consequence of differences in transcription between paternally and maternally inherited genes in the embryo and/or the endosperm. Genomic imprinting refers to a specific type of genetic regulation resulting from a mitotically stable epigenetic modification that consistently inactivates one of the parental alleles. Loci that are regulated by genomic imprinting will be differentially expressed in a parent-of-origin dependent manner. If a gene is controlled by genomic imprinting, transcription occurs exclusively from one of the two parental gene copies. Hence, imprinted genes are inherited in a silent state from one of the two parents, and in a fully active form from the other. Genomic imprinting results in a functional nonequivalence of parental genomes during embryogenesis and/or endosperm development. Due to particular features of the plant life cycle, it is often difficult to distinguish between the effects of maternal factors and the consequences of genomic imprinting on the regulation of a specific locus. A maternal effect refers strictly to a genetic definition: Any reciprocal cross resulting in differential phenotypes that are exclusively determined by the genotype of the female parent (or the

megagametophyte) is the consequence of a maternal effect. This broad type of parent-of-origin effect can result from the action of imprinted genes, but also from: 1) gene products that are stored in the cytoplasm of the egg cell; 2) dosage-sensitive genes acting in the embryo and/or the endosperm; or 3) products encoded by the genome of maternally inherited organelles. Maternal effects caused by cytoplasmic protein storage and genomic imprinting are clearly distinguishable if transcripts are present only prior to fertilization but not after (perdurance, implying a maternal effect *sensu stricto*) or if transcripts are present only after fertilization but not before (imprinting).

SEED DEVELOPMENT AND GENOMIC IMPRINTING

Whereas genomic imprinting has been extensively studied in mammals and insects, the first demonstration of a gene regulated by genomic imprinting was obtained for the *r1* locus in maize.^[1] Subsequently, pioneering studies by Lin^[2] and Kermicle used exceptional mutants in maize to manipulate genome dosage in the endosperm. In the *indeterminate gametophyte (ig)* mutant, several haploid nuclei fuse in the central cell, generating an endosperm of variable ploidy. By conducting reciprocal crosses involving genotypes with different ploidy levels, they showed that deviations from the normal 2:1 maternal to paternal genome ratio in the fertilized central cell resulted in an aborted endosperm. They inferred that the parental origin of each of the genomic contributions is crucial for normal endosperm formation. Similar conclusions were obtained from lines carrying chromosomal translocations in maize: Deletions of particular regions of a specific chromosome that were paternally inherited lead to a significant reduction in endosperm growth. The defects are not rescued by providing an additional maternal copy of the translocated region.^[3] These important results allowed dosage-dependent effects to be distinguished from the occurrence of genomic imprinting during endosperm development.

The FIS Class of Genes Is Regulated by Genomic Imprinting in *Arabidopsis*

More recently, direct evidence of genomic imprinting has been obtained for a handful of genes.^[4] Whereas in maize several genes are differentially expressed in a parent-of-origin-dependent manner, only members of the *FERTILIZATION-INDEPENDENT SEED* class of genes (*FIS*) have been shown to be regulated by genomic imprinting in *Arabidopsis*. These three *Arabidopsis* genes were identified on the basis of their gametophytic maternal effect mutant phenotype, which causes seed abortion, and by their ability to initiate endosperm formation in the absence of fertilization.^[5] Female gametophytes of *medea* (*mea*), *fertilization independent endosperm* (*fie*), and *fis2* give rise to abnormal seeds irrespective of the paternal genomic contribution. The embryo and/or endosperm of *fis* mutants show an increase in cell number, suggesting that the primary role of the *FIS* genes is to restrict cell proliferation. Consistent with this role, *MEA* and *FIE* encode Polycomb group proteins (PcG). In *Drosophila*, these proteins are known to form repressor complexes that regulate higher-order chromatin structure during animal development. The phenotypes shown by *mea* and *fie* suggest that their function is conserved in flowering plants. The *Arabidopsis FIS2* gene encodes a Zn-finger protein implicated in the formation of the PcG complex.^[6] All *FIS* genes are expressed during female gametophyte development prior to fertilization; *MEA* and *FIE* are coexpressed in the embryo and the chalazal domain of the free nuclear endosperm, whereas expression of *FIS2* could only be detected during the early stages of endosperm development. A combination of in situ hybridization and reverse-transcriptase polymerase chain reaction (RT-PCR) experiments provided the evidence that following fertilization *MEA* is only transcribed from maternally inherited copies in both the developing embryo and the endosperm, demonstrating that the gene is regulated by genomic imprinting.^[7] Similar approaches were used to show that *fie* and *fis2* are also imprinted.^[8]

Genomewide Mechanism of Paternal Imprinting in *Arabidopsis*

Because plant embryos can develop from somatic cells or microspores, it was generally considered that the maternal contribution is not crucial for embryogenesis. Recent studies in *Arabidopsis* suggest that early embryo development is mainly under maternal control due to a combination of maternal products deposited in the female gametophyte and a genomewide mechanism of paternal imprinting.^[9] Using reciprocal crosses to wild-type, more than 20 genes detected by gene trap approaches were shown to be expressed only when maternally inherited

Fig. 1 Silencing of paternally inherited gene activity during seed development in *Arabidopsis*. (A) When an enhancer detector is used as a female parent in crosses to wild-type, reporter gene expression can be detected in the developing embryo and endosperm of F1 seeds 50 hours after pollination (HAP). (B) When the same enhancer detector is used as the male parent in crosses to wild-type, reporter gene expression is absent from the embryo and the endosperm 50 HAP. (Figure courtesy of Gerardo Acosta-García.) (View this art in color at www.dekker.com.)

(Fig. 1). Analysis of gene expression using allele-specific RT-PCR demonstrated that the absence of transcription resulted from the silent state of the endogenous genes and not from the inactivation of the reporter gene present in the gene trap transgenic construct. All of these genes are randomly distributed across the *Arabidopsis* genome and encode a wide range of proteins, showing that the observed paternal silencing is not limited to a specific genomic region or a particular developmental mechanism. For some of these genes the activation of the paternal genome occurred 96 hours following fertilization, i.e., at the midglobular stage of embryo development. The correlation between allele-specific silencing and genetic activity was demonstrated by analyzing early embryonic defects in *emb30*, a recessive embryo-lethal mutant defective in the first zygotic division of *Arabidopsis*. Heterozygous *emb30/EMB30* embryos that inherited a wild-type allele from the male parent did show a mutant phenotype, confirming that early defects cannot be rescued by an active paternal *EMB30* allele. The degree of inactivation and the timing of initiation of paternal transcription may vary from gene to gene.^[10] Additional experiments have suggested that some specific genes or their regulatory elements escape this genomewide mechanism of paternal silencing and are active early following fertilization. Baroux et al.^[11] showed that embryo abortion can be induced as early as the 2- to 4-cell stage using a transactivation system that depends on the transmission of the elicitor through male gametes. These results suggest that either some regulatory elements can escape paternal

imprinting (in this case, the cyclin B1 promoter and the heterologous pOp promoter), or that the activity of the paternal genome is not completely abolished but rather attenuated by a very low level of transcription during early seed development.

THE REGULATION OF GENOMIC IMPRINTING

Based on the existing evidence, it currently appears that two distinct classes of imprinting mechanisms regulate seed development in flowering plants.^[12] A delayed activation of the paternal genome indicates that a wide mechanism of imprinting ensures that both parental genomes are not functionally equivalent following fertilization. In addition, specific loci such as members of the *FIS* class of genes could be imprinted until later stages of seed development, as has been shown for *MEA*. In both cases the evidence implies that a mechanism of allele-specific inactivation must be established during gametogenesis. Maintenance of the resulting imprint must be ensured through successive haploid mitotic cycles and finally lost in diploid cells at some stage of sporophytic development before being reestablished in the germline.

Despite extensive research in mammals, the regulation of genomic imprinting is far from understood. To date, the most common mechanism associated with the regulation of genomic imprinting in plants is DNA methylation. In animals, there is a correlation between methylation (epigenetic modification of CpG to 5-methyl-CpG) and the imprinted status of most of the genes described. In *Arabidopsis*, reciprocal crosses of transgenic *methyltransferase 1* antisense (*met1a/s*) to wild-type diploids produced seeds with defects similar to those observed in interploidy crosses. For example, hypomethylated females crossed to wild-type males gave rise to paternalized seeds containing a large endosperm and embryo. The reciprocal cross leads to the opposite effect. Moreover, mutations in the *FIS* genes can be rescued by reducing global methylation levels by either *met1a/s*^[6] or *ddm1* pollen.^[7] DDM1 is a member of the SWI/SNF family of ATP-dependent chromatin remodeling enzymes, and *ddm1* mutations reduce genomic methylation by 70%.^[13] In most cases, rescue of the embryo or the endosperm occurs even if the paternal genome carries a *fis* mutant allele, suggesting that unknown genes can substitute for *FIS* function in early seed development, and that *FIS* paternal alleles remain silent even in a hypomethylated context, implying that their regulation most likely involves additional mechanisms yet to be discovered. Additional epigenetic mechanisms involving chromatin remodelling, histone modification, or specific methylation could ensure the imprinted memory necessary for the occurrence of

mitotically stable reversible changes in gene expression.^[5] The fact that *FIS* genes encode chromatin remodelling factors and are regulated by genomic imprinting suggest that their target genes, involved in the regulation of seed development, are probably also imprinted. Interestingly, DEMETER (DME)—a DNA glycosylase with nuclear localization domains—has been shown to be required for the expression of the *MEA* maternal transcript in the developing endosperm.^[14] DME is preferentially expressed in the developing endosperm, and homozygous *dme* plants show a maternal effect, suggesting that DEMETER could also be imprinted.

CONCLUSION

How did genomic imprinting evolve? Haig and Westoby^[15] proposed that parent-of-origin specific effects evolved as a consequence of an intragenomic conflict over the allocation of nutrients from the mother to its offspring. This theory predicts that paternal interests favor selfish fitness for their own offspring, and not the fitness of full siblings from a distinct father. Therefore, paternally expressed genes would tend to promote the growth of the embryo. In contrast, maternal interests favor survival of all siblings irrespective of their paternal origin. Maternally expressed genes would tend to optimize overall survival by reducing the size of the embryo. The role of genomic imprinting in regulating parental interests may have been conserved in organisms that have acquired placental habits. Supporting evidence has been provided by studies of imprinted genes in mice and humans, but also in plants. Most imprinted genes identified in mammals fit the parental conflict theory. In flowering plants, the manipulation of gene dosage in the endosperm and the embryo of maize and *Arabidopsis* has shown that increasing paternal dosage promotes growth of the endosperm, whereas an increase in the maternal dosage reduces its size. In *Arabidopsis*, disruption of *MEA* leads to overproliferation of embryonic cells, albeit embryos arrested at an earlier stage than wild-type. In contrast to mammals, genes exclusively transcribed from the paternally inherited copy have yet to be discovered in flowering plants.

Although parental conflicts at the gene level are just starting to be investigated in flowering plants, the elucidation of the genetic basis and molecular mechanisms regulating a genomewide paternal silencing during early seed development has yet to be initiated. The synchronous evolution of parent-of-origin effects in mammals and flowering plants could be closely related to their sexual habits. In that regard, the investigation of imprinting in apomictic plants, in combination with the fast emergence of genomic technology, should provide important clues to determine the number of genes that are regulated by

genomic imprinting and their overall impact on plant growth and development.

Genomics of Fungal Plant Pathogens

Brett M. Tyler

Virginia Bioinformatics Institute and Department of Plant Pathology, Physiology and Weed Science, Virginia Polytechnic Institute and State University, Blacksburg, Virginia, U.S.A.

INTRODUCTION

Organisms historically called plant pathogenic fungi include two distinct lineages of organisms, those in the kingdom Mycota (true fungi) and those in the kingdom Stramenopila (oomycetes).^[1] Both groups of plant pathogens are heterotrophic, grow as multinuclear filaments and/or as single cells, and have evolved the ability to neutralize the defense responses of their plant hosts.^[1] The advent of genomics has transformed the molecular biology of fungal plant pathogens from a focus on individual genes and their contributions to infection to the contributions of large gene networks. Highlights of what genomic studies have revealed include the presence of large, rapidly evolving multi-gene families encoding proteins and metabolic pathways that potentially contribute to infection, the presence of extensive redundancy of function among these genes, and the extensive remodeling of pathogen metabolism during infection.

PLANT DEFENSE AND PATHOGEN ATTACK

Plants are largely resistant to infection by microbes as a result of well-developed defenses.^[2] Constitutive defenses include physical and chemical barriers. Defense responses induced by infection include production of reactive oxygen species, small-molecular-weight antimicrobial phytoalexins, hydrolytic enzymes and other antimicrobial proteins called Pathogenesis-Related (PR) proteins, and a form of programmed cell death called the hypersensitive response. Plant pathogens, including fungi and oomycetes, have evolved mechanisms to succeed in the face of host defenses.^[2] They must penetrate or circumvent physical barriers. They must either avoid or suppress the triggering of inducible defense responses. They must protect themselves against constitutive defense mechanisms and against defense responses they cannot avoid inducing. Finally, once established inside the plant host, the pathogens must adapt to the nutritional environment of the tissue sufficiently well to reproduce. These mechanisms determine the pathogenicity and virulence of the pathogen; in plant pathology, “pathogenicity” refers to the fundamental ability to infect the plant

while “virulence” refers to the amounts of disease caused, although in practice there is considerable overlap in the two concepts. A detailed understanding of the mechanisms of pathogenicity and virulence in plant pathogens will provide the basis for new and effective means for controlling plant disease.

Genetics and molecular biology have been used to identify many individual genes that contribute to pathogenicity and virulence. Examples include genes encoding enzymes that degrade plant defense compounds such as reactive oxygen species, phytoalexins or phytoanticipins, genes for inhibitors of plant hydrolytic enzymes, and genes for transporters that remove toxic plant metabolites. Further examples include genes specifying toxins, genes encoding enzymes that degrade plant physical barriers, and genes required for elaboration of morphological structures required for invasion of plant tissue such as appressoria and dikaryons.^[3] These studies have also characterized genes known historically but inaccurately as “avirulence genes.”^[4] These genes encode proteins that either directly or indirectly interact with plant defense receptors encoded by major resistance genes. Deletion or loss of expression of avirulence genes can enable fungal and oomycete pathogens to expand their host range to plants containing major resistance genes. The benefit to the pathogen of avirulence genes is best understood in bacterial pathogens, where these genes have been shown to encode effector proteins that can enter the plant cell to increase the susceptibility of plant tissue to infection;^[4] it is presumed that the function of many fungal and oomycete avirulence genes is similar, because some products of those genes appear to interact with plant defense receptors that have an intracellular location.^[1] Some fungal avirulence genes encode extracellular proteins that are toxins or can inhibit plant hydrolytic enzymes.^[1] The advent of genomics and bioinformatics techniques for rapidly characterizing very large numbers of genes has made it possible to examine the roles of all these genes, or genes like them, in an integrated fashion within the genome of a single pathogen.^[3,5] The interaction between a pathogen and its plant host clearly involves the interplay of a very large number of genes, many of which may have redundant, overlapping, and/or interconnected functions. Genomics and bioinformatics now make it

possible to investigate the interaction of fungal and oomycete pathogens with plants at a whole genome to whole genome level. The contributions of genes that have individually identifiable functions and those that do not now can be jointly characterized.

DNA SEQUENCING OF FUNGAL AND OOMYCETE GENOMES

High throughput DNA sequencing of mRNA or chromosomal DNA provides a way of rapidly creating an inventory of large number of pathogen genes and predicting their functions.

Expressed Sequence Tags

Expressed Sequence Tags (ESTs) are created by DNA sequencing of cDNA clones copied from mRNA from tissues of interest such as hyphae or spores. Generally, each randomly chosen clone is sequenced just once, from the end corresponding to the 5' end of the mRNA. ESTs thus provide information about genes transcribed into mRNA in specific tissues. The frequency with which ESTs are obtained from a given gene can also provide a semiquantitative measure of the levels of expression of that gene in the tissue. EST collections can also be obtained from an infection site containing a mixture of plant and pathogen tissue; in this case the plant or pathogen origins of the EST sequences can be identified bioinformatically. The limitations of ESTs are that an EST usually contains only a fragment of the corresponding gene sequence, and many gene sequences are absent from EST collections because the mRNA levels of those genes are very low in the tissues from which the cDNA libraries were made.

Despite their limitations, the cost effectiveness of EST sequencing has led to EST collections being developed for a wide range of fungal and oomycete plant pathogens.^[5,6] As of July 2005, National Center for Biological Information (NCBI's) dbEST database contained more than 100 ESTs for each of 27 species of fungal plant pathogens and 5 species of oomycete plant pathogens. Many of these ESTs are also available at the COGEME Phytopathogenic Fungi and Oomycete EST Database (<http://cogeme.ex.ac.uk/>).^[6]

Genome Sequencing

A more costly, but much more complete approach to cataloging the genes present in a species is to sequence the entire genome. The genome sizes of fungal plant

pathogens range from 9 to 70 Mb, while those of oomycete plant pathogens range from 25 to 240 Mb. The cost of DNA sequencing has rapidly dropped as automation and new technologies have been developed, making it increasingly feasible to determine the genome sequences of these relatively small genome sizes (compared to human 3000 Mb). Draft genome sequences, produced by randomly sequencing fragments of genomic DNA of defined sizes, are particularly inexpensive. Table 1 lists fungal and oomycete plant pathogens for which a draft or finished genome sequence is either available, or currently being completed.

Comparative Sequencing

Comparisons of the genome sequences of closely related species can provide valuable information about which genes are highly conserved and which are rapidly evolving, for example, in response to selection pressure from the plant host. Comparisons of the sequences of *P. sojae* and *P. ramorum* have been especially useful in this respect.^[7] Comparisons of the genome sequences of *A. gossypii*^[8] and *M. grisea*^[9] with their non-pathogenic relatives *Saccharomyces cerevisiae* and *Neurospora crassa*, respectively, have also been useful. As the cost of sequencing continues to fall, and with the advent of dramatically faster and cheaper technologies such as pyrosequencing, extensive comparative sequencing will likely become more and more feasible.

FUNCTIONAL GENOMICS OF FUNGAL AND OOMYCETE PLANT PATHOGENS

Functional genomics refers to high throughput experimental methods to determine the functions of genes identified from ESTs and genome sequences. Broadly, these methods fall into two categories: high throughput measurements of the levels of cellular components such as mRNA (transcriptomics), and high throughput generation of mutations that destroy or inhibit the functions of genes identified in genome sequence.

Transcriptomics

Microarray analysis is the most widely used method for high throughput measurement of mRNA levels in fungal and oomycete plant pathogens.^[10] Microarrays consist of hundreds or thousands of DNA probes attached to a solid support. Fluorescently labeled cDNA or cRNA derived from the mRNA of interest

is then hybridized to the microarray, and the intensity of hybridization is measured for each probe. Transcriptional profiles provide valuable information about when and in what tissues genes are expressed, e.g., in spores or during early or late infection. Thus they can provide information about possible functions even when there is extensive redundancy of function. The most common forms of arrays are cDNA arrays in which amplified cDNA fragments are attached to glass slides, “long-oligo” arrays in which synthetic oligonucleotides 50–70 nucleotides in length are attached to glass slides, or AffymetrixTM GeneChipsTM in which oligonucleotides of 25 nt in length are synthesized in situ on silicon chips. cDNA arrays have been created for *A. flavus*, *Blumeria graminis*, *Cryphonectria parasitica*, *F. graminearum*, *F. verticillioides*, *M. graminicola*, *S. sclerotiorum*, *Verticillium dahliae*, and *P. sojae*, long-oligo arrays have been created for *M. grisea*, and GeneChips have been created for *P. sojae*, *P. infestans*, *F. graminearum*, and *U. maydis*.

Mutational Analysis (Reverse Genetics)

Transformation of plant pathogenic fungi with exogenous DNA can be used to generate large collections of mutants in genes of known sequence. In species where incoming exogenous DNA integrates by homologous recombination at high frequency, deletions or gene replacements can be targeted to specific genes; this approach has been used in a high throughput manner in *A. gossypii*,^[11] *Cochliobolus heterostrophus*,^[3] and *U. maydis*.^[12] In species where integration by heterologous recombination occurs, genes in the chromosomes can be disrupted by insertion of the incoming DNA, and the site can be later characterized by sequencing the boundaries of the insertion. *Agrobacterium*-mediated transformation and restriction-enzyme mediated insertion have been particularly effective for this, and both have been used extensively in *M. grisea*.^[13] Alternatives to gene disruption strategies include gene silencing and TILLing.^[14] Gene silencing

has been used to test the functions of individual genes in fungi and oomycetes,^[1] and TILLing has been used extensively in plants,^[14] but neither approach has yet been implemented at a high throughput level in plant pathogenic fungi or oomycetes.

Forced Expression

Because many genes in a complex interaction such as that between a plant and pathogen may have overlapping or redundant functions, disruption or silencing of an individual gene may not be informative as to its role. An alternative approach is to force the expression and/or overexpress a gene so that its contribution becomes exaggerated to the point that it can be characterized. The roles of some individual genes have been characterized by making transgenic pathogen strains overexpressing a gene. However, technologies for doing this on a high throughput scale are still under development. An alternative approach is to overexpress pathogen genes in the host plant and then measure changes in resistance or susceptibility. This approach has been used very effectively on a high throughput scale in *P. infestans*, using a plant virus vector.^[15]

INFERENCES FROM GENOMICS STUDIES

Although relatively few fungal or oomycete genome sequences have yet been analyzed, several themes have emerged from those that have been analyzed. The most prominent theme is the extensive diversification of gene families associated with pathogenicity and virulence in these genomes. For example, in *M. grisea*, extended gene families were identified with similarity to the known *M. grisea* pathogenicity gene PTH11, which encodes a novel seven transmembrane-spanning-domain protein, to biosynthetic genes for polyketide and non-ribosomal peptide toxins, and to the *Cladosporium fulvum* *Avr4* gene, which encodes a chitin-binding protein.^[9] In *P. sojae* and *P. ramorum*, extended gene families were identified with similarity to genes encoding protein toxins and proteinase inhibitors, to *P. sojae* avirulence gene *Avr1b-1*, and to genes encoding ABC transporters.^[7]

CONCLUSIONS

Genomic approaches are changing our understanding of plant–pathogen interactions, enabling them to be studied as an interaction between large networks of

genes in each organism. Increased sequencing of genomes, cheaper and more powerful functional genomics technologies including proteomics and metabolomics, and increased sophistication in methods for bioinformatic analysis and mathematical modeling of genetic interactions will dramatically accelerate this revolution over the next 10 years.

ACKNOWLEDGMENT

Germplasm Acquisition

David M. Spooner

University of Wisconsin, Madison, Wisconsin, U.S.A.

Karen A. Williams

USDA, Beltsville, Maryland, U.S.A.

INTRODUCTION

Plant genetic resources—varying from wild relatives of crops to farmers' varieties—form the raw materials of crop improvement programs. They have proven economic value to improve a wide range of traits, ranging from disease and pest resistances to improved yields and improved agronomic traits, and are critical to global food security. Their importance has long been recognized, and many national and international institutes have been set up to acquire, increase, store, distribute, and use them for crop improvement. This article briefly reviews the steps involved in the acquisition of germplasm, from the planning and conduct through the follow-up stages of germplasm collecting expeditions.

WHY COLLECT GERmplasm?

Genetic resources, including landraces (farmer varieties) and wild relatives of our crops, are crucial to global food security. These resources are distributed worldwide, but with a concentration of diversity south of the tropic of Cancer (Fig. 1). The size and distribution of economic gains from yield increases in the major U.S. crops attributable to genetic improvements is impressive. Farmers have benefited from a 1% yield increase per year, half of this due to genetic improvements. Based on these assumptions, a one-time permanent estimation of the worldwide value to consumers of germplasm, as assessed by reduced food prices, is between \$8.1 billion and \$15.4 billion.^[1] Although the United States enjoys 50–60% of these benefits, consumers in developing and transitional economies enjoy between \$6.1 and \$11.6 billion of the benefits. Whereas the ultimate goal of germplasm acquisition is crop improvement, a major subsidiary benefit is the availability of these collections for characterization studies (e.g., taxonomic studies) to aid breeders.

Germplasm may be acquired either by exploration or from existing germplasm collections. Exploration is a means of obtaining germplasm that does not exist in ex

situ collections. For the major crops, relatively good coverage exists in some national programs and in the International Agricultural Research Centers (IARCs) of the Consultative Group on International Research (CGIAR). Examples are the International Rice Research Institute (IRRI) in the Philippines and the International Maize and Wheat Improvement Center (CIMMYT) in Mexico.^[2,3] However, collecting needs remain, even in the major crops; and many minor orphan crops have major collecting needs.

HISTORY OF PLANT COLLECTING

Germplasm acquisition has a long history, with records of exchanges between cultures dating back thousands of years. International germplasm collecting expeditions in the 16th and 17th centuries were largely focused on exotic foods and ornamentals for botanic and university gardens. The Royal Botanic Gardens at Kew, England, established a widespread network of botanic gardens, resulting in the movement of enormous numbers of samples worldwide. Botanic gardens published new collections in seed lists that facilitated free worldwide exchanges of germplasm. The number of introductions brought into cultivation by botanic gardens exceeded 80,000.^[4]

Private industry and gardening societies also collected, maintained, and exchanged germplasm, as did state and federal agencies. The early 19th century saw the development of major national collections, such as the All-Union Institute of Plant Introduction in St. Petersburg, Russia, later renamed the N.I. Vavilov All-Union Scientific Research Institute of Plant Industry (VIR). This institute, initiated by Nicolay Vavilov, sponsored collections worldwide and established an extensive system of national institutes to maintain, characterize, and use them. The U.S. Department of Agriculture (USDA) plant exploration program began formally in 1898 with the creation of the Section of Seed and Plant Introduction that evolved into an organized U.S. National Plant Germplasm System (NPGS). From 1898 to 2001, the USDA conducted 540 explorations, 80% to foreign countries.

Fig. 1 Regions of diversity of major cultivated plants. (Figure from Ref. 2. Used with permission of the United Nations Food and Agriculture Organization.)

Explorations were made in every year except the war years, 1942–1945. Today the NPGS is the largest national germplasm system in the world, with 450,000 samples covering more than 10,000 species.^[5] At least a quarter of the yearly distributions made by the NPGS are to scientists outside the U.S. National genetic resources programs are established in many other countries, and over six million collections are estimated to occur in ex situ genebanks worldwide.^[2] In the future, the International Treaty on Plant Genetic Resources for Food and Agriculture (IT) will govern access to germplasm for Plant Genetic Resources for Food and Agriculture, which has been agreed to by country members of FAO and will enter into force upon ratification by the required number of countries. The implementation of the Treaty will determine the future ease of access.

ACCESS

In the initial stage of germplasm collecting, and continuing through the 1960s and 1970s, most germplasm was generally freely available. Exchange of plant genetic resources is now the subject of the IT, which was adopted by

the FAO Commission on Plant Genetic Resources in November, 2001, and will become international law once it is ratified by 40 countries. The treaty establishes a multilateral system for the exchange of key crops and forage species. National laws of countries that are parties to the IT must be adjusted to conform. In some countries, national genetic resources programs are not yet established or their regulations have not yet been implemented. In others, access (including that required for plant exploration) has already been subject to new regulations. In order to address developing countries' concerns regarding benefit sharing, which is required by the new treaty, some developed nations are exploring the association of increased nonmonetary benefits, such as student training; the transfer of equipment, information; and technology; and other collaborative exchanges, with agreements on access.^[6]

PLANNING AN EXPEDITION

Extensive background work is critical to the success of germplasm explorations, beginning with the definition of

goals. Most explorations are initially intended to fill in gaps in current collections, as determined by taxonomic, ecological, or geographic criteria. Thus, an exhaustive search of available collections (national genebanks, international genebanks, and individual research collections) should be made before an exploration is contemplated. Some apparently available germplasm is not accessible because it is not increased, is diseased, or is otherwise restricted. Sometimes, discordant taxonomies of the same group make the task of comparing all sources of information difficult because of competing names and classifications (see an example in wheat at <http://wheat.pw.usda.gov/ggpages/DEM/9IWGS/taxonomy.html> and potato).^[3] Searching for germplasm currently available in genebanks is simplified by the on-line availability of the germplasm in the genebanks of the CGIAR (<http://www.singer.cgiar.org/>) and the U.S. NPGS (<http://www.ars-grin.gov/npgs/>), but germplasm holdings of many smaller genebanks require direct correspondence with managers. The determination of all germplasm collections available is facilitated by indices of common collections held in common among genebanks,^[7] although such indices are rare. Monographs (treatment of a particular group) and floras (treatment of all plants in a particular region) provide locality data, as well as identify regional herbaria. (An index of herbaria, *Index Herbariorum*, is available at <http://www.nybg.org/bsci/ih/ih.html>.)

Once the goals of an exploration have been identified, successful planning involves attention to access agreements, identifying and establishing contacts with knowledgeable in-country field collaborators, timing, logistics, and field equipment.^[4,8,9] The new political climate can make access agreements difficult to obtain, and planning must begin well in advance. Agreements with host countries should clearly state details of the collection, export, increase, intended use, and distribution of germplasm. An experienced collaborator—ideally one who knows the logistics, culture, and crop—is essential. Timing of the expedition is crucial, especially for highly seasonable species for which differences in rainfall the prior or current year can drastically affect the growth of plants in a given year and the availability of germplasm. Germplasm collecting expeditions are expensive and time-consuming. Logistical challenges of some areas are often daunting, and investments in reliable equipment, especially vehicles, pay off. Field equipment needs vary according to the crop and terrain, but a geographic positioning system (GPS—determines latitude and longitude), altimeter (in mountainous areas), and maps are essential for reliable locality data. Some maps can be obtained only in country. Time must be allotted at the beginning of the exploration to purchase maps, visit herbaria, and meet local officials.

CONDUCTING THE EXPEDITION

Important considerations in the field include number of sites to visit, number of plants to sample, sampling techniques, and the number and type of propagules to sample from each plant.^[4] These differ among species with different breeding systems and dispersal mechanisms. The number of collecting sites must be planned to maximize the amount of genetic variation sampled, within the constraints of time and funding. Marshall and Brown and others^[4] proposed mathematical formulas for these that are useful when germplasm is common, as when collecting landraces. For many crops, populations are often so scarce that these theoretical calculations give way to the practicality of collecting sufficient germplasm of all populations encountered to ensure a successful germplasm increase, taking care to maintain populations intact in the wild. Collecting methodologies depend on a number of factors, including the biology of the targeted taxon and the objectives of the expedition. Different types of propagules, whether seed or vegetative, require different sampling and handling techniques in the field.

Local markets provide a relatively easy means of collecting landraces for many crops, and are important sources of information on the diversity of a crop in a given area. However, visits to local farmers provide better information on plant characteristics, uses, and cultural methods; higher quality germplasm; and varieties grown only for home consumption. Visiting farmers of different ethnicity is as important as visiting different ecogeographic regions.

Minimal data to be recorded when collecting germplasm should describe country, lower-level administrative units, locality, latitude, longitude, altitude, collector number, type of material (seed, vegetative, pollen, in vitro material), improvement status (wild, weedy, landrace), abundance, morphological description of the accession, and habitat. Additional data that may be collected include slope, aspect, landform, and various descriptors for soil, drainage, and vegetation. Such basic data collected in the field have been referred to as passport data (as used elsewhere in this volume). The more data collected the better, but the need for data must be balanced with time constraints and the need to visit additional sites. Some descriptors applying only to landraces include farmer name, cultural methods used by farmers, length and time of growing season, history of landrace, and traits perceived by the farmer and other users. Herbarium vouchers are also needed to document the collection, with enough duplicates to ensure that sets are left in the country and others left in recognized institutions upon return home. Collections ultimately are studied by a wide array of broadly defined prebreeding studies to guide the

breeders in their use, as taxonomy, diversity screening, or resistance evaluations. Such studies vastly increase the value of collections, and can be greatly aided by the careful collection of the field data previously described.

CONCLUSION

Most agreements stipulate the deposition of duplicate germplasm and herbarium samples in the country, although others may state otherwise (e.g., collectors may be allowed to leave with all germplasm if the host country is provided with a sample of the first germplasm increase). Successful passage of samples through quarantine to the germplasm station is greatly facilitated by cleaning and processing samples properly. For example, herbarium specimens and fruits often harbor adult insects or larvae, so proper fumigation and seed extraction are crucial to successful introductions. Notes taken in the field are often scanty; it is best to write a complete report soon after the expedition, before facts are forgotten. Well-planned and conducted expeditions often merit publication in peer-reviewed crop-specific journals or journals devoted to germplasm collections and evaluations, such as *Genetic Resources Newsletter*, FAO. Such publication makes results of an expedition accessible to the world germplasm community. When published with cooperators, it generates goodwill and opens doors for continued collaboration.^[10]

Germplasm Collections: Regeneration in Maintenance

Linda Pollak

Iowa State University, Ames, Iowa, U.S.A.

INTRODUCTION

When seed samples are collected from populations and saved in a germplasm bank, they are maintained as separate accessions (entries) along with the passport data gathered during collection. When the seed viability decreases or supply falls short due to inability to meet user demand, regeneration is necessary. Vegetatively propagated plants have special problems of regeneration. The goal of regeneration is to preserve the genetic variability that existed in the population when it was collected.

QUALITY CONTROL MAINTENANCE OF SEED-PROPAGATED COLLECTIONS

Allard^[1] gives four primary reasons why genetic variability changes during maintenance or storage: differential survival rate during maintenance, selection during regeneration, outcrossing with other accessions, and genetic drift. There are substantial differences in the ability of different genotypes within a species to survive in storage, drastically altering the genetic composition of an entry.

During regeneration, selection can take place even under conditions designed to maximize survival and minimize selection, and can bring about substantial change in genetic composition.^[1] Over several cycles of regeneration, the entry could have little resemblance to the parent collected in nature. Many of the reasons why unintended selection takes place are environmental and are a result of regenerating accessions in an environment to which they are not adapted.

In outcrossing species, outcrossing with other entries can be a problem when pollination is not carefully controlled.^[1] Outcrossing can also be a problem with inbreeding species (self-pollinators) where pollination is not normally controlled, because a small percentage of outcrossing can still occur in self-pollinators. This can be a problem when regenerating a very large collection, because the percentage of outcrossing can vary among accessions. It is not normally feasible to control pollination in self-pollinators because it is usually difficult and time consuming, and therefore expensive.

When sample size of an entry is small (i.e., few seeds), there can be drift toward fixation of alleles (loss of variability) during regeneration in both outcrossing and

inbreeding species.^[1] Fixation is largely independent of selective value, so many entries become fixed for deleterious alleles and are difficult to maintain. If the collection is large, however, genetic variability can be preserved because genes will become fixed randomly in entries.

UNINTENDED SELECTION WHILE REGENERATING UNADAPTED ACCESSIONS

One needs to be aware of the breeding system of the species being regenerated regarding overdominance, additive effects of blocks of genes, level of ploidy and genome structure (auto or allopolyploidy), vegetative behavior (annual or perennial), and competitive ability at various stages of development.^[2] These characteristics are interactive so that the population can flexibly react to selective pressure in its natural environment. Therefore, all elements of this system have to be taken into account carefully when we preserve and regenerate the population in order to avoid inadvertent changes in the genetic makeup, which would result in permanent loss of some variability.

Transfer of ecotypes from original conditions to a collection center disturbs normal selection pressures.^[2] When artificial cross-pollinating is necessary, plant density needs to be optimal, and limiting factors of the environment not present in the area from which the population derives must be controlled (including abnormal frost, drought, heat, and pathogenic attack).

The primary environmental factors influencing flowering are day length (photoperiod) and temperature.^[3] In photoperiod-sensitive species, such as maize, photoperiod determines the location where successful regeneration of short-day accessions can take place. Response to day length is also influenced by temperature. Most plants have critical minimum and maximum temperatures, and temperature's effect on floral initiation and development is highly variable, even within species. Many species exhibit some form of dormancy.^[4] For example, some winter annuals and biennials require exposure to low temperatures before reproductive development can be initiated. Multiple planting dates while regenerating may restrict subpopulation segregation by day length or maturity, and thus maintain population outcrossing.

For wind-pollinated species problems can arise from a change in weather conditions.^[2] Pollen shedding is dependent on temperature, humidity, day length, etc. Under other climatic environments it could be reduced, and self-pollination would increase abnormally.

Adequate soil moisture is necessary for growing vigorous plants with minimal flower and seed abortion.^[3] Moisture stress can reduce seed production if the stress occurs during flowering and early seed filling. Moisture stress can also influence seed set of species that develop their fruit below ground. Maturity can be hastened by reducing available water toward the end of the growing season. Relative humidity is important at pollinating, but there is an upper limit above which pollen clumping and disease infections can occur. Successful flowering and seed set occur when soil fertility is maintained at a level that will produce healthy green plants.^[3] However, some plants have special nutrient requirements for seed development.

The following examples illustrate what can happen when accessions are regenerated in an environment without the natural pressures that occur in their environment of adaptation.^[2] In one example, insect pollinators have specific habits that allow pollination of plants normally pollinated by the insects. When transferring these plant populations we also have to consider transferring their original population of pollinators.^[2] There can be drastic consequences on the plant progeny when, after transfer to new conditions, the plant population does not have the proper pollinator. The problem can be alleviated by enclosing the regenerated population in screened cages with the appropriate insect, if it is available.^[4] Another example occurs in tropical grain crops or forages, where there are species complexes consisting of wild and cultivated varieties that undergo coevolution by permanent exchange of genic flow.^[2] Weed forms can give variability and fitness to cultivated forms, or compete in eliminating weaker phenotypes. Weeds contribute as pollinators but escape harvest, so crop collections do not include the specific weed population. After regeneration of these accessions, a bias occurs in the reproduced cultivar if the weed pollinator is not available.

Populations also coexist with an agricultural system of specific biological, chemical, and physical environments.^[2] There is a negative correlation between the sophisticated control system in the most intensive agricultural systems and the genetic diversity of the plant. When regenerating populations under management techniques that optimize crop production from an economic point of view, there may be effects causing reduced diversity. Thus the agricultural system must also travel with the population.

Changes in Allele Frequency

Allelic frequency is the percentage of a particular allele at a given locus in a population gene pool, considering all

alleles at that locus. While regenerating an accession, it is very important to maintain the frequency of alleles so that rare alleles are not lost. It is less important to preserve a representative sample of the target species than to preserve at least one copy of each of the different alleles.^[5] The common alleles are of far greater interest to plant breeders, but rare alleles may be important for special uses. Losses of samples and alleles can be controlled by judicious management of the collection and reduced to acceptable levels.

Allelic diversity in accessions decays during regeneration, based on three variables: the size of the population grown for regeneration; the mating system; and the variation in the number of gametes per plant.^[6] Procedures for maintaining accessions should be chosen based on optimizing these variables within the limited amount of resources available. Population size is the most important variable, but if populations of the needed size are not practical due to a large number of accessions that need to be maintained, the other two variables become more important.

Yonezawa et al.^[6] found that a single-seed-type regeneration (each plant leaves one progeny) gave the largest effective population size in regenerating seed of moderately or highly selfing species, whereas a biparental regeneration (plants are pollinated in pairs with one offspring left from each of the paired plants) gave the largest effective size for outcrossing species. However, differences between the systems were not appreciably large unless the accessions were regenerated over 10 or more cycles with 50 or fewer plants. They suggest that a single-seed system combined with selfing may be the most effective procedure for regenerating the seed of outcrossing species if the species is self-compatible and sufficiently tolerant to inbreeding depression.

Whenever possible, regeneration procedures should control the number of pollen parents through controlled hand pollination and control the number of female parent gametes by harvesting equal numbers of kernels from each seed plant.^[7] When pollen and seed parents are controlled during regeneration the effective population size is twice the size of the original population. Crossa et al.^[7] recommended a sample size of 150–350 maize plants to capture alleles at frequencies of 0.03–0.05 or higher in each of 150 loci, with a 90–95% probability.

Some studies show that genetic drift is not a large problem. In comparing three methods of pollination (plant to plant, chain crossing, and mixing pollen) there were no significant differences among frequencies observed using seeds of maize accessions with floury and flint endosperm characteristics in frequencies of 0.97 and 0.03, respectively.^[8] Wheat microsatellite markers were used to analyze eight bulks of seeds stored more than 50 years in a seed reference collection at room temperature and regenerated up to 24 times.^[9] No contamination

due to foreign pollen or incorrect handling was discovered. In one accession genetic drift was observed, and in another heterogeneity for two markers was maintained. This study showed microsatellites to be a simple and reliable marker system for the verification of the integrity and genetic stability of gene bank accessions. Biotechnology methods have primarily been of benefit for crops difficult to maintain, however, such as those requiring vegetative propagation and those with recalcitrant seeds that cannot be dried to low levels for optimum storage.^[10]

Vegetatively Propagated Plants

Vegetatively propagated germplasm is the most difficult and expensive to regenerate, and generally requires considerable space.^[4] Although some of these crops are sexually fertile, it is often not convenient to propagate them commercially from seed because of high levels of heterozygosity, and because breeders require uniform clones. Many are sterile or polyploids, or have reduced fertility.

Vegetative organs are short lived and deteriorate rapidly after harvest, unless stored in ideal storage conditions.^[11] Annual regeneration is costly, and there is danger of disease infection. It is extremely difficult to keep vegetatively propagated plants free from viruses, which leads to degeneration of clonal stocks. Because of these special problems, tissue culture or in vitro techniques are used.^[11] Keeping the cultures in ultra-low temperatures opens the possibility of storing the germplasm indefinitely. Tissue culture has a major advantage, in that a large number of genotypes can be stored in a relatively small area at a fraction of the cost of growing the material in the field. The two major problems with using tissue culture are high levels of somaclonal variation, which occurs when tissue is regenerated into seedlings, and the limited length of storage time before regeneration is required. Improved tissue culture techniques are leading to lower somaclonal variation levels, and work is proceeding on cryopreservation that will allow tissue to be preserved for long periods.^[10]

Cost-Benefit Ratios of Regeneration

The labor requirement of regeneration is reduced as storage conditions improve.^[11] If materials are extremely similar they can be combined as more is learned about them. We should aim to conserve sufficient stocks of each species to saturate the breeder's capacity to evaluate and utilize the conserved germplasm, both now and in the

future.^[5] Thus, evaluation and utilization should be the major limiting factors in germplasm conservation.

Germplasm Enhancement Through Mutation Techniques

Karin Nichterlein
Mirosław Maluszynski

Joint FAO/IAEA Division of Nuclear Techniques in Food and Agriculture,
Vienna, Austria

INTRODUCTION

Most of the available genetic variation used in crop improvement programs, existing in germplasm collections of cultivars, landraces, breeding lines, and related wild species, has been generated over time through spontaneous mutations and hybridization. When existing plant genetic resources lack the desired trait in a compatible accession, it is often possible to generate it by mutations. Because spontaneous mutations occur with relatively low frequency, mutation techniques are used to change one or two characters of an otherwise well-adapted cultivar or for the domestication of wild species. Mutagenic agents cause random changes in the nuclear or cytoplasmic DNA resulting in gene (point), chromosomal, genomic, or extranuclear mutations. Most induced mutations are recessive and deleterious. However, when combined with an efficient screening for desired variation, induced mutations have contributed significantly to crop improvement and, in some cases, have made a considerable impact on the productivity of a particular crop. Chemical, radiation, and insertional mutageneses are also used in genomic research for assessing gene function through induction of loss-of-function mutations.

INDUCED MUTATIONS IN ENHANCEMENT OF SEED AND VEGETATIVELY PROPAGATED CROPS

Mutagenesis has been known since about 1920 when Muller discovered increased mutation rate in *Drosophila* after X-ray treatment and Stadler found a similar effect in plants. Currently, most frequently used physical mutagens are gamma rays, fast and thermal neutrons, heavy particles, and cosmic rays. Several chemicals, such as ethyl methanesulfonate (EMS), sodium azide (NaN₃), *N*-methyl-*N*-nitroso urea (MNH=MNU), *N*-ethyl-*N*-nitroso urea (ENH=ENU), and ethylene-imine (EI), have been identified as mutagenic and used for mutation induction. Gustafsson^[1] in Sweden and Freisleben and Lein^[2] in Germany introduced induced mutations as a tool in plant

breeding. Research on the theoretical basis of mutagenesis in plants has been conducted since the 1940s with major activities in the 1960s. As a result, the methodological principles on the use of various mutation techniques to create and select desired genetic diversity were formulated and published as a guideline for plant breeders and scientists in the *Manual on Mutation Breeding*.^[3] The transfer of mutation methodologies developed for seed and vegetatively propagated crops to national plant breeding programs around the world led to the release of a great number of improved crop cultivars. Today, the FAO/IAEA Mutant Varieties Database includes 2252 officially registered mutant cultivars of more than 160 species. Over 170 new cultivars were released between 1995 and 2000. The majority of the accessions (75%) are of crops and 25% ornamental and decorative plants.^[4] Of the 2252 total accessions, 70.4% were released as direct mutants, i.e., through direct multiplication of selected mutants, and 20.6% through crosses with a mutant. Radiation was most frequently used (89%) for directly developed mutant cultivars, whereas the use of chemical mutagenesis was relatively infrequent. Gamma-ray treatment was employed for the development of 64.5% of the radiation-induced mutant cultivars followed by X-ray treatment (22.0%), chronic gamma-ray treatment (4.3%), fast neutrons (3.4%), and thermal neutrons (1.6%). Most crop mutant cultivars have been released in seed-propagated species (1603), with the majority in cereals and legumes, followed by industrial, vegetables, oilseeds, and other crops. In rice alone, 434 mutant cultivars have been released with improved characters, especially semi-dwarfness and earliness. Only 97 out of 1700 crop cultivars are vegetatively propagated species, among which fruit crops predominate.^[4]

The general procedures for using induced mutations in seed-propagated species are rather simple and have remained valid for the last 60 years^[3,5] (see Fig. 1). Mainly dormant seeds of the so-called parent variety (M₀ generation) are treated with mutagens. Pollen treatment is used only in few species such as maize.^[6] As a result of the mutagenic treatment, genes can be changed to another allelic form, and mutagenized cells of the M₁

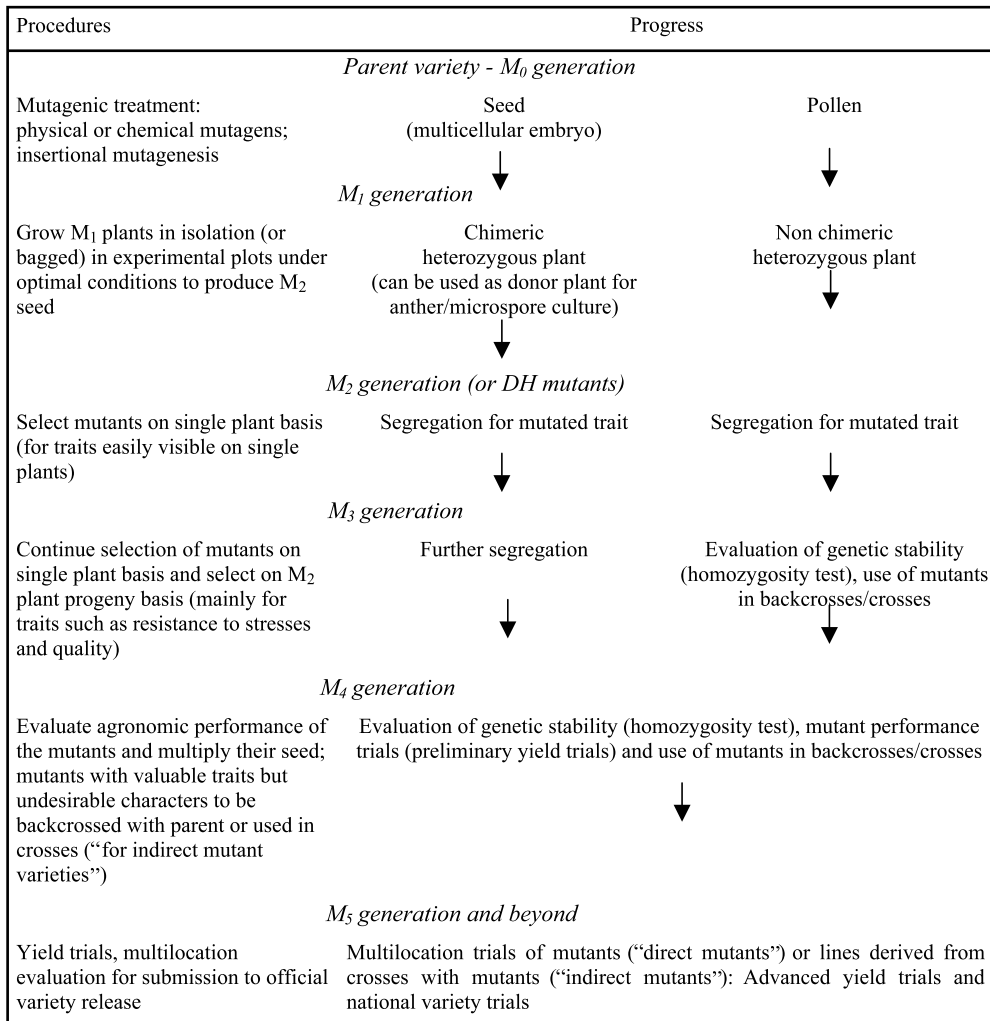

Fig. 1 Mutation techniques for the improvement of seed-propagated plants. (From Ref. [7].)

seeds become heterozygotic. Mutations are single-cell events, leading to plants having both nonmutated and mutated cells (chimerism). M₁ plants grown from mutagenized seeds produce seeds of the M₂ generation. The M₂ generation segregates for mutated traits. Very often, a deviation from the expected segregation ratio can be observed because of chimerism of the M₁ plants. Only mutations transferred into gametes are present in the next generation. Selection of mutants starts in the M₂ generation for traits that can be easily identified on a single plant basis. Selection continues in the M₃ generation, where further segregation appears. For traits that can be selected only on a row basis, selection will start in M₃. The procedure of selecting and handling mutants focuses on the separation of mutated genes from undesirable or even deleterious mutations at other loci.

Both the chimeric structure of the M₁ plants and the existence of simultaneous, unwanted mutations make it necessary to examine large M₂ and M₃ populations to pick up a desired mutant. Fast selection methods facilitate the screening of large mutated populations. Selfing and backcrossing of mutants are often required to develop true-to-type mutant lines before they are multiplied and evaluated in multilocation trials or used for crosses.

Because doubled-haploid (DH) techniques became routine tools in breeding, their combination with induced mutations, by using M₁ plants as donor plants for haploid cells (treatment before meiosis) or by mutagenizing cultures of haploid cells (treatment after meiosis), allows the immediate detection of recessive DH mutants. If a selection agent is available, screening can be performed at

the cell or embryo level on a large mutant population in vitro.^[7] Mutation induction protocols for microspore cultures have been developed for barley and oilseed rape and were successfully applied to produce herbicide-tolerant mutants and mutants with altered fatty acid composition of the seed oil.

In vegetatively propagated crops, a mutated cell of the meristematic tissues (bud, shoot apex) develops into a sectorial chimera. Before a desired mutated trait can be detected and screened, the mutated sector must develop into a selectable size such as a branch or shoot. The mutagenized shoot is called M_1V_1 generation, from which the M_1V_2 shoots develop. The new shoot from M_1V_2 is called M_1V_3 and so on. The percentage of chimerism reduces with each propagation step. Therefore screening for desired traits should start only in or after the M_1V_4 generation. Progress in plant tissue culture of some species made it possible to mutagenize cells and tissues instead of cuttings. The advantages of using in vitro cultures are: 1) relatively uniform and large population of cells in the small size explant, enabling the irradiation of many cells; 2) disease-free material; 3) separation of mutated sectors in a short time; and 4) possibility for in vitro selection.^[8] During the last two decades, commercial breeding companies routinely created new variations in flower color and morphology, leaf traits, and growth habit through induced mutations.^[9] In fruits, mutation techniques have been used to induce compactness, early maturity, and improved fruit quality in apple, disease resistance in pear, compactness and self-incompatibility in cherry, seedlessness and red fruit color in citrus, and early maturity.^[10,11]

ECONOMIC IMPACT OF INDUCED MUTANTS

Semidwarfness

Mutation techniques have been used as a simple and rapid tool to obtain semidwarf cultivars of cereals without changing other desired characters, such as adaptability, grain quality, and consumer preference. In rice, the mutant cultivars “Reimei” in Japan and “Calrose 76” in California have been widely used as major gene sources for modern semidwarf *japonica*-type cultivars in these countries, and mutant “IRAT 13” was developed in France for breeding semidwarf upland rice in Africa and South America.^[12,13] In barley, two radiation-induced mutant cultivars “Golden Promise” and “Diamant,” both semidwarf and released in the 1960s, were used for the development of a wide range of barley cultivars throughout Europe: 17 Golden-Promise-derived cultivars were released in United Kingdom and 112 Diamant-

derived cultivars were released in former Czechoslovakia and various European countries.^[5] In durum wheat, mutants and their derivatives with improved straw architecture, lodging resistance, and high yielding ability became leading cultivars in Italy.^[14]

Disease Resistance

Various mutant cultivars of chickpea with high yield and disease resistance were released in Pakistan, from which “CM-72” resistant to *Ascochyta* blight is still the major chickpea cultivar in that country. A black spot disease-resistant mutant cultivar of Japanese pear was released as “Gold Nijiseiki” in Japan with high economic impact. Two mutant cultivars of peppermint tolerant to *Verticillium* wilt which were released as “Todd’s Mitcham” and “Murray Mitcham” in the 1970s are still recommended to control *Verticillium* wilt in United States, where 90% of the world’s peppermint oil is produced.^[15]

Quality

Red grapefruit is important for export in Texas, and mutant cultivars with deep red fruit color were released after radiation treatment: “Star Ruby” released in 1970 and “Rio Red” released in 1984. The fruits of both cultivars are sold under the trademark “Rio Star.” In Texas, Rio Star grapefruit is currently grown on 7300 ha, which is 75% of the state’s total grapefruit production area. In sunflower, a mutant with increased oleic acid content was developed by chemical mutagenesis and officially released in 1977 in the former USSR. The mutated allele was used to develop sunflower cultivars, which are now widely grown in the United States for the production of more stable frying oil.^[15]

CONCLUSION

Induced mutations alone or in combination with tissue culture techniques offer plant breeders and geneticists an efficient tool to improve specific traits of both seed and vegetatively propagated crops. Selected mutants can be used for direct multiplication and release as new improved cultivars or in crossbreeding and, recently, for genomic research. In each case, the use of mutation techniques will depend on the specific objectives and the plant species. For the improvement of vegetatively propagated crops, the combination of in vitro and mutation techniques seems to be very suitable. The use of doubled-haploids in combination with induced mutations allows obtaining rapidly desired genotypes in a homozygous state in all seed-propagated crops, for which routine doubled-haploid techniques exist.

Germplasm Maintenance

Henry L. Shands

USDA–ARS National Center for Genetic Resources Preservation, Fort Collins, Colorado, U.S.A.

INTRODUCTION

The apparently mundane task of maintaining germplasm^a for a genebank^b is anything but mundane. Huge responsibilities are incumbent upon all those involved in the processing of germplasm, from acquisition to distribution. Scientists expect a high-quality and adequately documented product. To ensure quality in germination, freedom from disease, and adequate documentation, managers must examine all aspects of management, from initial receipt of seed to storage conditions.^[1]

SOURCE OF GERMLASM

Sites receiving germplasm must review the process through which they received it because authenticity is essential. Plant collecting is most easily documented through direct collectors^[2] using Global Positioning System (GPS) locators and herbarium specimens. When it is received from another genebank's collection, there may be gaps in the existing information, especially if the donor genebank is not the original source. If there are many points of handling between field source and genebank, there are more chances for errors in the documentation and integrity of the material. This is especially true if the sample has had multiple growouts since being acquired. End users must assess the source and determine their risk in data and germplasm accuracy. Maintenance of a nonoriginal source of germplasm is only as good as the many intervening waypoints.

Resource Documentation

If the material is not collected first-hand, documentation is often absent, inaccurate, or deficient. Most samples acquired through exchanges include little information provided with the sample.^[3] For some end users, this is a minor omission but for others, it is of serious concern.

^aGermplasm—a whole organism or any propagule of genetic resources that can be stored in ex-situ or in-situ conditions and used to identify, multiply or preserve the original individual's genetic identity.

^bGenebank—a repository for germplasm.

Breeders screening for a specific trait will evaluate the sample for that trait while assessing other virtues. To the extent possible, those data will be put into the database. Curators will assess all regular passport data characters and qualities and document them under their growout conditions to confirm and compare with any original passport data. The Food and Agriculture Organization of the United Nations (FAO) International Treaty on Plant Genetic Resources^[4] requires that data be supplied to the requester. If data are not available, however, the requirement is hollow.

Field Growouts of Seed Crops

For the curator to properly maintain germplasm, sufficient critical data must be provided relative to the initial sample. Wild relatives of crop plants may be uniquely restricted to a specific point of origin but collectors try to collect many different samples throughout an area. A landrace would likely be more variable than a bred variety.

If a landrace acquisition is not the original sample, the curator must assess what population size and environmental biases have already occurred or been introduced. A recommended population size is dependent on numerous factors, including pollination method (selfing or outcrossing), heterogeneity of population, and goals of the curator to purify the sample or retain any heterogeneity or heterozygosity.^[5]

If the sample has been regenerated under curator conditions (in contrast to in a farmer's field), how many plants were grown and how were they pollinated? Unknown contamination from foreign pollen of like or compatible species is a concern to curators. To maintain the genetic integrity of the sample, the curator must take measures such as maintaining appropriate isolation distances or bagging to prevent contamination. The isolation distance is dependent on method of pollination (whether windblown or insect commuted), flowering type (whether open or closed, self or cross-pollinated), and, for some species, whether self-compatible or not. If pollination is carried out by hand, isolation distance is immaterial but some of the other factors remain critical.

If the material is from a tropical or subtropical environment, what biases have been or are being introduced

by growing it in a temperate zone? When it is grown outside its normal eco-zone the population will likely be biased due to a truncated flowering period. Photoperiod-induced late flowering and subsequent seed set and seed development may be impaired and not represented in the harvest sample. The flowering date of the next population may thus be biased to be earlier, and the population may lose genes and traits physically associated with linkage groups containing flowering factors.

Some concern is raised about maintaining base collection samples free from gene constructs of genetically modified organisms (GMOs). Where regeneration occurs in areas where commercial GMO crops are grown, adventitious GMOs may result from cross-pollination.^[6] When base collection supplies are replaced by regenerated samples that possibly contain GMOs, notation to database records should be made. As with any contamination of the base sample, future regenerations will likely further deviate from the original description. The deviation will reflect any selective advantage of the GMO even if the regeneration site is removed from areas of GMO crops. Field collections of non-GMO clonally propagated crops would not normally be affected by the presence of new fields of GMO cultivars of the same species, or be affected by the same issues as seed crops as long as their reproduction is through the somatic buds of the original clone or its sports. However, seed sources would likely be affected.

Field, Laboratory, and Greenhouse Maintenance

Regeneration is one of the most costly operations for a genebank. This cost is not only in time and money but also in the risks involved. In all aspects of genebank management, clean seed/propagule practices must be followed expressly in seed room and laboratory preparation, in hand or mechanical planting, in hand bagging and pollination, and in harvest and seed processing techniques. Precision of accession and location information can be assisted with bar coding, but labels must be carefully applied. Mixtures from improper human procedure are as problematical as those from weather-related events. Torrential rains—whether alone, or associated with tropical storms, or coupled with tornadoes' destructive winds—can move or destroy plants in the field, greenhouse, or laboratory. Maps of exact plantings should be safely stored for reference. Maps of clonal orchards are critical to reconstructing locations of individual plants or trees. Whatever the causal event for the mechanical mixture of seed, propagules, pollen, or plants, the result is the same—an inferior product to deliver to future generations. Preventive measures should be taken to

minimize the risk of mixture and loss of genetic purity at all steps.

GENETIC STOCK MAINTENANCE

Not all germplasm is varietal material. Genetic stocks as a group include various gene mutations, chromosomal aberrations (such as translocations, additions/deletions, and inversions), and even increases or decreases in levels of ploidy of one or more of the chromosomes or whole chromosome sets.^[7] For most of these stocks, some genetic or cytogenetic analysis must be made of the resultant progeny to confirm the changes contained therein. A growout test is usually necessary to confirm the presence of a lethal mutant that must be maintained in a heterozygous condition with its allele. In all cases, the subsequent generation is analyzed to validate the genetic constitution of the progeny of the original regeneration. One must be careful not to expend valuable seeds in needless growouts. Also, a competent analysis is often required by a skilled scientist. Seed distribution is often limited to a few seeds due to their unique nature and cost. Genetic stocks are thus found mostly at special stock centers where the necessary expertise is available to maintain them. The same stock centers may also maintain the related wild relatives used in improving the crop. Scientists will often conduct interspecific and intergeneric crosses to move potentially useful alien genes and chromosomes into the cultivated form. This differs from the GMO issue discussed earlier because the generations subsequent to the crosses are subject to natural chromosome rejection, and few plants survive or lead to useful crop plants. The process is quite random—more in the realm of research than in the realm of contamination, as in the case of GMO field crops.

Storage of Germplasm

Storage is often the most cost-effective process in a genebank's operation.^[8] Proper storage helps abate the high cost of regeneration and risk of loss of genetic integrity. Seed storage protocols for any seed crop begin at the time of pollination when procedures are put in place to assure accuracy of bagging notation. Insecticides are often dusted in the bags to reduce loss to predator insects that find the warm, moist environment enticing for feeding and reproduction. Seed maturity and drydown are important, so harvest must be made timely and seeds must be dried to remove excess moisture.^[9–11] Overheating in dryers and stacking in greenhouses without aeration or

elsewhere where rodents and other animals can do damage is obviously poor management.

Once at the genebank, the seed material must be dehydrated through a combination of heat and dehumidification to reach optimum seed storage moisture.^[11,12] The moisture level is critical prior to placing seed in sealed foil bags or in liquid nitrogen vapor (cryopreservation). Data are evolving to suggest that long-term storage in liquid nitrogen vapor has merit over the conventional 20°C in extending seed life (Walters, personal communication). In some cases too little moisture will result in damage in storage.^[12] Data are available for many seed crops showing that lipids are a critical determinant of optimum seed storage moisture^[10,12] and that lipids influence aging kinetics^[10,13] and cell damage during cryopreservation.^[14]

Clonally propagated material in tissue culture must be carefully managed to reduce transfers and opportunity for somatic mutation.^[15] Cool storage and experimentation with culture media to extend storage life before transfer are essential. Cryopreservation for vegetative tissue of a limited number of species has only begun, and new protocols are evolving, giving hope that life expectancy can be improved and samples stored for long periods of time.^[15,16]

Although DNA storage has been given considerable discussion, there is little evidence that it will play a large role in genebank storage. It obviously will play a role in helping to validate genetic change and to elucidate individual's genetic makeup for many purposes in the future.

CONCLUSION

Germplasm maintenance requires implementation of many pieces of information, careful techniques of propagation, and rigidly employed laboratory-type sanitation for stocks and their environment. Anything less subjects the germplasm to loss of genetic integrity and truisms, and incorporates imperfections to pass on to future generations.

Germplasm: International and National Centers

Jonathan Robinson

Murthi Anishetty

Food and Agriculture Organization of the United Nations, Rome, Italy

INTRODUCTION

It is estimated that ex situ plant germplasm collections comprise six million accessions, over half of which represent base collections, kept solely for conservation. The remainder are active, working collections available for distribution and use by plant breeders and researchers. One third of the total number of accessions is thought to be unique. The 11 genebanks of the Consultative Group on International Agricultural Research (CGIAR) and International Agricultural Research Centers (IARCs) together house major collections of accessions (ca. 600,000). The rest are conserved in about 1300 regional and national genebanks. The CGIAR collections have been built up over 25 years and, following agreements signed in 1994, are held in trust for the world community under the inter-governmental authority of the Food and Agriculture Organization of the United Nations (FAO).

DISCUSSION

Most plant germplasm is conserved as seeds, but approximately 500,000 accessions, many of which represent fruit trees, are maintained in field genebanks. An additional 40,000 accessions are conserved in vitro through cryopreservation or tissue culture. Botanical gardens, arboreta, and herbaria are also important centers for plant germplasm conservation. There are approximately 1500 such centers spread around the globe. The majority are located in Europe, the Commonwealth of Independent States, and the United States. A little over 10% are privately owned. Germplasm seedbanks are also maintained by 150 botanical gardens. About half the botanical gardens conserve germplasm of ornamental species, crop relatives, medicinal plants, and forest trees.

International and regional centers conserve broad ranges of plant germplasm derived from diverse locations. Many national germplasm centers conserve mainly indigenous material, whereas others, including those in Australia, the United Kingdom, and United States for example, conserve mainly imported germplasm. National

genebanks such as the N.I. Vavilov All-Russian Research Institute for Plant Industry (VIR) in Saint Petersburg, Russia, maintain accessions collected from around the world and more resemble international centers than national ones. The Institute of Plant Genetics and Crop Plant Research (IPK) at Gatersleben, Germany, is another such institute that houses large and diverse collections of crop germplasm. Whereas the international and regional centers for plant germplasm are generally able to conserve collections under optimal conditions, the state of national collections varies enormously. The number of unique accessions is often difficult to determine, as duplication—deliberate as well as unintentional—is often not easy to gauge. Developed countries invariably have seed and field genebanks and botanical gardens, but many developing nations do not. However, substantial germplasm collections do exist in some developing countries, including Brazil, China, Ethiopia, and India. India, Indonesia, and Sri Lanka, moreover, have among the best maintained tropical botanical gardens in the world, at Calcutta, Bogor, and Kandy, respectively.

Useful information on genebanks and their operations is available in several general texts.^[1–4]

INTERNATIONAL CENTERS

The CGIAR centers have mandates to breed and research a limited number of crop species, including most of the major staples of the developing world; their genebanks consequently house germplasm geared toward those ends. Several of the collections—including CIMMYT's wheat (*Triticum* spp.), IRRRI's rice (*Oryza* spp.), CIAT's bean (*Phaseolus* spp.) and cassava (*Manihot* spp.), and ICRI-SAT's chickpea (*Cicer arietinum*) and pigeon pea (*Cajanus cajan*)—represent the world's largest ex situ collections of those crops. Detailed information on international agricultural research center holdings is available from the System-wide Information Network for Genetic Resources (SINGER) database.^[5] These data are summarized in Table 1.

Table 1 In-trust germplasm collections of the International Agricultural Research Centers of the Consultative Group on International Agricultural Research

Center ^a	Crop	Genus	No. of accessions
CIAT	Cassava	<i>Manihot</i>	> 5,700
	Forages		> 16,300
CIMMYT	Beans	<i>Phaseolus</i>	> 28,700

REGIONAL CENTERS

There are five principal regional centers for plant germplasm. The Asian Vegetable Research and Development Center (AVRDC) is located in Taiwan and holds over 47,000 accessions, concentrating on tomato (*Lycopersicon esculentum*), pepper (*Capsicum* spp.), soybean (*Glycine* spp.), and mung bean (*Vigna* spp.) germplasm. It is one of the world's largest genebanks for vegetable species. The Centro Agronómico Tropical de Investigación y Enseñanza (CATIE) in Costa Rica conserves more than 35,000 accessions of cucurbits, peppers, beans, coffee (*Coffea* spp.), and cocoa (*Theobroma* spp.) in seedbanks and in decentralized field genebanks. Large ranges of temperate

fruit and berry crops are maintained in the field genebanks of the Nordic Gene Bank (NGB), headquartered in Sweden. In total it manages more than 27,000 accessions, including vegetable, root, oil, and pulse crops. The Southern African Development Community (SADC) has a plant genetic resources center in Zambia that contains approximately 5000 germplasm accessions, representing collections and duplicate collections of southern African national collections. Last, the Arab Center for the Studies of Arid Zones and Dry Lands (ACSAD) in Syria has a sizeable collection of fruit trees from West Asia and North Africa. Other regional genebanks are being developed. For instance, a taro (*Colocasia* spp.) genebank is being established in Fiji that will serve the 22 member states of

the South Pacific Commission. There is also a multiple-site International Coconut (*Cocos nucifera*) Genebank hosted by Brazil, Côte d'Ivoire, India, Indonesia, and Papua New Guinea.

NATIONAL CENTERS

National genebanks comprise a range of institutions administered by governments, universities, nongovernment organizations (NGOs), and the private sector. Most countries in Europe have established genebanks. Many of those genebanks contain working collections, but university genebanks, for example, often hold important collections of genetic stocks. The Royal Botanic Gardens at Kew in England have substantial living plant collections—including native and exotic species—at two sites. There is also a national reference collection of over seven million plant specimens (including 250,000 type specimens) and 20,000 seed accessions in the herbarium carpological collections. The Millennium Seed Bank is the largest seed bank in the world for wild plants and holds seed of more than 5000 species from 600 genera. The Russian national genebank, VIR, has vast germplasm collections of a range of crop species, including large collections of maize, *Zea mays* (18,000 accessions) and wheat (36,000) and the world's largest potato (*Solanum tuberosum*) collection (8500 accessions). Some major genebank holdings for a range of crops are given in Table 2.

Africa has relatively few centers for plant germplasm that function effectively. Facilities are most advanced in Côte d'Ivoire, Ethiopia, Kenya, and Nigeria. However, more than 80% of oil palm (*Elaeis guineensis*) accessions are maintained in the Democratic Republic of the Congo, and Uganda has an important collection of banana (*Musa* spp.) germplasm (250 accessions). In the Near East, Turkey has one of the few facilities with long-term storage capacity, but genebanks in Iran, Israel, Pakistan, and Turkey operate at a high level. The Hebrew University of Jerusalem has an important sesame (*Sesamum indicum*) collection. Field genebanks in the Near East are quite numerous. Turkey has several field genebanks devoted to crops including fruit trees, olives (*Olea europea*), and garlic (*Allium sativum*). In South Asia, the genebank facilities in India are the most advanced. The Indian Agricultural Research Institute, for example, has the world's largest collection of maize germplasm (25,000 accessions) and the National Bureau of Plant Genetic Resources has the world's second largest chickpea collection (ca. 15,000 accessions).

There are several major national collections of germplasm in the East Asia region, especially in China, Japan, and the Republic of Korea, as indicated in Table 2. Those collections include soybean, citrus, and sesame. In terms

of total numbers of genebank accessions, China ranks second in the world (350,000) after the United States (555,000) and ahead of India (342,000). In Southeast Asia and the Pacific, Indonesia, Malaysia, the Philippines, and Thailand have important centers for germplasm conservation, including many important field genebank collections. Only two genebanks holding substantial numbers of accessions of banana and plantain germplasm are in the center of origin of the crop. These collections are in Papua New Guinea (The National Agricultural Research Institute), which has the highest number of unique banana/plantain accessions, and the Philippines (Davao National Crop Research and Development Center). The National Plant Genetic Resource Center of the Philippines holds the world base collections of several minor crops and duplicate collections of some Asian vegetables. Kebun Raya, the Indonesian botanical gardens at Bogor, were established in 1817 and now cover four sites and contain over 15,000 species of trees and plants. Oil palm was introduced into Southeast Asia in 1859 from plants grown there.

In the Americas, the United States and Canada have numerous large seed genebank and field genebank collections. Argentina, Brazil, Chile, Mexico, and Venezuela also have good long-term storage facilities. The two Brazilian agencies, Centro Nacional de Recursos Genéticos e Biotecnologia (CENARGEN) and Empresa Brasileira de Pesquisa Agropecuária (EMBRAPA), manage large collections of a range of crops including beans, cassava, cocoa, citrus, rice, and soybean. There are several major bean germplasm collections in Mexico. Honduras (Fundación Hondureña de Investigación Agrícola, FHIA) has a large and very important collection of 430 banana and plantain accessions. Cuba is relatively alone in having adequate facilities in the Caribbean, but Trinidad and Tobago holds a major cocoa germplasm collection (2300 accessions). The United States Department of Agriculture (USDA) Agricultural Research Service (ARS) has national plant germplasm collections at about 30 sites. The National Small Grains Collection (NSGC) at the University of Idaho, Aberdeen, has sizeable collections of wheat (>46,500); barley (ca. 27,000); oats, *Avena sativa* (21,000); rice (>17,000); rye, *Secale cereale* (>2000); triticale, *X Triticosecale* (ca. 2,000); and *Aegilops* (>2000). The USDA, moreover, has a very important potato germplasm collection at Sturgeon Bay and a substantial fruit, nut, and horticultural crop germplasm collection in Corvallis, at Oregon State University (11,430 accessions representing 54 genera and 745 species). The National Seed Storage Laboratory is located in Fort Collins, Colorado, and is a base collection repository for 23,827 accessions representing 207 genera and 514 species. There are numerous other germplasm centers at the many agricultural universities in the United States, including a particularly important

tomato germplasm collection maintained at the University of California, comprising nearly 6000 accessions.

CONCLUSION

The recently signed International Treaty on Plant Genetic Resources for Food and Agriculture, adopted by the thirty-first session of the FAO Conference (November, 2001) represents a legally binding international commitment to the improvement of the world's key food and feed crops. The Treaty is based on a multilateral system of facilitated access and benefit sharing. This multilateral system covers plant genetic resources for food and agriculture, including a list of crops established according to the criteria of food security and interdependence. The list of crops covers species from 54 major crop genera, but excludes some genera of major importance, including *Glycine*, *Arachis*, and *Elaeis*. Also included are over 80 species of forages from 29 genera. It is anticipated that if there is unrestricted access to the listed genetic resources they will be better conserved for the future.

Although the germplasm in the genebanks of the developed world is generally well conserved, that in many of the developing countries is in a precarious position. Moreover, some germplasm collections—particularly field genebanks—are naturally vulnerable. Banana and taro collections are two examples prone to hurricane damage and disease, respectively. In addition, potentially important sources of wild relative germplasm grow in vulnerable ecosystems and environments, which are at risk of being lost. Through an initiative begun by the System-wide Genetic Resources Program of the CGIAR, termed the Global Conservation Trust, it is hoped to ensure that

some of the most important and vulnerable germplasm collections in the world can be conserved for the well-being of humankind.

Glycolysis

Florencio E. Podestá

Universidad Nacional de Rosario, Rosario, Argentina

INTRODUCTION

Glycolysis is a universal metabolic route present in all living cells, at least in part. It is commonly defined as the catabolic pathway leading to the conversion of sugars into pyruvate.

As presented, this equation, which applies well to animal or yeast glycolysis, implies a simple, straight path of degradation from glucose to pyruvate. This assertion has become increasingly outdated, when applied to plants, by the vast amount of new information gathered within the past three decades of research.

DISTINCTIVE FEATURES OF PLANT GLYCOLYSIS

Research in the carbohydrate metabolism area has provided unequivocal information showing that plant glycolysis has distinctive features that encompass the existence of unique enzymes, the use of pyrophosphate instead of ATP as phosphate donor, and a different mode of regulation.^[1–3] In plants, carbon may enter glycolysis from two pools: the hexose phosphate pool and the triose phosphate pool.^[2] The first is fed by sucrose or starch degradation. The second pool is the result of hexose-phosphate degradation, photosynthetic carbon fixation, or the action of the oxidative pentose phosphate pathway.^[2] Additionally, the presence of enzymes specific to plant glycolysis can change the final product and/or the ATP yield.^[1] Having these facts in mind, it is easy to visualize that the glycolytic metabolism in plants is not a mere linear sequence of reactions leading from one substrate to a final product; on the contrary, the actual substrate and products will depend on the metabolic status of the plant tissue at that particular time.

Plant Glycolysis Is Compartmentalized

Unlike heterotrophic organisms, plants are able to synthesize hexoses through photosynthesis and thus do

not depend on an external carbon source. In chloroplasts, carbon is fixed and transiently stored as starch. In nonphotosynthetic tissue, plastids also serve as carbon stores, using imported carbohydrate that comes in the form of sucrose. Thus, at least part of the glycolytic machinery has to be used in plastid carbon metabolism to degrade starch products and provide ATP, NADH, pyruvate for fatty acid synthesis, triose phosphates that are exported to the cytosol, and intermediates for secondary metabolism.^[1]

Meanwhile, cytosolic glycolysis is the source of pyruvate for the tricarboxylic acid cycle, with the concomitant production of ATP and NADH. It also generates the carbon skeletons needed in N assimilation through associated anapleurotic reactions and the PEP used in primary carbon fixation in crassulacean acid metabolism and C₄ plants.^[4] The plastid and cytosolic hexose-phosphate and triose-phosphate pools are connected through the Pi translocator of the inner plastid membrane.

It is of paramount importance to realize that glycolysis in plants goes far beyond being a merely catabolic metabolism designed to obtain energy and reductive power from hexoses. Its products serve as precursors for several anabolic pathways leading to the synthesis of amino acids, lipids, and other cell constituents. The separation of roles and operational timeframe among the cytosol and plastid carbon metabolism calls for different regulatory needs, and compartmentation provides a means of integrating different metabolic pathways with diverse control requirements.

THE OPERATION OF PLANT GLYCOLYSIS

Individual Reactions

Beyond a description of each of the reactions involved in glycolysis, this section presents a summary of the main features that characterize plant glycolysis and differentiate it from animal and yeast counterparts, offering an account of the recent knowledge regarding its particular chemistry and mode of regulation.

The first step of glycolysis consists of the phosphorylation of hexoses that will then enter the hexose phosphate pool (Fig. 1). Hexose phosphates are produced

Fig. 1 Glycolysis in plant cells. Individual reactions are catalyzed by the following enzymes or transporters: (1) sucrose synthase; (2) UDPglucose pyrophosphorylase; (3) invertase; (4) hexokinase; (5) phosphoglucomutase; (6) phosphoglucoisomerase; (7) PFK; (8) PFP; (9) amylase; (10) starch phosphorylase; (11) phosphate translocator; (12) aldolase; (13) glyceraldehyde-3-phosphate dehydrogenase; (14) 3-phosphoglycerate kinase; (15) non-phosphorylating glyceraldehyde 3-phosphate dehydrogenase; (16) phosphoglyceromutase; (17) enolase; (18) pyruvate kinase; (19) PEP phosphatase; (20) PEP carboxylase. (View this art in color at www.dekker.com.)

in the cytosol during degradation of sucrose by sucrose synthase and UDP glucose pyrophosphorylase. The action of invertase gives rise to hexoses, which are phosphorylated by a hexokinase. As in animal cells, plant hexokinase has also been reported to be bound to mitochondria.^[2] Cytosolic hexokinase has also been implicated in the sugar-sensing pathway that governs specific carbohydrate metabolism gene expression.^[5] Plastid hexokinase is used to phosphorylate glucose produced by amylolytic starch degradation, although its presence is not universal in all plants.

The hexose phosphate pool exists in a thermodynamic equilibrium maintained through phosphoglucomutase and

phosphoglucoisomerase, which catalyze reversible reactions. The next step is where one of the crucial differences between animal and plant glycolysis surfaces. The phosphorylation of Fru-6-P in the cytosol can be achieved by two different enzymes: the classical PFK reaction using ATP, or the alternative reaction that uses PP_i as phosphoryl donor, catalyzed by the pyrophosphate-dependent PFK or PFP (Fig. 1).

The latter reaction is exclusive to the plant cytosol, and although it is also present in some bacteria and unicellular parasites it has not been found in animals or yeast.^[1] PFP, unlike PFK, catalyzes a reversible reaction, which is remarkable considering that the Fru-6-P/Fru-1,6-P₂

interconversion is a key regulatory step in glycolysis. The presence of PFP and the fact that PP_i concentrations remain stable in the plant cytosol under a variety of conditions make this reaction a bypass to that catalyzed by PFK (and FBPase in the opposite direction), eliminating the use of one ATP molecule. Although its precise role in plant metabolism is not yet clearly defined, it could fulfill a role in the glycolytic breakdown of sugars under nutrient stress conditions.^[6] In certain CAM plants, where a massive flux of carbon through the glycolytic pathway is required, PFP activity can exceed PFK by an order of magnitude.^[7] Recent studies also hint at this enzyme being a potentially important target for glycolysis regulation.^[8]

Fru-1,6- P_2 is converted to triose phosphates by aldolase. Plant aldolases, both cytosolic and plastidic, are structurally related class I aldolases. Although not a regulatory enzyme, aldolase plays an important role in photosynthesis control.^[9]

Upon interconversion of DHAP in Ga3P, the ATP-yielding phase of glycolysis starts (Fig. 1). Ga3P is oxidized to 1,3DPGA by GaPDH, which conserves the energy obtained from oxidation by the formation of a high-energy mixed anhydride between the phosphate and a carboxyl group. In this reaction, reductant is formed as NADH in the cytosol or NADPH in plastids. This energy-conserving step may be bypassed by an enzyme unique to the plant cytosol, the nonphosphorylating GaPDH. It uses $NADP^+$ but does not incorporate a phosphate group, rendering 3PGA that cannot be used to produce ATP.^[6]

The following reactions do not offer substantial differences from classical glycolysis, and they lead to the formation of PEP through the combined action of 3PGA kinase, phosphoglyceromutase, and enolase.

The metabolism of PEP is a metabolic branchpoint, both in plastids and in the cytosol. In plastids, PEP is used by pyruvate kinase to obtain pyruvate and ATP, or it may enter the aromatic amino acid and secondary metabolites biosynthetic pathway.^[1]

In the cytosol, the situation is more complex. A cytosolic pyruvate kinase may also catalyze the energy-conserving reaction that yields ATP and pyruvate, but PEP can also be used by the ubiquitous cytosolic enzyme PEP carboxylase, which carboxylates PEP to oxaloacetate. PEP carboxylase exists in various isoforms. One is a housekeeping enzyme that has an anapleurotic role and is implicated in providing building blocks for amino acid synthesis; another is a C_4 or CAM plants-specific isoform, present at high levels and implicated in the auxiliary CO_2 fixation mechanisms specific to these plants.^[10] The PEP carboxylase and pyruvate kinase reactions are strictly coordinated through different regulatory mechanisms. Additionally, a third enzyme catalyzes PEP hydrolysis. This enzyme, PEP phosphatase,^[11] has no certain function, but it has been implicated in a bypass reaction of

carbon metabolism under P_i stress, as mentioned above for PFP, in which the nonphosphorylating GaPDH^[6] also intervenes.

Regulation

Regulation of plant glycolysis follows a notably different strategy from that observed in other organisms. One of the main differences is the role of the signal metabolite Fru-2,6- P_2 . In animals, this compound activates PFK and inhibits FBPase. In plants, Fru-2,6- P_2 does not affect cytosolic PFK, whereas it strongly activates PFP and inhibits FBPase.^[1,2] Since PFP is saturated by cytosolic Fru-2,6- P_2 levels, its participation in regulating carbon metabolism *in vivo* has been argued. Recent work shows that physiological concentrations of metabolites—in particular P_i —reduce the affinity of PFP for Fru-1,6- P_2 to the extent that physiological variations of this metabolite could affect glycolysis *in vivo*.^[8] Although plant PFKs are not responsive to Fru-2,6- P_2 , both plastid and cytosolic isoforms show strong inhibition by PEP, which is relieved by P_i .^[1,2] Thus, activity of PFK depends on the activation state of the enzymes involved in PEP metabolism. Within this regulatory scheme, an increase in pyruvate kinase (not sensitive to FBP activation in plants) or PEP carboxylase activity, for instance, would lower PEP levels, thus activating PFK. This bottom-up regulation model clearly differs from the classical top-down scheme proposed for animal glycolysis, in which flow through the lower part of glycolysis depends on the activation state of PFK.

On the other hand, cytosolic pyruvate kinase and PEP carboxylase are subject to a variety of regulatory mechanisms. Depending on the tissue, cytosolic pyruvate kinase is inhibited in a pH-dependent fashion by several tricarboxylic acid cycle intermediates, ATP and notably the amino acids Asp and Glu, linking glycolysis to N metabolism. Accordingly, plant PEP carboxylases are strongly feedback-inhibited by malate and activated by glucose-6-phosphate. This regulation is, in turn, modulated by a sophisticated signal transduction mechanism that affects the phosphorylation state of the enzyme, which is linked to the illumination state of the leaf and other signals.^[10] The reduction state of disulfide groups in glycolytic enzymes has also been implicated in regulation, as is the case for plastid and cytosolic GaPDH or PFP, which are activated by reduction.

GLYCOLYSIS AND CROP PRODUCTIVITY

Given the widespread impact of the glycolytic pathway in the general metabolism of plant cells, it is not surprising that an important effort is being conducted to fully understand its operation. The beneficial aspects of the potential manipulation of plant glycolysis are not restricted

to higher crop yields in terms of total starch or sucrose produced; a change in the nutritional content of crop plants is also possible as a result of the cross talk with nitrogen and lipid metabolisms.

Herbicide-Resistant Crops, Impact of

Micheal D. K. Owen

Iowa State University, Ames, Iowa, U.S.A.

INTRODUCTION

Food production necessary to meet the growing demands of the world population is a critical issue today and will continue to be a concern in the future. One of the most important constraints on efficient food production is the ability to effectively manage weeds. If weeds are not managed, no food can be produced. Weeding crops has required more expenditure of energy and time than any other task. Historically, man has managed weeds by hand. Mechanical weed management began a new era in crop production efficiency. In the mid-20th century, the management of weeds with herbicides dramatically improved crop production efficiency. The next technological step in weed management is the development of herbicide-resistant crops.

TRANSGENES AND CROPS

The ability to transform plants by the introduction of selected genetic characteristics has dramatically changed the ability of plant breeders to improve agronomic crops.^[1] The first genetically modified (GM) crops contained transgenes that conferred resistance to herbicides, diseases, or insects.^[2] Commercial utilization of GM crops has increased to over 52 million ha worldwide with most of the increase occurring in the industrialized countries.^[3] However, proponents of biotechnology suggest that increases in yields and quality attributable to GM crops will also be critically important to developing countries.^[4-6]

The adoption of GM crops is thought by some to be environmentally benign or beneficial, but there is concern that there may be some undesirable impacts with commercial-scale GM crop production.^[2] The inclusion of transgenes that code of the *Bacillus thuringiensis* protein has resulted in reduced use of insecticides. Transgenes that result in glyphosate resistance in crops allow growers to use glyphosate for weed management. Glyphosate is suggested to be an environmentally safer herbicide. However, there are concerns that the inclusion of transgenes that code for protein may cause a hypoallergenic reaction in some people. Interestingly, there has not been a

general societal consensus that reflects the attitude toward GM crops despite the unprecedented adoption of the technology by industrialized agriculture.^[7]

One of the most important and widely successful concepts resulting from transgene technology confers herbicide resistance (HR) to crops. However, herbicide resistance also has been introduced into crops with traditional breeding techniques. Herbicide-resistant maize (*Zea mays*), soybean (*Glycine max*), canola (*Brassica napus*), rice (*Oryza sativa*), and cotton (*Gossypium hirsutum*) are widely planted in North America, and HR sugar beets (*Beta vulgaris*) and wheat (*Triticum aestivum*) are likely to be introduced commercially in the near future.^[8] A primary benefit attributed to HR crops is the ability to use environmentally benign herbicides. Given the public concerns about herbicide use, this is an important consideration supporting the adoption of HR crops.^[9] Other benefits supporting the adoption of HR crops include selective herbicides where none were previously available, choices of cheaper herbicides, ease or simplicity of weed management, increased adoption of tillage practices that minimize soil erosion and improve soil quality, and the elimination of herbicide injury to crops.

Herbicides are the primary, if not sole tactic used to control weeds in most crops including HR crops. Farmers in the United States apply herbicides to more than 220 million crop acres at a cost of \$6.6 billion.^[10] The adoption of HR crops will increase the emphasis on herbicidal weed control and undoubtedly focus on a few herbicides. This paper will report on the implications of HR crops on agriculture and review the implications of this technology on agroecosystems and the socioeconomic aspects of an agriculture that is based on HR technology.

WEED MANAGEMENT WITH HERBICIDE-RESISTANT CROPS

Fundamentally, weed management with HR crops is no different than using other selective herbicide technologies—a herbicide is applied to the crop, and the weeds are selectively controlled. The difference is how selectivity between crops and weeds is achieved.^[11] For most herbicides, selectivity between crops and weeds is the

result of differential abilities to metabolize the herbicide to nonactive products. Crops are able to more effectively and efficiently metabolize the herbicide than the weeds. Differential metabolism of herbicides is influenced by a number of factors including application timing relative to crop and weed stage of development and the overall growth conditions of the plants. The insertion of transgenes, or selection for critical plant enzymes through traditional breeding programs, greatly elevates the differential response of the HR crop and weeds. The mechanism by which the HR crop is protected from the herbicide is either by an alteration of the target enzyme (i.e., glyphosate resistance in soybean) or by the addition of genetic code that allows the crop plant to metabolize the herbicide (i.e., glufosinate in maize).

As the utilization of HR crops does nothing to change the emphasis on herbicides for weed control, public concerns for the negative impacts of herbicides on health and the environment cannot be discounted.^[12] Furthermore, whereas the use of herbicides and HR crops are described to be generally beneficial to the environment,^[12] provide lower cost of weed management, and allow the farmer to use simpler weed management tactics,^[13] there are consequences from using HR crops and herbicides on weed management and weed populations.

These consequences include weed population shifts that favor weed species not effectively managed by the target herbicide,^[14] the evolution of biotypes resistant to the target herbicide,^[13] the hybridization of the HR crops with closely related weed species and the potential to confer resistance to the resultant progeny,^[15] the likelihood that volunteer crops will become HR weeds in rotational crops,^[14] and the potential for the HR crops to contaminate non-HR and organically produced crops because of the inability to segregate grain^[7] or via pollen movement.^[16,17] In addition, given that multiple applications of the target herbicides are typically required to provide acceptable weed control, there is a greater opportunity for off-target movement of the herbicide.^[7]

Generally, the adoption of HR crops and subsequent weed control has been a major commercial success.^[11] The ability to use registered herbicides that previously did not provide sufficient selectivity between crops and weeds provides an excellent potential to improve the profitability of agriculture and increase weed management options for farmers.^[14] Furthermore, many crops do not represent a large enough market opportunity for the agrochemical industry either because of the limited hectares grown or an unacceptable risk of crop injury relative to the profit potential from selling an existing herbicide. Thus weed control options are limited in these crops. Developing HR varieties of these crops will improve weed management options and thus increase yields, grain quality, and

profitability.^[16] This is an important opportunity to growers who farm smaller areas to achieve more efficient and less expensive weed management.

IMPACT OF HERBICIDE-RESISTANT CROPS ON CROP PRODUCTION AND ECONOMICS

The adoption of HR crops has largely been driven by the perceived production benefits ascribed to the HR trait. In Western Canada, an estimated 76% of the hectares seeded to canola are HR varieties.^[16] However, most of the HR crop adoption reflects the unprecedented acceptance of HR soybean. An estimated 33.3 million ha of HR soybeans were seeded in 2001 and represented 63% of the GM crops grown worldwide.^[3] Herbicide-resistant maize, canola, cotton, and soybean accounted 77% of the hectares planted to GM crops in 2001. The total area planted to HR crops in 2001 was 40.6 million ha. Other HR crops that are approved for production include carnation (*Dianthus carophyllus*), chicory (*Chichorium intybus*), linseed (*Linum usitatissimum*), and tobacco (*Nicotiana tabacum*).^[3] As many as 14 other crops have transgenic HR cultivars currently under development worldwide.^[2]

In total, HR crops represent a major change in crop production tactics and have required major efforts by regulative groups in the federal government to insure that food safety has not changed because of the inclusion of transgenes.^[18] From a regulatory perspective, HR and non-HR crops are identical. Importantly, the Environmental Protection Agency has determined that the major HR transgenes are safe, and food developed from HR crops was determined to be no different than food derived from non-HR crops. Canadian regulatory authorities determined that the glyphosate-resistant canola was the same as other cultivars after conducting an extensive series of compositional, processing, and feeding studies.^[19] There can be, however, pleiotropic consequences to the addition of the transgene in HR crops.^[20]

The economic impact of HR crops on the global agricultural economy is debatable.^[8] Farmers and manufacturers of the HR crops report that there are clear and consistent savings in weed management costs compared with weed management not based on HR technology. However, economic analysis suggests that only the manufacturers gained from the HR technology, and farmers received no additional return on their investment when compared with non-HR crops.^[21,22] Furthermore, HR crops may actually incur greater production costs if acceptable tolerances for contamination/segregation (pollen and grain) are not established.^[23] The movement of the HR pollen into non-HR crops can result in contam-

ination of the grain. In addition, the grain-handling industry is not currently able to segregate HR grain from non-HR grain, further increasing the risk of contamination and subsequent economic penalty to the producers.

CONCLUSION

There can be no question that the development of HR technologies has been one of the most important and contentious changes in agriculture. Whereas the adoption of HR technology by farmers has been unprecedented worldwide, acceptance of the technology by consumers is less clear. In fact, the issues about the benefits and risks of HR crops are similar to those voiced by consumers about the adoption of pesticide technologies.^[24] On the other hand, the introduction of HR traits by transgene technology could not be readily accomplished by traditional crop breeding tactics, with the exception of resistance to imidazolinone herbicides in several crops. Regardless, the resultant HR traits are portrayed as environmentally and economically beneficial;^[25] reports also suggest that the HR crops may have inherent economic risks for growers.^[4,21–23] A major component of the debate is that the HR trait is based on herbicidal weed management. The historic baggage of the herbicide use debate has not placed the HR crops in a positive position with the consumers. However, it is clear that farmers have decided that HR crops represent an important benefit to agriculture.

It is interesting to note that the technology that allowed the development of HR crops is predicted to provide new weed management tools not based on herbicides. Three novel approaches to utilizing transgene technology in weed management were reported by Gressel.^[26] These were the alteration of biocontrol agents to improve their effectiveness, the use of transgenes to develop more competitive crop either by improving the growth habit or allowing the production of natural allelochemicals, or the alteration of cover crops to make them more applicable in weed management. Thus, whereas it is unclear what the future impact of HR crops will be on world food production, it is clear that transgene technology will play an important role.

Herbicide-Resistant Weeds

Carol Mallory-Smith

Oregon State University, Corvallis, Oregon, U.S.A.

INTRODUCTION

The introduction of synthetic herbicides revolutionized weed control. However, the repeated use of herbicides led to the selection of herbicide-resistant weeds. The selection of resistant weeds reduces control options and may increase control costs. In many cases, the most effective and economical herbicide is lost because of resistance. Herbicide-resistant weeds are one of the major challenges in weed management. Although resistance presents a challenge, herbicide-resistant weeds can be controlled with herbicides with different sites of action or other methods of weed control.

BACKGROUND INFORMATION

Herbicide resistance is the inherited ability of a biotype to survive and reproduce following exposure to a dose of a herbicide that is normally lethal to the wild type.^[1] Herbicide resistance is an evolved response to selection pressure by a herbicide.

Herbicide-resistant biotypes may be present in a weed population in very small numbers. The repeated use of one herbicide or herbicides with the same site of action allows these resistant plants to survive and reproduce. The number of resistant plants increases until the herbicide is no longer effective. There is no evidence that the herbicide causes the mutations that lead to resistance.

Cross-resistance is the expression of one mechanism that provides plants with the ability to withstand herbicides from different chemical classes.^[2] For example, a single point mutation in the enzyme acetolactate synthase (ALS) may provide resistance to five different chemical classes including the widely used sulfonylurea and imidazolinone herbicides.^[3] However, cross-resistance at the whole-plant level is difficult to predict because a different point mutation in the ALS enzyme may provide resistance to one chemical class and not others. Cross-resistance also can result from increased metabolic activity that leads to detoxification of herbicides from different chemical classes.

Multiple-resistance is the expression of more than one mechanism that provides plants with the ability to withstand herbicides from different chemical classes.^[2] Weed

populations may have simultaneous resistance to many herbicides. For example, a common waterhemp (*Amaranthus rudis*) population in Illinois is resistant to triazine and ALS-inhibiting herbicide classes. However, resistance to these two different classes of herbicides is endowed by two different mechanisms within the same plant.^[4] The weed species has two target site mutations, one for each herbicide class. An annual ryegrass (*Lolium rigidum* Gaud.) population in Australia is resistant to at least nine different herbicide classes.^[5] In this case, herbicide options may become very limited. As with cross-resistance, multiple-resistance is difficult to predict; therefore, management of weeds with these types of resistance is complicated.

HISTORY OF HERBICIDE RESISTANCE

It was not long after the commercial use of herbicides that Able^[6] and Harper^[7] discussed the potential for weeds to evolve resistance. However, the first well-documented example for the selection of a herbicide-resistant weed was triazine-resistant common groundsel (*Senecio vulgaris* L.), which was identified in 1968 in Washington State.^[8] The resistant biotype was found in a nursery that had been treated once or twice annually for 10 years with triazine herbicides. There were earlier reports of differential responses within weed species, but these variable responses to herbicides were not necessarily attributed to resistance.^[8]

To date, 281 herbicide-resistant biotypes from 168 species have been identified.^[9] The reason that the biotype number and the species number are different is that the same species has been identified with resistance to different herbicides in different locations. Of the 168 species, 100 are dicots and 68 monocots. Resistance has occurred to most herbicide chemical families.

MECHANISMS RESPONSIBLE FOR RESISTANCE

Several mechanisms theoretically could be responsible for herbicide resistance. Those mechanisms include reduced herbicide uptake, reduced herbicide translocation,

herbicide sequestration, herbicide target-site mutation, and herbicide detoxification. In the cases where the resistance mechanism has been determined, the mechanism responsible in most instances has been either target-site mutations or detoxification by metabolism.^[10]

Target-site mutations have been identified in weeds resistant to herbicides that inhibit photosynthesis, microtubule assembly, or amino acid production. Most often there is a point mutation, a single nucleotide change, which results in an amino acid change and is responsible for the resistance.^[10] The shape of the herbicide binding site is modified and the herbicide can no longer bind.

Metabolism-based resistance does not involve the binding site of the herbicide, but instead the herbicide is broken down by biochemical processes that make it less toxic to the plant. Several groups of enzymes are involved in the process. Enzymes that are thought to be most important in herbicide metabolism are glutathione *S*-transferases and cytochrome P450 monooxygenases.^[11,12]

FACTORS THAT INFLUENCE THE SELECTION OF RESISTANT BIOTYPES

Resistance usually occurs when a herbicide has been used repeatedly, either year after year or multiple times during a year, and the herbicide is highly effective, killing more than 90% of the treated weeds. The more effective a herbicide, the higher the selection pressure for resistance. Therefore, all herbicides do not exert the same selection pressure.

If a herbicide has only one site of action, it is easier to select a resistant biotype because only one mutation is needed. A herbicide that has soil residual activity will provide more selection pressure because the herbicide remains in the environment and any new seedlings will be exposed to the herbicide. If a herbicide has a very short residual, repeated applications during one growing season can have the same effect.

Herbicide factors influence the selection of herbicide-resistant weeds, but agronomic factors can also be important. Many resistant weed species have been selected in monoculture production systems. These systems result in the repeated use of the same herbicide. The increased reliance on herbicides for weed control along with a concurrent decrease in other weed management tactics further increases selection of resistant biotypes. The introduction of herbicide-resistant crops also increased the use of a single herbicide with decreased alternative controls.

Some weed species seem to be more prone to herbicide resistance than others. Some species have increased mutation rates or increased genetic variability. Increased variability is usually found in cross-pollinating species.

Selection of resistant biotypes varies depending upon how likely it is for the resistance mutation to be lethal.

Weeds that produce more than one generation per year may be exposed to herbicides with the same site of action more often than those that produce only one generation per year. Because the selection of a resistant biotype is dependent on the number of individuals that are exposed to the herbicide, those weed species that produce more seeds may also produce a resistant individual more quickly.

Breeding systems and inheritance of the trait will influence how fast resistance spreads once it occurs. If the trait is controlled by one recessive gene, the heterozygote and the homozygote dominant plants will be susceptible, so only $\frac{1}{4}$ of the population will survive herbicide treatment. If the trait is dominant, the heterozygote and the homozygote dominant plants will be resistant, and the population will build quickly because $\frac{3}{4}$ of the plants will survive herbicide treatment. The trait will be readily moved within and between populations if the weed species outcrosses. In a selfing population, the trait will have reduced movement with pollen. Maternal inheritance will prevent herbicide resistance from moving with the pollen. An example of maternal inheritance is triazine resistance.^[13]

Fitness is the reproductive ability of an individual, and competitive ability is the capacity of a plant to acquire resources. Initially, researchers assumed that herbicide-resistant weed species would have reduced fitness and competitive ability. Indeed, triazine-resistant weed species do have reduced growth and competitive ability.^[14–16] However, weeds resistant to ALS-inhibiting herbicides have not consistently had reduced fitness or competitive ability.^[17,18]

Refuges are a common tactic for the management of insect and pathogen resistance. Susceptible populations are maintained in surrounding areas and can be used to swamp resistance alleles. Generally, pollen and seed are not sufficiently mobile to swamp resistant weed populations. Migration is probably more important in the movement of resistance to a susceptible population than vice versa. This is particularly true with the tumbleweeds. Long-distance movement of a herbicide resistance gene out of an area is most likely to occur through seed movement.

PREVENTION AND MANAGEMENT OF HERBICIDE-RESISTANT WEEDS

Any management strategy that reduces the selection pressure from a herbicide will reduce the selection for a herbicide-resistant weed in the system. Recommendations for the prevention or management of herbicide-resistant weeds are often the same.^[1] The recommendations from

the herbicide industry and university personnel include many common factors. Common recommendations are to rotate herbicides with different sites of action to reduce selection pressure, to use short-residual herbicides so that selection pressure during a cropping season is reduced, to use multiple weed-control methods in conjunction with herbicides, and to plant certified crop seed so that herbicide-resistant weed seeds are not introduced into a field. Growers need to keep accurate records of herbicides that have been used on a field so that they can adopt a weed management plan that reduces the selection of herbicide-resistant weeds. The integration of these recommendations will reduce selection pressure for herbicide-resistant weeds.

CONCLUSION

Herbicide-resistant weeds will continue to be an issue for weed management as long as herbicides are used for weed control. Herbicide-resistant weeds can be managed, and no herbicides have been removed from the marketplace because of resistance. When growers use multiple weed-management techniques, the selection of herbicide-resistant weeds is reduced. An integrated approach using crop rotation, herbicides with different sites of action, and alternative weed control such as physical and mechanical weed control is useful in both the prevention of herbicide-resistant weeds and the management of herbicide-resistant weeds if they do occur.

Herbicides in the Environment: Fate of

Kim A. Anderson

Jennifer L. Schaeffer

Oregon State University, Corvallis, Oregon, U.S.A.

INTRODUCTION

Herbicides are an integral part of our society; they are used by the general public, governments, institutions, foresters, and farmers. The benefits of herbicides need to be delivered without posing unacceptable risk to non-target sites. Therefore, understanding (and predicting) the environmental fate of herbicides is critically important. Environmental fate is determined by the individual fate processes of transformation and transport. Chemical and physical processes are primary determinants of transformation and transport of herbicides applied to soils and plants. Transformation determines what herbicides are degraded to in the environment and how quickly, while transport determines where herbicides move in the environment and how quickly. Jointly, these processes affect how much of a pesticide and its metabolites (degradation products) are present in the environment, where, and for how long. Herbicide fate also varies in response to changes in environmental conditions and application management practices (e.g., spray drift, volatilization), so it is important to understand these variables as well.

Major environmental compartments for herbicides can be considered as surface waters, the subsurface (soil and groundwater), and the atmosphere. Each medium has its own unique characteristics; however, there are many similarities when considering herbicide movement. Herbicides are rarely restricted to only one medium; therefore, chemical exchange among the compartments must be considered.

Wind erosion, volatilization, photo-degradation, runoff, plant uptake, sorption to soil, microbial or chemical degradation and leaching are potential pathways for loss from an application site. Chemical and microbial degradation are critically important factors in the fate of herbicides. Chemical conditions in soil are important secondary determinants of herbicide transport and fate. The importance of interactions between herbicides and solid phases of soils, soil water, and air within and above soil depends on a variety of chemical factors. Adsorption of herbicides from soil water to soil particle is one of the

most important chemical determinants that limit mobility in soils. Environmental fate of herbicides depends on the chemical transformations, degradation, and transport in each environmental compartment.

TRANSFORMATION

Transformations determine how long a herbicide will stay in the environment. Molecular interactions of herbicides are based in part on the herbicide's chemical nature and are predicated on the physical-chemical properties and reactivities of the herbicide. Several generalized exchange processes between compartments are shown in Fig. 1. In order to understand (and therefore predict) environmental fate, the physical-chemical properties of herbicides must be known. Physical-chemical properties such as molecular formula, molecular weight, boiling point, melting point, decomposition point, water solubility, organic solubility, vapor pressure (V_p), Henry's law constant (K_H), octanol/water partitioning (K_{ow}), acidity constant (pK_a), and soil sorption (K_d , K_{oc}) are important in predicting transformations. How some of these chemical-physical properties affect herbicide fate is briefly discussed (Fig. 2). Table 1,^[1-4] demonstrates the wide variation of chemical-physical properties of a selected group of herbicides. Water solubility, the solubility of a herbicide in water at a specific temperature, determines the affinity for aqueous media and affects movement between air, soil, and water compartments. Vapor pressure, the pressure of the vapor of a herbicide at equilibrium with its pure condensed phase, measures a herbicide's tendency to transfer to and from gaseous environmental phases. Vapor pressure is critical for predicting either the equilibrium distribution or the rate of exchange to and from natural waters. Henry's law constant (K_H), the air-water distribution ratio for neutral compounds in dilute solutions in pure water, determines how a chemical will distribute between the gas and aqueous phase at equilibrium. Henry's law constant, therefore, only approximates the air-water partition in natural

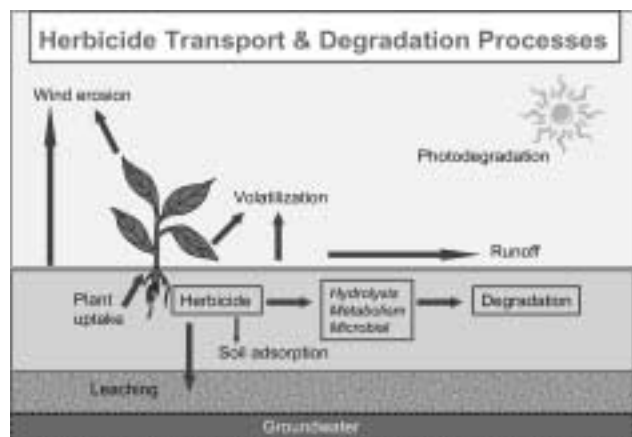

Fig. 1 Illustrated are pathways for loss of herbicide from a herbicide application site. Each pathway (arrow) illustrates a particular loss process occurring at some rate constant (k). The importance of each pathway and magnitude of each rate constant will vary substantially between herbicides and environmental conditions. (View this art in color at www.dekker.com.)

waters. Octanol-water partition coefficient (K_{ow}), the partition of organic compounds between water and octanol, is used to estimate the equilibrium partitioning of nonpolar organic compounds between water and organisms. The octanol-water partition coefficient is also proportional to partitioning of organic compounds

(herbicides) into soil humus and other naturally occurring organic phases.

In the environment, many herbicides are present in a charged state (not neutral). Charged species have different properties and reactivities as compared to their neutral counterparts. Therefore, the extent to which a compound forms ions in environmental ecosystems is important. The pK_a is a measure of the strength of an acid relative to water. Strong organic acids ($pK_a \approx 0-3$) in ambient natural waters (pH 4-9) will be present predominantly as anions. Conversely, very weak acids ($pK_a \geq 12$) in ambient natural waters will be present in their associated form (neutral). In an analogous fashion, strong bases ($pK_a \geq 11$) will be present as ions.^[5] Examples of weak acids are 2,4-D and triclopyr, and examples of weak bases are atrazine, dicamba, and simazine (Table 1).

Sorption of a herbicide is when the herbicide binds to the soil or sediment particles (K_d). Soil sorption is an important process since it can dramatically affect herbicide fate. Figure 2 illustrates the relationship between herbicides sorbed to soil particles versus those dissolved in soil water. Soil sorption is dependent on soil type and influenced heavily by the organic matter content. Typically, soils high in clay and organic matter have a higher sorption capacity. To account for organic matter content, sorption is sometimes normalized for % organic matter, referred to as K_{oc} . K_d , K_H , and V_p describe the potential for exchange of herbicide compounds between soil, water, and air over short distances

Fig. 2 Illustrated are pathways for transformation processes for loss of herbicide from a herbicide application site. Each pathway (arrow) illustrates a particular loss process occurring at some rate constant (k). The importance of each pathway and magnitude of each rate constant will vary substantially between herbicides and environmental conditions. (View this art in color at www.dekker.com.)

by diffusion. Transport over longer distances involves mass transfer (advection-dispersion).

TRANSPORT

Transport of herbicides from runoff from soil is an important route of entry into surface waters. Herbicide runoff can be classified into two categories: herbicides that are either dissolved or suspended in runoff waters. Dissolved herbicides are characterized by low adsorption and high water solubility, while suspended herbicides are characterized by high soil sorption. Leaching depends strongly on local environmental conditions, such as percolation rates through local soils. Adsorption decreases herbicide leaching mobility by reducing the amount of herbicide available to the percolating soil water. However, herbicide runoff and leaching also are controlled by the amount of herbicide degradation.

DEGRADATION

Herbicide degradation ultimately ends with the formation of simple stable compounds, such as carbon dioxide; however, there are intermediates of varying stability on the way to complete mineralization (e.g., H_2O and CO_2). The rate of degradation of a particular herbicide can vary widely. The chemical nature of the herbicide is important, as discussed previously, but the degradation rate also depends on the availability of other reactants, as well as environmental factors. There are three major degradation pathways for herbicides: photo-degradation, chemical degradation, and microbial degradation.

Photo-degradation is the breakdown of a herbicide by sunlight at the plant, soil, or water surface. Direct photolysis occurs when the herbicide absorbs light (some portion of the solar spectrum), and this leads to dissociation of some kind (e.g., bonds break). Indirect photolysis occurs when a sensitizer molecule is radiatively excited and is sufficiently long-lived to transfer energy, such as an electron, a hydrogen atom, or a proton to another "receptor" molecule. The receptor molecule (herbicide), without directly absorbing radiation, can be activated via the "sensitizer" molecule to undergo dissociation or other kinds of chemical reactions leading to photo-degradation.

Chemical degradation is the breakdown of herbicides by processes not involving living organisms (abiotic). Hydrolysis may be one of the more important mechanisms

of degradation for herbicides. Hydrolysis is the reaction of a herbicide where water interacts with the herbicide, replacing a portion of the molecule with OH. The following functional groups and chemical classes are known to be susceptible to hydrolysis: ethers, amides, phenylurea compounds, nitrile, carbamates, thiocarbamates, and triazines. Hydrolysis is influenced by environmental conditions including pH, water hardness, dissolved organic matter, dissolved metals, and temperature. Half life ($t_{1/2}$) is the amount of time it takes the parent compound (herbicide) to decay to half its original concentration. The half life for chemical degradation via the hydrolysis pathway is strongly dependent on environmental conditions. For example, the $t_{1/2}$ for 2,4-D at pH 6 is four years, while the $t_{1/2}$ at pH 9 is 37 hours.^[6]

Microbial degradation is the breakdown of compounds (herbicides) by microorganisms. Bacteria and fungi are the primary microorganisms responsible for biotransformations (biotic reactions). Rates of microbial degradation are largely determined by environmental conditions such as temperature, pH, reduction-oxidation conditions, moisture, oxygen, organic matter, and food. Complete biodegradation, mineralization, yields carbon dioxide, water, and minerals.

CONCLUSION

The perfect herbicide would be one that controls weeds as necessary and then quickly breaks down and never moves off-site. The development of new herbicides over the last decade has focused in part on minimizing unacceptable risk to non-target sites. This has resulted in the development of more biologically active herbicides that greatly reduce application rates. Other research developments include minimizing the leaching of herbicides. When herbicides are applied in the environment, many transport and transformation processes are involved in their dissipation. Predicting herbicide environmental fate and behavior is complicated and is determined by the chemical processes for each environmental compartment.

In addition to understanding the fate of herbicides in the environment, emerging research also endeavors to look at the risk to non-target organisms. The risk of herbicides to organisms is relative to the bioavailability of the herbicide. Bioavailability may be approximately inversely proportional to K_d . Herbicides with larger K_d 's tend to have lower bioavailability. Along with the determination of transport and transformation chemical processes, understanding the complete risk to non-target sites, therefore, should include the determination of the bioavailability of the herbicide.

Herbs, Spices, and Condiments

Katerina P. Svoboda

Scottish Agricultural College Auchincruive, Ayr, Scotland, U.K.

INTRODUCTION

Herbs and spices include plants whose leaves, stems, flowering tops, fruits, and roots are used—either fresh, dried, or frozen—in seasoning of foods; in the beverage industry; as dietary supplements; in pharmaceutical, perfumery, and cosmetic products; and for numerous other purposes, including dyeing, potpourris, insect deterrents, and aromatherapy. The distinction between culinary herbs and spices is an imprecise one, and recently the most common term used for both groups is “aromatic and medicinal plants.” Scientific and regulatory information is systematically presented and published world-wide at a high rate.

CULINARY HERBS

Culinary herbs are usually defined as edible plants, consumed in small quantities and providing flavor and aroma to foods and beverages.^[1,2] They are predominantly grown in temperate and Mediterranean regions, and can be consumed as vegetables or as condiments. Extracts of these plants, in the form of essential oils and oleoresins, are also increasingly employed in various industries.^[3]

Herbs have been used traditionally for centuries to add flavor to monotonous diets. Onion, garlic, leek, parsley, sage, celery, mustard, dill, and lovage (Fig. 1) can serve as examples. Each country and locality, however, offers the local population a collection of potential herbs, shrubs, and woody plants that have been employed in culinary traditions among ethnic groups. Among culinary herbs, 85 genera are described comprehensively by Small,^[4] who gives examples of traditional herbs, edible sprouts, and edible flowers. Many herbs can contribute significantly to nutrient food value, specifically for their content of vitamins and minerals, and for their antioxidant and/or anticancer properties. Over 100 species of herbs and spices are used to brew tea, but the safety of some of these is open to question. It is important to be sure about high standards for the labeling, safety, and efficacy of any herb obtained on the market.

There are few true varieties of even the most familiar culinary herbs that would pass the rigorous testing applied

to major crops (distinctness, uniformity, and stability). Most named varieties arise from simple selection, and they can display large variation in morphology, physiology, and the chemistry of both primary and secondary metabolites. Many varieties are selected on the basis of their suitability for a particular region, and the behavior of such cultivars in another environment may be quite different. Herbs can be subjected to various treatments such as extraction, distillation, expression, fractionation, purification, concentration, or fermentation (Fig. 2). The extraction process has a big influence on the composition of the resulting extract. It is important to control every part of the process in order to obtain reproducible and commercially marketable extracts.

The commercial growing of a herbal crop requires a stable supply of uniform seeds or propagules. The composition and quantity of flavor and fragrance chemicals in plants changes during the growing season; consequently, harvest time is very important. The effects of fertilizers, herbicides, pesticides, and heavy metals have to be considered for each species. Sun radiation, rain, altitude, and day-length also play an important role in the production of these chemicals in plants, and, finally, post-harvest processing and storage can markedly influence the quality of the final product.

MEDICINAL HERBS

Knowledge of medicinal properties of herbs has been handed down from generation to generation for thousands of years. Ancient herbal records from China, India, and Egypt dating back to 3000–1000 B.C. belong to the oldest archaeological finds. Plants mentioned in Western herbals, mainly by Greek physicians (for example, *De Materia Medica* by Dioscorides, from the 1st century A.D.), followed by herbals from Middle Ages Europe (Gerard, Culpeper), and many new herbals from the 18th and 19th centuries were used continuously until the onset of synthetic medicinal products in the 20th century. These plants are potentially a vast source of new drugs. Thousands of compounds have been isolated and tested for their pharmacological activities: antibacterial, antiviral, antitumor, antiinflammatory, antioxidant, hypo-

Fig. 1 *Levisticum officinale* (lovage) grown for seed. (View this art in color at www.dekker.com.)

glycemic, and antiulcer.^[5] Many other biologically active compounds can be identified, with hallucinogenic, cardiovascular, muscle relaxant, and antileukemic properties. Some 80% of the world's population still relies on traditional, plant-based medicine, despite major advances in developing synthetic drugs. The World Health Organization has compiled a list of 20,000 medicinal plants in use.

Medicinal plants possess therapeutic properties, and many plant species are not just medicinal, but can be used also as herbs or as an edible vegetable. Certain species can be highly poisonous, such as *Hyoscyamus niger* (henbane), *Datura stramonium* (Jimson weed), *Veratrum album* (white hellebore), and *Digitalis lanata*. A large group of herbs is not poisonous, however, and these are widely used for their medicinal properties. Their pharmacological activities depend on plant metabolism products: carbohydrates, lipids, proteins, phenols, coumarins, flavonoids, anthocyanins, tannins, quinones, terpenoids, steroids, and alkaloids.^[6] These plant products form starting materials for the synthesis of drugs, food additives, fragrances and flavors, and insecticides and pesticides.

Claims for the effectiveness and safety of herbal remedies are generally based on historical experience, but therapeutic effects have been recently demonstrated in scientific investigations, and this validation process continues. The world-wide herbal products industry is worth an estimated £11 billion per annum, and this is increasing

at 5–10% per annum. The increased demand for herbal medicines and alternative remedies is driven by consumers for a number of reasons, including an aging population, increased recognition of the importance of diet to long-term health, and an increase in the availability of pharmaceuticals and natural remedies. Significant numbers of herbs (70–90% of 21,000 species used all over the world) are obtained through commercial collection from their natural habitat. The underground parts include the root (*radix*), rhizome (*rhizoma*), tuber (*tuber*), and bulb (*bulbus*); the aerial parts are the leaf (*folium*), herbage (*herba*), flower (*flos*), fruit (*fructus*), seed (*semen*), and bark (*cortex*). There are particular problems in collecting from the wild, including a mistaken identification of the plants leading to poisoning, and the localized extinction of plants leading to reduced biodiversity. At least 150 medicinal and aromatic plant species are threatened as a result of overcollection and destructive harvesting techniques, as well as habitat loss and changes in their area of distribution.

Qualified medical advice should be sought before using the information provided by various books and leaflets. Herbal remedies are very powerful and are not safe simply because they are natural. Standardization is done in order to obtain herbs and their extracts with reproducible therapeutic activity from batch to batch. The herbs and their extracts must not be toxic, must not interact with other medicines that the consumer may be taking, and

Fig. 2 Field-scale mobile distillation equipment for chamomile harvest. Norfolk, UK, summer 2001. (View this art in color at www.dekker.com.)

must not be contaminated with pesticide residues, heavy metals, or microbes. The main concerns involving yeasts and filamentous fungi are caused by species of *Aspergillus*, *Penicillium*, *Mucor*, *Rhizopus*, *Absidia*, *Alternaria*, *Cladosporium*, and *Trichoderma*. Both fresh and dried herbal material can also support heavy bacterial loads. Imported plant material can be of poor quality due to the use of irrigation water contaminated with sewage sludges. The guidelines for good agricultural practice (GAP) for aromatic and medicinal plants in the European Union are intended to be applied to the growing and primary

processing of all these plants used in the food, feed, medicinal, flavoring, cosmetic, and perfume industries.

SPICES

Spices are usually of tropical or subtropical origin, highly aromatic, and with a high percentage of volatile oils.^[7] Spices from plant sources have been used throughout history for their presumed preservative properties, and for

perfumery and flavor purposes. The economies of many countries were based on trade in spices, which brought them wealth and power. At present, the bulk of the world spice trade is concentrated in black and white pepper, clove, nutmeg, cardamom, cinnamon, ginger, mace, and allspice. Accurate statistics are difficult to obtain, because the figures for individual species are not recorded separately. The American Spice Trade Association provides up-to-date information on importing, market trends, quality standards, production, and processing.

Spices can be used either whole or ground, single or blended, or in dried or frozen form. They can be further processed, encapsulated, dispersed, solubilized, and sterilized. Detailed specification standards concerning the amount of volatile oils, total ash, fiber, moisture, specific gravity, and other characteristics are increasingly more strict.

ESSENTIAL OILS

Essential oils are isolated from various parts of the plant: leaves (mint, savory, oregano, lavender), bark and wood (cinnamon, frankincense, juniper), root (vetiver), rhizome (ginger), flower bud (cloves), seed (nutmeg, caraway, dill), or flowers (jasmine, roses). Over 3000 es-

sential oils have been identified from a vast number of plants belonging to some 87 families. The knowledge of botany, taxonomy, chemotaxonomy, and biochemistry greatly added to the production and utilization of these oils in the food, drink, pharmaceutical, and cosmetics industries.

Accumulation and secretion of volatile oils in plants is generally associated with the presence of glandular structures, either external or internal, such as oil cells, glands, glandular hairs, resin ducts, canals, and laticifers.^[8] It is assumed that the volatile oils are produced within the secretory cells of these structures, which are characteristic for each plant species (Fig. 3). Extraction techniques (using olive oil, for example) and basic distillation have been known since pre-Christian times. Considerable improvement and development occurred from the 14th century, when various pharmacies started to prepare plant-based oil remedies. In the first half of the 19th century the production of essential oils was industrialized and was followed by isolation of single organic compounds from the oil (e.g., cinnamaldehyde from cinnamon oil). Later, the first synthetic aroma molecules were synthesized by the chemical industry. At present, thousands of flavor and fragrance molecules have been isolated, and their structures have been elucidated. Consequently, these molecules can be synthesized. Natural products are obtained directly from plant sources. Nature-

Fig. 3 Stalked and sessile secretory cells ($\times 437$) on the flower surface of *Salvia sclarea* (clary sage).

identical compounds are produced synthetically, and they are chemically identical to their natural counterparts. Artificial flavor substances have not been yet identified in plant or animal products, but they are produced artificially.^[9] Lists of approved flavoring substances (GRAS—generally recognized as safe) are published in the CFR (Code of Federal Regulations of the U.S.A.); by the FEMA (Flavor and Extract Manufacturers Association of the United States); and by EC Regulation No. 2232/96. Hundreds of monographs on fragrance material and essential oils have been published by the Research Institute for Fragrance Materials in Food and Chemical Toxicology.

CONDIMENTS

The word condiment is derived from the Latin *condimentum*, which means seasoning, and from *condire*, which means to pickle. Salt, pepper, mustard, various sauces derived from fruit, vegetables, herbs and spices (soya, horseradish, wasabi, mooli, onion, garlic, chilli, mint, cranberry, dill, watercress, curry, basil), chutneys, relishes, and preserves belong to this group. Practically any type of herb or spice can be used for flavor, preserves, spiced sauces, and drinks.^[10]

Heterosis: Effects of Long-Term Selection

O. S. Smith

Pioneer Hi-Bred International, Johnston, Iowa, U.S.A.

INTRODUCTION

Hybrid vigor or heterosis in plant hybrids was first studied by Koelreuter in 1763. The commercial utility of heterosis traces back to the studies of the effects of cross- and self-fertilization in maize, done by E. M. East and G. H. Shull in the early 1900s. This work led to the development of hybrid maize, which by the 1940s had replaced open pollinated varieties of maize in the United States. Almost immediately after the discovery of the commercial utility of heterosis, studies were undertaken to understand the genetic basis of heterosis. For many years these studies attempted to determine the underlying cause of heterosis focusing on the dominance hypothesis vs. the overdominance hypothesis. Numerous scientific conferences have been held on heterosis starting with the Heterosis Conference held in Ames, Iowa, in 1950, where a relatively young scientist by the name of James Crow gave a presentation on "Dominance and Overdominance" and concluded that based on the then available information overdominance was likely a major contributor to heterosis in maize. G. F. Sprague also gave a presentation at this conference entitled "Early Testing and Recurrent Selection," detailing the results of recurrent selection studies (started in the early 1940s) as a method of developing improved source populations. Two long-term recurrent selection programs in maize that were initiated in the 1950s, as well as other shorter term programs, have allowed the examination of the effects of long-term selection on heterosis in species of agronomic importance. In addition, several long-term selection studies have been conducted in model species, i.e., *Drosophila* sp. and *Tribolium* to look at the effects of recurrent selection on heterosis.

HETEROSIS AND RECURRENT SELECTION

East and Hayes at the turn of the century demonstrated the importance of heterosis in maize.^[1] Crow^[2] argued that the large amount of heterosis in maize was likely due to overdominant gene action (but see Ref.^[3]) and Sprague^[4] demonstrated the effects of recurrent selection in the parental populations on the performance of the population cross. Falconer^[5] and Wilhelm and Pollack^[6] developed single locus heterosis

theory, which demonstrated that the heterosis in an F_1 cross, whether the F_1 is a cross between two inbred parents or a cross between two random mating populations, is a function of the difference in allele frequencies in the parents and the degree of directional dominance. More recent work^[6] has shown that both additive-by-additive and dominance-by-dominance types of epistasis for loci showing differences in allelic frequencies also contribute to the observed heterosis.

Reciprocal recurrent selection (RRS)^[7] was proposed as a breeding method that would utilize all types of gene action in simultaneous improvement of two populations where the goal was to develop hybrids. After RRS was proposed several long-term selection programs, involving several species, were initiated to examine the efficiency of RRS and to look at the performance of the improved population hybrids.^[8-11] In general, the population crosses showed a linear response to selection with little or no gains in the populations per se. Therefore, there is an increase in heterosis in the population cross for these populations undergoing selection. The increase in performance of the population cross for the maize populations involved in RRS does not appear to be specific to the populations involved in the RRS programs. In two of these programs the population cross between populations undergoing intrapopulation improvement, Jarvis(FS) and Indian Chief(FS), showed nearly identical response to selection in crosses with each other, and with the version of these populations undergoing RRS. This rate of improvement was comparable to the rate of improvement in the population cross developed from the versions of these populations undergoing RRS. This was also true for the BSSS(R) and BSSS(HT) (RRS and half sib selection with a double cross tester) populations when crossed to BSCB1(R), the reciprocal population in the Iowa State RRS program. The change in heterosis for the population cross was not quite as great as for the populations undergoing interpopulation improvement as for populations undergoing intrapopulation improvement. The improvement in the populations per se was greater for the interpopulation vs. intrapopulation improvement programs. For both selection schemes, the expectation is that favorable alleles for genes with additive and or partial dominance effects will move to fixation for the favorable allele. However, for loci showing complete dominance,

as soon as the favorable allele becomes fixed in one of the populations undergoing RRS, the selection differential goes to zero^[12] and the allele in the second population changes randomly due to drift and may even be lost from the population, depending on the allele frequency at the time the favorable allele is fixed in the other population. For loci showing overdominance or pseudo-overdominance, the expectation is for different alleles to be fixed in the two populations undergoing RRS but stay at intermediate frequencies in the populations undergoing intrapopulation improvement. Smith^[13,14] and Hanson^[15] proposed two different methods to look at the changes in heterosis in long-term selection populations. The method by Smith is based on linear functions of population and population cross means to estimate changes in allele frequencies of alleles with additive and dominance effects, changes in heterosis effects, as a function of differences in allele frequency changes in the two populations undergoing selection, and effects due to drift resulting from finite population sizes. This analysis is based on a genetic model that includes simple additive and dominance effects, and multiple alleles. Individual loci effects are then summed over loci and no epistatic effects are included. This analysis has been used to analyze several populations undergoing long-term selection and has shown that the increases in heterosis in the long-term selection populations can be attributed to the effects of drift, whereas significant changes in the amount of heterosis due to selection have not been observed. The analysis proposed by Hanson is based on using diallel crosses to estimate the divergence of the populations undergoing selection as a function of changes in allele frequencies of alleles showing nonadditive effects, i.e., dominance and epistasis. This analysis has demonstrated that the genetic distance between these long-term populations has increased and that there has been an increase in heterosis in the population cross. However, the analysis does not determine if the changes in allele frequencies are a function of drift or selection. The changes in allele frequencies have been examined in the long-term RRS program involving the Iowa Stiff Stalk BSSS(R) and BSCB1(R) populations with the use of molecular markers.^[16] The analysis indicated that these two populations are moving toward fixation of different alleles in the two populations. Some of the allele frequency changes appear to be due to selection, whereas drift effects could not be ruled out as contributing to changes in allele frequencies at the majority of the loci that showed allele frequency changes.

The results of these and other studies in model species demonstrate that recurrent selection is effective in increasing the heterosis in population crosses of these populations. However, because so little is still known about the genetics of heterosis, and due to

the effects of finite population size on allele frequency changes, it is not known precisely what the effects of the long-term selection on the phenomenon of heterosis are. These long-term selection populations should be extremely valuable resources as new molecular tools are applied to provide a better understanding of the genetics and of the molecular basis of heterosis. Recent studies have pointed to two areas that may be important to the understanding of heterosis, allele specific expression^[17] and the lack of microsynteny.^[18,19]

Human Cholinesterases from Plants for Detoxification

Tsafrir S. Mor

Arizona State University, Tempe, Arizona, U.S.A.

Hermona Soreq

The Hebrew University of Jerusalem, Jerusalem, Israel

INTRODUCTION

Acetylcholinesterase (AChE) is a major component of central and peripheral neurotransmission, terminating signals at cholinergic synapses by hydrolyzing the neurotransmitter acetylcholine. During the past decade, nonenzymatic roles for AChE and the homologous enzyme butyrylcholinesterase (BChE) were recognized. Cholinesterases in the bloodstream may play a protective role by metabolic inactivation of many nerve agents, including natural and synthetic anticholinesterases (e.g., organophosphate nerve gases and pesticides), street drugs (e.g., cocaine and heroin), and muscle relaxants (e.g., succinylcholine). The use of exogenously applied cholinesterase in treatment and prevention of intoxication by these toxicants is being evaluated. For therapy based on cholinesterases to be feasible, large amounts of properly folded and stable enzymatic preparations that are free of mammalian pathogens are needed. Transgenic plants are emerging as one of the more promising alternative production systems for pharmaceutically important proteins; however, very little is known about the rules controlling posttranslational processing of such proteins, including protein folding, glycosylation, etc. Human AChE in tomato plants has recently been expressed; this system is being evaluated as an expression system for other variants of cholinesterases. Beyond the importance of these cholinesterases as scavengers of a wide scope of toxicants, these enzymes are an excellent model for studying posttranslational modifications of recombinant proteins produced in plants.

HUMAN CHOLINESTERASES

Cholinesterases (ChEs) can be distinguished by their substrate and inhibitor-binding specificities.^[1–3] The hydrolytic activity of acetylcholinesterase (AChE) is limited to the neurotransmitter acetylcholine (ACh) which selectively interacts with a narrow group of inhibitors.^[1,2] Mammals possess a homologous serum enzyme—butyrylcholinesterase (BChE)—that has a broader catalytic

spectrum with preference for longer-chain substrates^[3] and noncholine substrates such as cocaine.^[4,5]

In humans, AChE and BChE are encoded by single genes, with the primary transcript of the *ACHE* gene subjected to alternative splicing, yielding three mRNA variants resulting in three protein isoforms with distinct C-termini with clearly defined spatiotemporal expression patterns, subunit structures, subcellular localization, and subtly different enzymatic properties. (Fig. 1).^[6] The catalytic core of human AChE, common to all variants, is sufficient for ACh hydrolysis. Posttranslational modifications of ChEs include glycosylation oligomerization and membrane anchoring via protein-protein interactions (AChE-S) or a glycolipid (AChE-E).^[7]

Exposure to anti-AChE agents leads to overstimulation of cholinergic pathways and potentially death.^[2] Whereas some naturally occurring AChE inhibitors are very potent, clinically relevant human exposure to them is rare. However, synthetic anti-AChE compounds—especially organophosphates (OPs)—are widely used as pesticides and pose a substantial occupational and environmental risk. Even more ominous is the fear of deliberate use of OPs as chemical warfare agents. Current medical intervention in the case of acute exposure to anticholinesterase agents includes use of the muscarinic ACh-receptor antagonist, atropine, and oximes to reactivate the OP-modified AChE. The reversible carbamate pyridostigmine bromide is also used for prophylaxis.^[2] However, these conventional treatments have limited effectiveness and may have serious short- and long-term side effects, including significant performance deficits and even permanent brain damage.

A different approach in treatment and prevention of anti-AChE toxicity seeks to mimic one of the physiological lines of defense. In humans, ChEs can be found in the bloodstream, either in the serum (BChE and AChE-R) or anchored to erythrocytes (AChE-E). Evidence suggests that these enzymes act as scavengers of potentially harmful substances, preventing them from accumulating and reaching their targets. For example, these circulating ChEs can bind and inactivate anticholinesterases, thereby protecting AChE-S, the vital synaptic isoform of AChE.

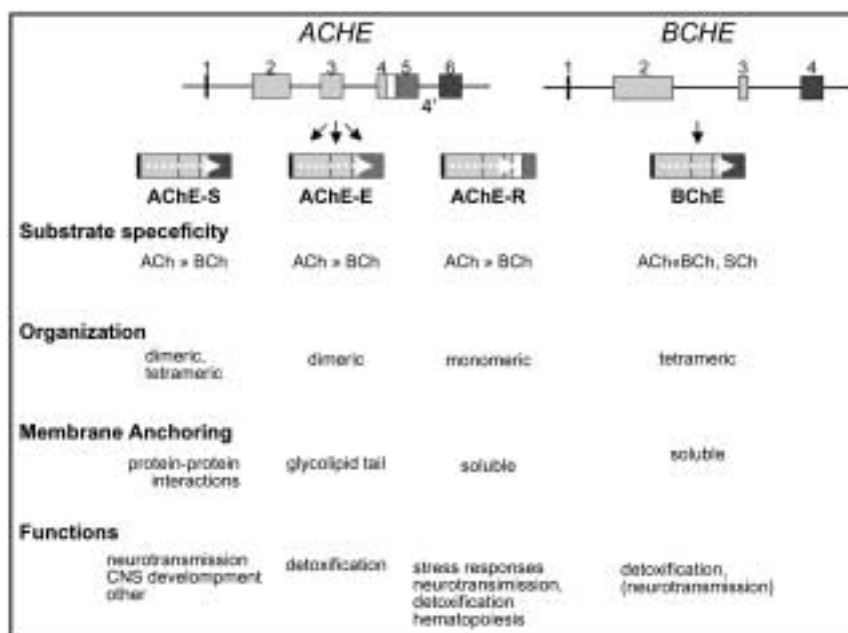

Fig. 1 Molecular biology of human ChEs. 3'-alternative splicing events of the primary transcripts of the *ACHE* gene yield three mRNA species, which give rise to three AChE variants with distinct C-termini. In contrast, transcription and splicing of the *BCHE* gene product results in only one mRNA, giving rise to a single BChE protein. These ChEs have distinct biochemical properties and expression patterns. CNS = central nervous system; NMJ = neuromuscular junction.

Administration of exogenous ChEs to boost the potential of the native circulating enzymes to scavenge anticholinergic agents is an efficacious and safe approach for the treatment of anti-AChE toxicity. The efficacy of this therapeutic paradigm to protect against a challenge of organophosphates was proven in a variety of animal models.^[8,9] Similarly, administered BChE is effective in the metabolic inactivation of cocaine (in case of overdose) and muscle relaxants (e.g., to treat succinylcholine post-anesthesia apnea that occurs in patients with genetic or acquired low-plasma BChE activities).^[4,5]

HUMAN AChE PRODUCTION IN PLANTS

To be used as detoxifiers, ChEs can be purified from human or animal blood, but these sources are supply-limited and have inherent problems (e.g., potential contamination with human pathogens and prions). Various cell cultures have been explored as systems for the production of recombinant ChEs but suffer from disadvantages. Recombinant ChEs expressed in *Escherichia coli* must be denatured and renatured, and even then have only partial activity. In addition, they are extremely labile as compared to the native enzymes.^[10] Production of ChEs by yeast cultures^[10] or in insect cells by the baculovirus vector system^[11] is possible but remained small

scale, perhaps reflecting yield problems. Production in mammalian cell cultures is possible and was extensively studied;^[12] however, the costs of production (and scaling up) as well as the safety of this system are major shortcomings.

We recently introduced transgenic plants as a novel production system for human AChE, when we successfully expressed the catalytic domain of the enzyme (common to all variants) in tomato plants and reported on the initial characterization of this recombinant protein (Fig. 2).^[13] This was the first demonstration of expression in plants of a key protein component of the human nervous system. Some of the transgenic tomato lines express high levels of AChE activity, comparable to those reported for production of the enzyme in yeast. The activity is typical of authentic human AChE activity as judged by its substrate and inhibitor interactions. The plant-derived enzyme is relatively stable in the crude plant extract.^[13] More recently, we introduced the same construct to *Arabidopsis thaliana* and demonstrated the presence of AChE in such putative transformants by activity assays. Indeed, the AChE activities measured in leaf extracts of these plants were higher than previously seen in our best-expressing tomato lines (Fig. 2), probably reflecting the presence of a naturally occurring ChE inhibitor in the tomato extracts (Mor et al., manuscript submitted).

Fig. 2 Expression of core domain of AChE in plants. Leaf extracts of two *Arabidopsis thaliana* AChE transformants, an AChE-expressing tomato plant, and their untransformed (UT) counterparts were assayed for AChE activity. Insert: Plant-derived AChE migrates as a discrete band in nondenaturing gel electrophoresis. Protein samples from the indicated transgenic tomato plant lines, untransformed plant (UT), and a commercially available preparation of AChE-E were resolved on a nondenaturing gel, which was then stained for AChE activity. (View this art in color at www.dekker.com.)

CONCLUSION

Anticipating a growing need for large amounts of ChE that will be properly folded, stable, enzymatically active, and free of mammalian pathogens, we advocate transgenic plants as a suitable system for production of these human enzymes. Our previous results demonstrate that as an expression system for ChEs, the potential of transgenic plants is still far from being fully realized. To make this prospect a reality the system must be optimized to maximize expression of the recombinant protein. For example, we have redesigned the coding regions of the DNA constructs encoding the various AChE isoforms to conform their codon usage to that which prevails in plants and to eliminate deleterious sequences that might hamper their expression in plants. As this encyclopedia goes to print, we are analyzing transgenic plants that harbor these plant-optimized synthetic genes, that show a dramatic increase in their expression levels. We are also exploring various options for targeting the transgenic enzyme to subcellular compartments that would allow maximal accumulation of the recombinant proteins, and for screening for the best host plant species for the purpose. Further challenges include establishing a purification scheme for the recombinant plant-produced AChE (made easier with increased expression levels) and subsequent testing of the enzyme's ability to protect animals from OP intoxication.

In more general terms, whereas the basic requirements for expressing mammalian proteins in plants are quite well

established, little is known of the rules controlling the posttranslational processing events (including protein folding, glycosylation, etc.) that such recombinant proteins undergo in plant cells. ChEs are appropriate models for studying these topics because in mammals they exist as different, wellstudied variants with distinct posttranslational modifications that give them their unique biochemical properties. By biochemical characterization of the plant-produced ChEs and comparison to their native counterparts, important insights can be gained to establish the universal utility of plants for the production of pharmaceutically valuable proteins.

Hypersensitive Response in Plants

Ron Mittler

University of Nevada, Reno, Nevada, U.S.A.

INTRODUCTION

The hypersensitive response is a programmed cell death process activated in many plants in response to pathogen attack. It inhibits the rate of pathogen spread during infection and, in coordination with other defense mechanisms, such as pathogenesis-related proteins and phytoalexins, serves to protect plants from infection by different obligatory pathogens, including viruses, bacteria, and fungi.

BACKGROUND

The hypersensitive response (HR) is a rapid cell death process activated in many plants in response to pathogen attack. During this response, the plant sacrifices some of its cells to circle the invading pathogen with a layer or a ring of dead cells (Fig. 1). It is believed that this response serves to inhibit the growth of the invading pathogen by killing of infected and noninfected cells and producing a physical barrier composed of dead plant cells. The rapid dehydration that follows the death of plant tissue may also have deleterious effects on pathogen growth by limiting the availability of nutrients. During the HR, dying plant cells strengthen their cell walls by deposition of different phenolic compounds, synthesize different toxic compounds called phytoalexins, and accumulate many proteins with antimicrobial activity called pathogenesis-related proteins.^[1,2] Activation of the HR results in the formation of a distinct lesion on leaves or stems, termed a HR lesion (Fig. 1), and the pathogen is generally restricted to this lesion. Many plant pathogens that invade and successfully colonize plants lead eventually to the formation of disease symptoms in the form of lesions or patches of dead cells. However, these mostly develop within days, while HR lesions develop within hours, hence the term “hypersensitive response.”

Different pathogens such as bacteria, fungi, and viruses induce different types of HR cell death with different morphological and physiological characteristics. Nevertheless, it appears as if the sacrifice of cells by the plant to inhibit pathogen growth and prevent systemic infection is the main function of the HR. This function may be similar to the activation of apoptosis or programmed cell death

(PCD) in response to infection with viruses or bacteria in animal cells.^[3,4] Thus activation of cell death as a means of preventing further infection by an invading pathogen appears to be a general theme in the biology of multicellular organisms.

The HR can be very successful in preventing obligate parasites, which absolutely require living cells, from replicating within plant tissues. However, it was recently shown that some pathogens that feed on dead plant tissue (necrotrophic pathogens) deliberately activate the HR of some plants to propagate on the resulting dead plant tissue.^[5]

Genes and Pathways of the Hypersensitive Response

Major players involved in the activation of the HR are reactive oxygen intermediates (ROI), nitric oxide (NO), calcium and proton pumps, mitogen-activated protein kinases (MAPKs), and salicylic acid (SA). It is believed that the initial recognition of the pathogen via a plant-pathogen receptor (part of the gene-for-gene response) activates a signal transduction pathway that involves the translocation of calcium and protons across the plasma membrane into the cytosol, protein phosphorylation/dephosphorylation events, the activation of enzymes that generate ROI such as NADPH-oxidase and peroxidases, and the accumulation of NO and SA.^[6] Manipulations of proton and calcium homeostasis were shown to activate the HR. These include pharmacological studies and the expression in plants of a proton channel that localized to the plasma membrane and activated the HR.^[7] A combination of enhanced production of ROI and NO was also shown to activate the HR in the absence of a pathogen, and SA was shown to facilitate the formation of ROI as well as to inhibit catalase and ascorbate peroxidase, two of the key ROI removal enzymes in plants.^[6,8] These processes are thought to be orchestrated by a cascade of MAPKs.^[9]

Several lines of evidence suggest that the HR results from the activation of a PCD process.^[2,4,10] These include the activation of cell death in the absence of pathogens by mutations in certain genes thought to be involved in the cell death pathway, the activation of cell death upon

Fig. 1 A photograph of a HR lesion, resulting from the infection of a tobacco leaf with tobacco mosaic virus. The diameter of the lesion shown in the photograph is about 0.75 mm.

recognition of elicitors which are compounds produced by the pathogen, and the activation of the HR by expression of different foreign genes in plants. That cell death resembling the HR can be activated in the absence of a pathogen strongly suggests that this type of cell death is not directly caused by the invading pathogen but rather results from the activation of a host-encoded pathway for PCD. Moreover, activation of cell death during the HR was shown to require the activity of the plant transcription and translation machinery.^[11] These findings further suggest that genes encoded by the plant are actively involved in the death of plant cells during the HR.

Perhaps the most compelling evidence that the HR is a PCD process is the existence of mutants that spontaneously activate the HR in the absence of a pathogen.^[2] These mutants are often referred to as “disease lesion mimics.” Two additional terms used to describe these mutants are “accelerated cell death” and “lesion-simulating disease.” The mutations that cause the appearance of HR lesions in the absence of a pathogen are thought to occur in plant genes that control PCD. Thus mutations in these genes would result in the abnormal activation or suppression of pathogen-induced PCD. Disease lesion mimic mutants have been isolated from tomato, maize, barley, rice, and *Arabidopsis*. They were classified according to their appearance into two groups: initiation and feedback or propagation mutants.^[12] This classification is based on the assumption that two mechanisms are involved in coordinating the HR: a pathway for the initiation of PCD and a pathway for the inhibition of cell death.

Cell death mutants are powerful tools for the study of PCD in plants. By crossing of these mutants for complementation studies, the order of the cell death genes along the PCD pathway may be determined.^[13,14] For example, it was recently reported that LSD1, a novel zinc

finger protein that regulates PCD induced by superoxide or pathogen infection, down-regulates a PCD pathway that is driven by ROI, SA, and the plant genes PAD4, EDS1, and NPR1. This pathway is activated in cells that surround the initial infection site. Thus when LSD1 is mutated, it can no longer suppress PCD in these cells, and the lesion that is formed upon infection or superoxide application becomes a runaway cell death process that spreads to the entire leaf instead of being confined to only a few cells.

Programmed Cell Death Genes in the Hypersensitive Response

The sequencing of the entire genome of the flowering plant *Arabidopsis thaliana* failed to identify plant homologs of key regulators of PCD in animals such as caspases, Bcl-2, or Bax. Plants were, however, found to contain a group of proteases called metacaspases, homologs of Bax inhibitor-1 (BI-1), and Defender Against Death-1 (DAD-1).^[15] Molecular and pharmacological studies support the involvement of caspases in the HR (possibly mediated by the metacaspase family). These include the suppression of HR by synthetic peptides that act as inhibitors of caspase activity and measurements of caspase-like protease activity in plant cells undergoing HR-PCD.^[15] Thus in plants, metacaspases may play a similar role to caspases in animals. Additional players that may be similar to some of those controlling PCD in animals are small GTP-binding proteins of the Ras class and cystein-sensitive proteases.

Although Bax homologs were not found in plant cells, expression of Bax in plants induces PCD.^[16] Moreover, this induction requires the proper oligomerization and cellular localization of Bax in plants. The animal protein BI-1 was recently found to inhibit Bax toxicity in yeast. Homologs of this protein were found in plants. Co-expression of Bax and the plant homolog of BI-1 resulted in the inhibition of Bax-induced cell death in plants.^[16] These results as well as the finding that mitochondrial permeability transition and release of cytochrome *c* from mitochondria accompany certain types of PCD in plants suggest an active role for the mitochondria in plant HR-PCD processes. Further support for this hypothesis comes from overexpression of animal anti-apoptotic genes such as Bcl-2, Bcl-X_L, and Cell Death-9 (CED-9) in plants. These were found to inhibit pathogen-induced PCD and oxidative stress-induced PCD in plants.^[17,18] A recent homology search using BI-1 sequences revealed the possible existence of a functional homolog of Bcl-2 in plants (called ABR proteins; Ref. [15]). However, further experimental work is required to support this possibility.

CONCLUSION

The hypersensitive response is a programmed cell death process activated in different plant tissues in response to pathogen attack. It inhibits the rate of pathogen spread during infection, and in coordination with other defense mechanisms, such as pathogenesis-related proteins and phytoalexins, it serves to protect plants from infection by different obligatory pathogens, including viruses, bacteria, and fungi.

In Situ Conservation for Genetic Diversity: Reserve Designation and Design

Ayfer Tan

Ahmet Semsettin Tan

Aegean Agricultural Research Institute, Menemen, Izmir, Turkey

INTRODUCTION

In this article we will briefly define the basic terms of designation and design of genetic reserves for the in situ conservation of the genetic diversity of wild crops and plant species. Readers are encouraged to refer to the citations and “[Articles of Further Interest](#)” for more information.

EMERGENCE OF IN SITU CONSERVATION

Many species, which are the component of natural resources, are declining to critical population levels. Important habitats are being destroyed, fragmented, and degraded, and ecosystems are being destroyed through climate change, pollution, invasive species, and direct human impacts such as overexploitation. The International Union for Conservation Nature (IUCN) has been developing a system for describing the conservation status of species since 1963. About 5700 plants were assessed as threatened in 2002^[1] and in need of protection by the various means of conservation strategy in banks and/or in natural habitats.

Following considerable public awareness about nature conservation, national and international in situ biodiversity conservation programs have increased. The Convention on Biological Diversity (CBD) promotes in situ conservation and calls on signatory nations to conserve the biological diversity with the aim of insuring the conservation of ecosystems and agrobiodiversity for sustainable utilization of natural resources.

In situ conservation can be defined as “the maintenance of viable diverse population of species in their original surroundings or in their ecosystem and natural habitat.”^[2] No species is static but is continually interacting with the physical environment and is competing with the other species in the ecosystem. Consequently, in situ conservation is more dynamic in nature and allows the continuity of evolution.

Crops still depend upon the broad genetic base that exists in their wild relatives. This base is used as a source

for crop improvement by means of conventional inter-specific hybridization methods and modern genetic manipulation techniques. There is tremendous success with ex situ conservation of wild species, but in situ conservation has been inadequately applied. In situ implementation requires appropriate strategies to overcome socioeconomic and political considerations, scientific understanding of the natural environment, and genetic and biological mechanisms directly related to the conservation of the species.

ROLE OF NATIONAL PROGRAMS

Many supporting agencies, such as the Global Environment Facility (GEF) through the United Nations Environment Program (UNEP), World Bank, United Nations Development Program (UNDP), are available to assist countries in dealing with in situ conservation of rich and diverse nature resources. Few programs have been set up for in situ conservation of wild-crop relatives. A GEF-funded program has been undertaken in Turkey^[2] for in situ conservation of the wild-crop relatives of wheat and legumes, wild fruit trees (Figs. 1, 2), and forest tree species at multiple sites in different ecosystems. This led to the development of a substantial national program to conserve wild-crop relatives in situ as genetic reserves. Other programs that have been conducted are for wild emmer wheat (*Triticum dicoccoides*) in Ammiad, Israel,^[3] wild corn (*Zea diploperennis*) in the sierra de Manantlan Biosphere reserve, Mexico,^[4] and wild bean (*Phaseolus lunatus*) in Costa Rica.^[5]

The conservation of wild species in genetic reserves, termed gene management zones (GMZs),^[6] involves target species, site, policy, and socioeconomic parameters. Reserves are locations for the continuation of the evolution of plant populations with endangered and/or vulnerable as well as high and unique genetic diversity in their selected habitats.^[6] Their number and size may vary. Reserves should consist of core, buffer, and, if necessary, transitional zones. A clear and detailed management plan is required to manage and maintain the genetic diversity of

Fig. 1 Chestnut reserve at Kazdag, Turkey (by Ahmet Semsettin Tan). (View this art in color at www.dekker.com.)

target species, which interact with associated species at reserves. A national plan for in situ conservation can be developed to provide a mechanism for countries to set priorities and present a plan of action for effective designation, design, management of sustainable utilization, and monitoring of the reserves to ensure sustainable conservation in situ.^[2] Detailed information about different parameters from different sources is required (Table 1) to achieve sustainable natural reserves. The use of geographic information systems (GIS) can aid in performing a spatial analysis of the data for selection, designation, management, and monitoring of genetic reserves.

RESERVE DESIGNATION

In the planning stage of in situ conservation, identification of key interventions is required: what species (either the most threatened or the already protected), which population, and which areas. Selection of target species should be objective, based on logical, scientific, and economic principles related to the perceived value of species. Many factors that provide a species with value have current conservation status; potential economic use; threat of genetic erosion; genetic distinction; ecogeographic distinction; natural, global, cultural importance; relative cost of conservation; and conservation sustainability.^[2] Following the selection of target species or group of species, the biological, genetic, socioeconomic, and physical data about sites and target species should be collected by a series of ecogeographic and socioeconomic surveys and laboratory studies to assess the genetic diversity (Figs. 3–5).

Reserves should be accessible, suitable, and sustainable, and large enough to maintain a viable population size and biological interactions. The gene flow to target species from related species should also be considered.^[6]

The species richness of the site is also important. If a keystone species has priority, its associated species can be maintained at the same reserve. The reserves can be established in either natural or seminatural habitats. Two or more reserves should be designated representing the ecological ranges of target species to support sufficient environmental heterogeneity.^[2]

RESERVE DESIGN

The design of genetic reserves for in situ conservation, including questions about optimal size and shape, zonation and networking, has been discussed in various articles.^[6–8] The reserves should be designed appropriately for target species. The reserve design involves consideration of various factors such as structure, size, number (either a single large site or smaller sites joined with corridors are sufficient for target species), reserve shape, environmental variability, and potential stakeholders and users. The currently agreed reserve structure is a central core with a stable habitat, surrounded by a buffer zone and outside this, where possible, a transition zone to protect the core population.^[6,8] Practically, the majority of the wild relatives of crop plants are widely distributed and a single reserve would not be sufficient. But this is not always the case if species are naturally found in only one single area (Fig. 6).

Fig. 2 Chestnut reserve at Kazdag, Turkey (by Ahmet Semsettin Tan). (View this art in color at www.dekker.com.)

Table 1 Data required for efficient in situ conservation

Target species data	Site data	Policy and socioeconomic data	Species diversity data
Conservation status	Ownership (private/state owned/protection status)	Socioeconomic status of local community	Morphological variation
Geographical spatial distribution	Physical description (topography, sort, etc.)	Community awareness and participation to conservation/protection	Genetic diversity assessment (rare and unique alleles, linkage and polymorphism)
Reproductive biology/gene flow/seed production	Biological/demographic description	Conservation policy	Determination of population differentiation
Dispersal mechanism/seed bank in soil	Threat and impact (fire history, logging, grazing, etc.)	Rural development policy	
Population size			

Reserve size is critical to adequate and sustainable in situ conservation of plant species; therefore, the rate of species loss and genetic deterioration for most species is inversely proportional to the reserve size. Reserve size may vary according to the availability of resources as well as depending on the target species structure and nature. But it should provide a minimum viable population (MVP) size, minimum adaptive variation, and spatial multiniche flexibility to ensure the continued presence of target species. The suggested numbers of individuals in the reserves are in the range of 1000 to 5000.^[6,8] Effective population size should be considered (50 to 100 randomly

sampled individuals) for assessment of the genetic diversity of the population.

The management plan for each genetic reserve should be developed to regulate human intervention and to ensure the maintenance of genetic diversity of target species populations. This plan should consist of the articulation of purpose, biological and genetic description of target species, physical description and biological environment of reserve sites, description of problems related to reserve, required management practices, and monitoring to assess the management effectiveness. Further intervention, grazing pressure, and harvesting should be included in

Fig. 3 Sampled tree at chestnut reserve, Kazdag, Turkey (by Ahmet Semsettin Tan). (View this art in color at www.dekker.com.)

Fig. 4 Sampling for genetic diversity study at chestnut reserve, Kazdag, Turkey (by Ahmet Semsettin Tan). (View this art in color at www.dekker.com.)

Fig. 5 Studying for in situ conservation of endangered endemic species in Central Anatolia, Turkey (by Ayfer Tan et al.). (View this art in color at www.dekker.com.)

the management plan.^[2] Local community participation is also necessary. The conservation of plant species in many areas is likely to succeed if the area is yielding in some form of income to local people. But this should be applied in the buffer or transitional zones. Research should be conducted at the buffer or transitional zones.^[2]

A comprehensive data management system incorporated with the GIS is required for each stage of in situ conservation program. All parameters given in Table 1 are necessary for effective reserve design. The spatial analysis generated by the process of conservation using GIS can provide feed back to enhance, facilitate, process, and add value to genetic resources conservation.^[2,9,10] Finally, reserve design includes a means for monitoring population

Fig. 6 Important plant area for in situ conservation of *Termopsis turcica* Kit Tan, Vural & Kucukoduk found in a single area in Turkey (by Ayfer Tan et al.). (View this art in color at www.dekker.com.)

sizes and diversity over time and space so that modifications in design can be made as needed.

CONCLUSION

As a consequence of the extinction or decline of natural resources, in situ conservation in reserves should be mandated by national conservation programs. The establishment of genetic reserves recognizes the long-term objectives and the need for continued evolution with natural environments. Most of the in situ practices have been directed toward habitat preservation and have focused on ecological rather than genetic considerations. Genetic conservation goes further in recognizing the need for a wide genetic base. In situ conservation of wild species of plants is well recognized and more recently becoming an activity of national programs. There are few examples for conserving wild-crop relatives, which are in the gene pools of crop species. These examples can be a model for other countries to conserve national plant resources in situ. However, it is not always possible to propose in situ conservation strategies for all wild species occurring in different parts of the world with different characteristics, as there is still inadequate knowledge of their breeding systems, conservation biology, etc. To support a complementary approach between in situ and ex situ conservation, target species and associated species should be collected for ex situ conservation at gene banks.

In Situ Genetic Resource Conservation: Local Parks and Reserves

V. Arivudai Nambi

L.R. Gopinath

M.S. Swaminathan Research Foundation, Chennai, India

INTRODUCTION

The concept of “reserve” with regard to natural resources has been to set aside areas for exclusive current use as well as unperceived future uses. Precolonial states had several reserves where royalty protected valuable species like elephants, deer, teak, or sandalwood. Systematic and organized conservation efforts have largely been undertaken only in the last two centuries or so. Such conservation efforts closely followed conquest, expanding trade, commerce, and capital accumulation by colonial powers. Colonial expansion clubbed with the Industrial Revolution opened up the possibility of large-scale movement of raw material and goods from one region to another. What was considered inexhaustible resource at one point in time turned out to be exhaustible, leading to threats of scarcity. Such a threat led to the emergence of systematic and organized efforts at conservation of valuable resources.^[1,2]

Conservation efforts can broadly be classified into the following: Managed in situ conservation was pursued through National Parks, Protected Areas, Biosphere Reserves, and World Heritage Sites while ex situ conservation was through botanical gardens and gene banks. The above are widely recognized efforts; conservation in the public domain, community conservation, or in situ on-farm conservation by rural and tribal women and men remain largely unrecognized (Fig. 1).^[3,4] These communities continue to possess multifaceted traditional knowledge related to biodiversity, such as medicinal properties or food value of plants and animals.^[3]

CONSERVATION STRATEGIES IN AGRICULTURE AND FORESTRY SECTORS

The last century saw worldwide conservation efforts that focused on a package of physical and biological entities such as soil, water, and individual species within ecosystems and excluded humans. The present century poses human societies with a formidable challenge: sustainable management of physical and

biological resources where agriculture and forestry sectors move in opposite directions with regard to conservation. The agriculture sector has moved from the level of species to varieties and gene, while the forestry sector has moved from the level of species to ecosystem and landscape. A balance of competing interests of individuals and society in the multiple uses of natural resources is required.

Community conservation encompasses not only genetic resources such as landraces, folk varieties, cultivars, and breeds, but also ecosystems and landscapes in which sacred species, groves, and landscapes are embodied. There is a growing realization about the biodiversity-cultural diversity link and its importance. Changes in the social values with regard to traditional lifestyles, emerging new economies, livelihoods, and lifestyles have weakened community conservation to a significant extent. There is a pressing need to revitalize on-farm in situ conservation, as it is the key link between traditional knowledge, livelihoods, and lifestyles. Human beings always remained as managers of natural resources, through which they gained knowledge on animals, plants, climate, soil, and water and evolved various techniques and technologies for survival. This process continues to the present time. Communities living in hilly and inaccessible forested regions continue to hold traditional knowledge as well as generate new knowledge for the management of natural resources. It was through centuries of conservation and use by communities across continents that facilitated transfer of plants, such as rubber, tea, coffee, cotton, and groundnut to new locations for human use. The noted Russian scientist N.I. Vavilov undertook theoretical and applied work on economically important plants, to identify center of origin climatic analogies and wild relatives.

Since the Second World War, community-conserved genetic material was the feedstock for the crop varieties of the Green Revolution. The Green Revolution and the global environmental movement since 1960 together shaped conservation strategies for the domesticated and the wild species. With the passage of time, a number of global agreements were signed on realization that community-conserved genetic wealth

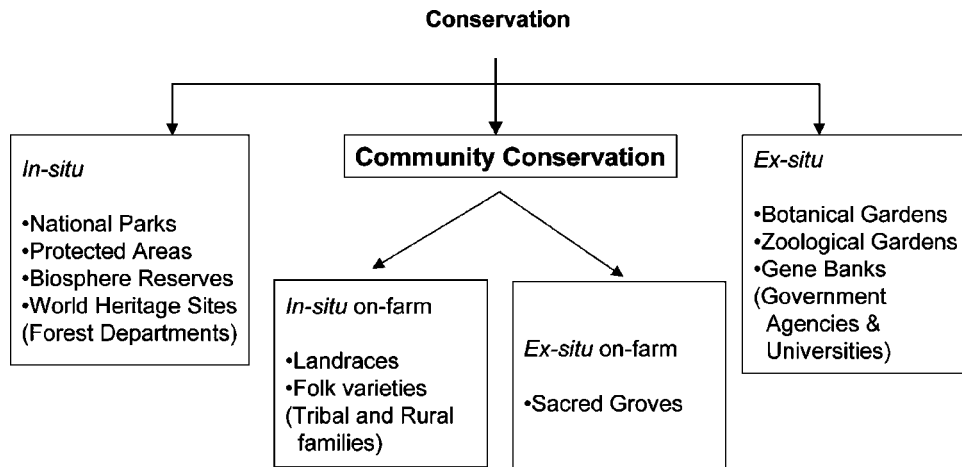

Fig. 1 The integrated gene management system. (From Ref.^[3].)

(domesticated and wild) and its associated traditional knowledge would leave more options for the morrow.

ECOLOGY IN COMMUNITY CONSERVATION

Species coexist under different relationships like competition, predation, parasitism, symbiosis, commensalism, and mutualism. Although humans are a part of this relationship, they have been able to control nature because of their intelligence. In the light of the above, community-conserved biological diversity has three important functions (Fig. 2): 1) ecological functions that maintain soil fertility and conserve water, leading to synchronized utilization of natural resources; 2) economic functions include food, fuel, fodder, timber, fiber, and medicine that contribute to local incomes

Fig. 2 Functional role of biodiversity of a system.

both on-farm and off-farm; and 3) socio-functions that lead to diversity in resource use, tenures (private or public property), and social customs. Such relationships have a major impact on the demography of the region, political system, and social customs that are reflected in cultural diversity. Long-term sustainability of a species or diversity of species in a system depends upon the level of synergy among these three functions.^[5]

However, the economic function of a system assumes a vital role, since transactions among various social groups are determined by economics. The synergy of the above system is lost when there is a reduction in the economic function. A reduction in the local economy leads to direct negative environmental impacts that further reduce local biodiversity. It is within this context that institutions can contribute to biodiversity conservation.

NATURAL RESOURCE MANAGEMENT: THE ROLE OF COMMUNITIES

Although initial conservation at the species level largely excluded human activity, the establishment of national parks (Fig. 3) entailed some amount of inclusion of the human element. The evolution of the concept of the biosphere at the level of the landscape considers humans and their activities as part of nature. Such conservation efforts at the landscape level undertaken in the recent past have proved to be far more effective and sustainable.^[6]

In general, biosphere reserves act as havens for endangered animals and plants with a core zone in the center surrounded by buffer and transition zones. Traditional communities live in the core zone, and buffer zone depends on forest resources such as wild food, minor forest products, and traditional agriculture.

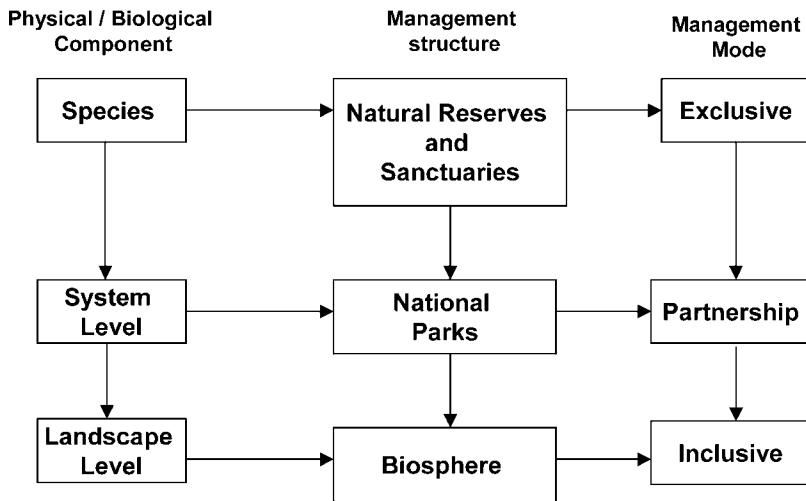

Fig. 3 Management strategies in natural resources: historical perspective.

Buffer zone and the core zones are restricted in access to nonlocal people. The buffer zone withstands changes from inner core and the outer transition zones. The transition zone is sandwiched between the human modified modern industrial world and the buffer zone. It is this zone that assumes importance with regard to community conservation of crop genetic resources.

AN INTEGRATED APPROACH TO CONSERVATION

The biosphere concept considers humans as a natural component of the landscape, but there is no legal basis for its implementation. As a result, biosphere reserves share the rules and regulations of national parks, reserves, and sanctuaries as their management strategy. However, such overlap of different management strategies in the same region may lead to conflicts. Therefore, the concept of biosphere reserve needs more synchronized pathway for operationalization.

A multistakeholder approach trusteeship model and participatory conservation system (PCS) evolved by the M.S. Swaminathan Research Foundation (MSSRF) is an attempt to balance several issues addressed above through a process of share and care. This model is being implemented in the Gulf of Mannar Biosphere Reserve, a coastal aquatic system in southern India. For example, in the Gulf of Mannar Biosphere Trust in the Indian state of Tamil Nadu, MSSRF partners with the local communities; fisheries, forestry, and agricultural departments; research institutes such as the Central Marine Fisheries Research Institute to enhance sustainable harvest of natural resources. The activities in the area concentrate on providing land- and water-based income gen-

eration activities to local communities to reduce overexploitation of the bioresources of the Gulf of Mannar. Charcoal production, dairy farming, renovation of freshwater tanks are the land-based activities. Community-based agar production and pickled fish unit, creation of artificial reefs, and pearl culture are some of the marine-based livelihoods.

An integrated conservation strategy that combines in situ and ex situ conservation by blending traditional knowledge with modern conservation science should be developed in centers of high natural biological and agrobiodiversity. In situ conservation cannot be pursued without the component of traditional knowledge of communities associated with genetic resources. Moreover, given the present genetic erosion due to industrial agriculture, it makes practical sense to create agrobiodiversity sanctuaries in areas that are rich in agrobiodiversity and have a living traditional knowledge. In addition, eco-agriculture strategies^[7] may be required to integrate at the landscape level agricultural and forestry concerns.

CONCLUSIONS

Natural systems are complex and multifunctional, providing differential services to different sections of the populations. While financial capital is crucial to the continued management of plant and animal genetic resources, social capital involving multiple stakeholders to manage natural capital at the landscape level is essential for sustainable natural resource management. This will be possible through a three-pronged strategy for the conservation and use of genetic resources: 1) regulations on conservation, enhancement, sustainable use, and equitable sharing of benefits; 2) social mobilization and community

participation in conservation, enhancement, use, and sharing of benefits; and 3) public education on the importance of conservation, enhancement, sustainable use, and equitable sharing of benefits.

In Vitro Chromosome Doubling

V. Sarasan

Royal Botanic Gardens, Kew, Surrey, U.K.

A. V. Roberts

University of East London, London, U.K.

INTRODUCTION

Chromosome doubling occurs when a cell fails to divide into two daughter cells at mitosis. As a result, a single restitution nucleus is formed that contains the chromosomes that would normally have segregated to two daughter nuclei. A polyploid plant may emerge if the cell with doubled chromosomes develops into a complete plant. In nature, polyploid plants may be created by the spontaneous doubling of chromosomes in somatic cells or by the fusion of unreduced gametes. In the laboratory, it can be induced by the application of antimetabolic agents to sporophytic or gametophytic tissues. Chromosome doubling also occurs when protoplasts of somatic cells are fused. This review focuses on the objectives of chromosome doubling, the use of antimetabolic agents, and methods of detecting and isolating polyploidy variants.

POLYPLOIDY AND ITS ADVANTAGES

The chromosomes of a gamete are denoted by the letter n , and the chromosomes in each genome of a gamete by x . Thus, a diploid cell can be represented by the formula $2n = 2x$ and a tetraploid plant obtained by chromosome doubling by $2n = 4x$. Doubling the number of chromosomes of a tetraploid results in an octoploid ($2n = 8x$). Hybrids between diploid and tetraploid plants are triploids of usually low fertility. Doubling the chromosome number of a triploid results in a hexaploid ($2n = 6x$). A distinction is drawn between autopolyploids and allopolyploids on the basis of their origin and fertility.^[1] An autopolyploid is derived from a fertile plant, such as a typical representative of a species, whereas an allopolyploid is of interspecific origin. An autopolyploid is typically less fertile than the original undoubled plant because, as each chromosome has more than one homologous partner, irregular pairing occurs at meiosis. An allopolyploid is usually fertile because chromosome doubling provides each chromosome with just one homologous partner and

meiosis is regular. Allopolyploids benefit from a type of hybrid vigor, which results from the combination of the genes of two or more species. A well known example is evolution, in cultivation, of the bread wheat *Triticum aestivum*. This allohexaploid originated in two stages, each of which involved interspecific hybridization associated with chromosome doubling. First there was the formation of an allotetraploid from two diploid species and then an allohexaploid from the allotetraploid and another diploid species. There was an increase in vigor at each stage.

Although chromosome doubling of somatic cells and fusion of unreduced gametes are events that occur at low frequency in nature, as many as 80% of angiosperm species may be of polyploid origin.^[1] The commercial importance of polyploids in agriculture and horticulture has led to the use of antimetabolic agents that induce chromosome doubling in somatic cells by interfering with spindle formation. One common reason for inducing polyploidy is to obtain a fertile allopolyploid from a sterile hybrid. Another is to obtain a plant with the larger leaves, flowers, or fruits often associated with both auto- and allopolyploidy.

ANTIMITOTIC AGENTS

During cell division, chromosomes are segregated to opposite poles of a cell by spindle fibers. The spindle fibers are composed of microtubules that are formed rapidly at the onset of cell division by a process that involves the polymerization of α - and β -tubulin polypeptides.^[2] Antimetabolic agents such as colchicine typically destabilize the microtubules and prevent new ones from forming. Consequently, the daughter chromosomes cannot segregate to opposite poles of the cell at anaphase. The two chromatids of each chromosome are initially held together at the centromere but eventually the association lapses, creating separate chromosomes. Cytokinesis fails to occur, leading to the formation of a restitution nucleus and a polyploid cell.

Colchicine was first used for chromosome doubling by Levan^[3] and has been widely used for that purpose to date. However, in many species it is reported to cause undesirable effects such as sterility and abnormal growth.^[4] More recently, chromosome doubling has been achieved with antimetabolic herbicides, which prevent the synthesis or polymerization of the tubulin molecules into the microtubules of the spindle. Of these, the dinitro-aniline herbicides oryzalin and trifluralin, the phosphoric amide herbicide amiprofos methyl (APM), and pronamide have been found to be effective in chromosome doubling.^[5] Colchicine has a higher affinity for animal than plant microtubules but the reverse applies to the herbicides.

DETECTION OF POLYPLOIDS

The traditional method for assessing ploidy is by counting chromosomes in root meristematic cells. The recent method of flow cytometry^[6] enables ploidy to be determined more rapidly and, as several thousands of cells can be assessed in a single leaf sample, cytochimerism can be detected more readily. Some morphological characteristics such as stomatal length, the number of chloroplasts in guard cells, and pollen grain diameter (which are often greater in tetraploids than diploids) can sometimes be used as indicators of ploidy. Other features that have been commonly noted following chromosome doubling include shorter stems, thicker and darker green leaf laminae with more serrated margins, thicker petioles, thicker stems with shorter internodes, and wider crotch angles (see references listed in Table 1).

STRATEGIES AND OBJECTIVES IN IN VITRO CHROMOSOME DOUBLING

Treatment of Sporophytic Tissues

Antimetabolic agents can be applied to somatic tissues in vitro or in vivo. The treatment of seeds may be satisfactorily achieved in vivo by soaking germinating seeds in solutions of an antimetabolic agent. There is a good chance the antimetabolic agent will be imbibed when the seed swells and that it will reach the target tissue at a suitable concentration. However, the delivery of the antimetabolic agent to the meristems of an established plant can be more difficult. In this event, in vitro culture is a widely used approach (Table 1). Delivery of the antimetabolic agent may be easier through cut surfaces of an explant than through the protective cuticle of an in vivo plant. In some species, plants can be regenerated through adventitious shoots or somatic embryos after treatment, which greatly reduces the occurrence of cytochimerism.

If all cells in a meristem divided at the same rate, the optimum period of exposure to a spindle inhibitor would correspond to the cell cycle time. However, there are slow cycling cells that may remain undoubled and, therefore the duration of antimetabolic agent application required for polyploidization must be determined empirically for each species. Compared to colchicine, oryzalin was found to be, for example, more phytotoxic to the leaves of *Actinidia deliciosa*^[7] and more efficient in inducing polyploidy in *Rhododendron*,^[8] but reports on the relative merits of oryzalin and colchicine vary. Recent examples of chromosome doubling in sporophytic tissues are listed in Table 1.

^aAfter pollination with irradiated pollen.

(Data from Refs. 7–9 and 11–17.)

Treatment of Gametophytic Tissues

The major objective of chromosome doubling of gametophytic tissues is to produce homozygous dihybrids. These can be used as pure breeding parents and two homozygous lines can be hybridized to produce genetically uniform F₁ hybrid seed. The more conventional method of producing pure breeding parents involves the slow procedure of selfing over about seven generations. Culture of haploids can be achieved through androgenic or gynogenic culture (Table 1). This can be combined with spontaneous or induced chromosome doubling to give dihaploids. The suitability of androgenic or gynogenic culture differs according to the species involved. In some species, regeneration is difficult to achieve in the presence of a chromosome-doubling agent. It may then be more efficient to first establish haploid shoot cultures to which antimutagenic agents can subsequently be applied, as in gynogenic cultures of *Allium cepa*.^[9]

Androgenic culture can be achieved by anther or microspore culture. Chromosome doubling may occur spontaneously or as a result of treatment with antimutagenic agents. Adjustment of in vitro culture conditions may increase the frequency of spontaneous chromosome doubling. Gynogenic cultures may be obtained from unfertilized ovules. Haploids and dihaploid embryos may also be obtained by pollination with pollen of the same species that has been exposed to ionizing radiation, which disrupts normal chromosome function but permits pollen germination. This method was applied by Todorova et al.^[10] to sunflower. In gerbera, 76–100% of plants regenerated from unpollinated ovule cultures were haploid but treatment with colchicine resulted in 34% dihaploid plants. Oryzalin was found to be less phytotoxic than colchicine in doubling the chromosome number of gynogenic haploids of *Gerbera*.^[11]

CONCLUSION

The use of chromosome doubling for crop improvement has increased in the last decade because two crucially important techniques—plant tissue culture and flow cytometry—are now more widely available. It can be expected that this trend will continue as in vitro techniques, including those for adventitious regeneration, are successfully applied to recalcitrant species. As a method for crop improvement, interspecific hybridization linked with chromosome doubling has some advantages over the development of transgenic crops. It is a relatively low-cost technology, and can be used by small or large commercial enterprises with no public resistance. It is also likely that new applications of this technology will

emerge in the future. Conservation of endangered species with reduced reproductive potential is an example. In *Ramosmania rodriguesii*, an endangered species,^[12] stylar incompatibilities prevent fertilization and seed setting. Chromosome doubling of sporophytic tissues may in itself result in self-compatible plants. Alternatively, doubling of gametophytic tissues may result in dihaploids with the essential diversity of genotypes required for sexual compatibility.

In Vitro Flowering

INTRODUCTION

Flowering—the transition from the vegetative to the reproductive phase in plants—is an important developmental process with considerable biological and economic significance. Despite decades of research and rapid advances in technology, our understanding of this important developmental process is still fragmentary. From the results of previous research, it is evident that the majority of plants use environmental cues to regulate flowering. Environmental variables with regular seasonal patterns such as temperature, photoperiod, and irradiance are the key signals for floral transition. These factors are perceived by different plant parts, and strong and diverse interactions between the environmental variables are required for floral induction to occur in many species.

Classical physiological, genetic, and grafting experiments, although invaluable in deciphering various aspects of flowering, have failed to unravel the true nature of the flowering stimulus or the mechanism(s) by which various environmental cues induce flowering. Novel approaches involving *in vitro* and molecular techniques offer unique opportunities to investigate the flowering process from new perspectives. This article summarizes the major achievements of *in vitro* techniques in understanding flowering, and highlights the merits and future prospects of such approaches in resolving the questions surrounding floral transition.

ADVANTAGES OF IN VITRO FLOWERING

As compared to whole plant-based, *in vivo* experimental conditions, *in vitro* methods present several advantages to investigate flowering. They allow for much greater control of experimental conditions under investigation. For instance, precise and efficient application of different treatments and elimination of interfering factors can be achieved relatively easily under *in vitro* conditions. This ensures more reliable analysis of the role of growth regulators, nutrients, and environmental variables on flowering. Under tissue culture conditions, whole plants

and individual plant parts (including isolated meristems) can be used for floral induction. *In vitro* cultures are more amenable to bioassays and model systems development than *in vivo* methods because growth conditions can be precisely controlled and monitored in culture. *In vitro* systems have been successfully used for the determination of molecular elements involved in flowering and reproductive development.^[2] They can be exploited for *in vitro* breeding, which may reduce the breeding cycle considerably in perennial crops.

FACTORS INFLUENCING IN VITRO FLOWERING

Successful induction of flowering *in vitro* has been reported for numerous species from both monocotyledonous and dicotyledonous families. Considering the complexity of the regulation of flowering, it is not surprising that no common set of growth conditions exist that could be applied to *in vitro* floral induction in diverse species. From the available evidence, the key regulatory factors that induce flowering *in vitro* include photoperiod, irradiance, temperature, growth stage, and phytohormones. Besides these controlling factors, *in vitro* studies also showed that various nutrients, particularly nitrogen and carbon, and many nonhormonal bioactive compounds such as polyamines, jasmonates, and benzoic acid derivatives play a role in the regulation of vegetative to reproductive phase transition.

Phytohormones and In Vitro Flowering

Whereas there is no conclusive evidence to establish a particular compound as the master signal evoking floral transition under *in vivo* conditions, hormones in general are emerging as important factors regulating floral induction in *in vitro* cultures in a large number of species.^[3] As with any other developmental process, flowering *in vitro* is promoted by some hormones while inhibited by others. More intriguingly, in some species, the same hormone

elicits contrasting flowering responses under different culture conditions.

Auxins in general do not promote flowering in vitro. However, there are examples of auxin-induced flowering in culture. For instance, *Pharbitis nils* seedlings grown in vitro could be induced to flower in noninductive conditions by the application of α -naphthaleneacetic acid (NAA). Auxin also promoted flowering in *Perilla frutescens*, *Streptocarpus nobilis*, *Phlox drummondii*, and *Torenia fournieri*.^[3] Nonetheless, more evidence points to an inhibitory role for auxin in flower induction. Indeed, experiments with day-neutral tobacco cultures indicate that auxin has the potential to even revert the plants that are already in the reproductive phase to vegetative state. Working with *Torenia*—the most extensively investigated plant in relation to auxin involvement in flowering—Tanimoto and Harada^[4] concluded that auxin is unlikely to be a component of floral stimulus, although it promotes flower bud differentiation.

Among the different phytohormones, cytokinins are the most effective inducers of flowering in vitro. In most of the species tested, at least one cytokinin was required for flower induction and normal development of floral parts.^[3] It is important to note that in many species, for example, *Plumbago indica*, *P. frutescens*, and *Browallia demissa*, cytokinins were able to induce flowering in explants obtained from strictly vegetative plants maintained under noninductive conditions. Floral induction occurred only in a narrow range of cytokinin concentrations, and supraoptimal levels of cytokinin in the medium always resulted in vegetative bud formation in all the species investigated. Although the vast majority of the reports indicate a promotive role for cytokinin, it inhibited flowering in cultures of *Scrofularia arguta* and different cultivars of *Kalanchoe* and tobacco.

Different plant species require different types of cytokinins to induce flowering in culture. As an example, 6-benzyladenine is the most effective cytokinin for flower production in many orchids, bamboos, and passion fruit, whereas kinetin was more favorable than others for floral induction in *Arabidopsis* stem explants. In many species, however, a combination of different cytokinins or of cytokinin and auxin was needed for in vitro flower induction.

Gibberellins, the most potent florigenic compounds in vernalization-requiring plants, received much less attention in in vitro studies compared with cytokinins and auxins. Both promotive and inhibitory roles have been suggested for gibberellins with regard to in vitro flowering. Unlike cytokinins, there is little conclusive evidence to suggest that gibberellins evoke floral induction in vitro, as the explants used for floral induction studies involving gibberellin were derived from already flowering or florally-determined plants. Considering its importance in

the development of reproductive structures, there is an obvious void of information about the inductive role of gibberellin in flowering of tissue-cultured plants.

Despite the fact that inhibitors have been implicated in the regulation of reproductive development, little work has been done on the action of abscisic acid (ABA) and ethylene on in vitro flowering. ABA induced flowering in in vitro cultures of *T. fournieri* and *P. nils*, and markedly enhanced flower production in *P. indica* and *P. frutescens*. A close parallel between the endogenous ABA level and the ability to flower in vitro was noticed in *Torenia*. In this species, applied ABA inhibited flower bud formation in tissues taken from old plants, whereas a promotive effect on flowering was noticed in explants from younger plants.

Nonhormonal Compounds and In Vitro Flowering

Besides the known phytohormones, many bioactive compounds were found to have florigenic activity in vitro. The most significant ones are nicotinic acid, salicylic acid, benzoic acid, and coumaric acid.

Knowledge about the inductive role of mineral nutrients in in vitro flowering is limited. Investigations on *Torenia* found that low salt concentration and the absence of NH_4NO_3 were supportive of flowering in vitro. Nitrate appears to be the most florigenic of all the forms of nitrogen, and a high carbon:nitrogen ratio brings about flowering in some plants. In *Sinapsis alba* and *Cuscuta reflexa*, sucrose could induce or eliminate the requirement of high light intensity for flower induction, whereas even a brief removal of tobacco explants from glucose delayed flower formation.

CONTRIBUTION OF IN VITRO STUDIES ON FLOWERING

From the foregoing discussion it is evident that considerable effort has been expended to develop in vitro flowering systems for a large number of species. Many of these culture systems could be used to develop reproducible and sensitive bioassay systems to verify the role of chemical, biological, and environmental factors in controlling flowering. In addition, such systems are often the only ways to gain more insight into certain aspects of flowering, which are otherwise impossible to achieve in an in vivo environment. For example, experiments with florally determined tobacco and orchid plants have shown that determination to flower can be carried through from the flowering parent plant to the explant, and that it can persist for long periods in culture, often for several generations in orchids.

In vitro approaches provide unique opportunities to test and interpret the theories of the multicomponent model of flowering. To cite an example, it is almost impossible to verify the antagonistic effects exerted by the root on flowering without resorting to tissue culture systems. With appropriate experimental strategies, this aspect of flowering has been elegantly demonstrated in *Kalanchoe*, *Cichorium*, and sunflower.

The value of having a precisely defined and reproducible in vitro system to further our knowledge of flowering is best exemplified in the recent research by Yu and Goh on orchids.^[2,5] They exploited a cytokinin-induced flowering system of *Dendrobium* orchid to investigate the profile of gene expression during flowering,^[2] and identified three MADS-box genes of the AP1/AGL9 subfamily expressed specifically at the time of floral transition.^[5] In addition, the *Dendrobium* in vitro flowering system allowed them to identify and characterize *DOH1*, a gene required for maintenance of basic plant architecture and floral induction.^[6]

IN VITRO FLOWERING AND PLANT BREEDING

An in vitro system producing fertile flowers would be an invaluable breeding tool, especially for difficult-to-flower plants such as trees, bamboos, etc. In bamboo, which usually has 12 to 24 years of juvenile growth and is gregarious (i.e., all the bamboos in a local population flower simultaneously), the development of an efficient in vitro flowering system capable of producing viable seeds will be an important advancement in breeding this species.^[7] A similar tissue culture system producing fertile flowers and viable seeds has been described for various orchids.

CONCLUSION

From the preceding discussion, it is apparent that in vitro flowering is not only an efficient approach to understanding various facets of flowering, but could also be exploited for practical applications. Considering the success obtained with numerous plant species, the development of an in vitro flowering system for most of the angiosperms is now within reach. The physiological and developmental status of the donor plant, composition and concentration of mineral salts in the medium, and presence of

cytokinin are emerging as key factors controlling floral transition in culture. Clearly, in vitro systems are presenting unique opportunities to unravel the mysteries of flowering. With advances in molecular biology, remarkable progress in the molecular characterization of this developmental process can be expected in the near future.

In Vitro Morphogenesis in Plants—Recent Advances

Gregory C. Phillips

Arkansas State University, State University, Arkansas, U.S.A.

INTRODUCTION

The capacity of cultured plant tissues and cells to undergo morphogenesis, resulting in the formation of discrete organs or whole plants, has provided opportunities for numerous applications of in vitro plant biology in studies of basic botany, biochemistry, propagation, breeding, and development of transgenic crops. Whereas the fundamental techniques to achieve in vitro plant morphogenesis have been well established for a number of years, innovations in particular aspects of the technology continue to be made. Tremendous progress has been made in recent years regarding the genetic bases underlying both in vitro and in situ plant morphogenesis, stimulated by progress in functional genomics research. Advances in the identification of specific genes that are involved in plant morphogenesis in vitro, as well as some selected technical innovations, will be discussed.

FUNDAMENTAL ASPECTS OF IN VITRO MORPHOGENESIS

The two primary morphogenic pathways leading to whole plant regeneration—which is a prerequisite for most plant breeding and genetic and transgenic applications of in vitro biology—involve either somatic embryogenesis, or shoot organogenesis followed by root organogenesis. Both developmental pathways can occur either directly without a callus intermediate stage, termed adventitious; or indirectly following an unorganized callus stage, termed *de novo*.^[1] Few plant species have been shown to regenerate by both organogenic and somatic embryogenic pathways, but many plant species can regenerate by one or the other of these pathways.

Somatic embryogenesis may be the best example of totipotency expressed among a large number of plants.^[2] Various culture treatments can be manipulated to optimize the frequency and morphological quality of somatic embryos, which are bipolar structures containing both shoot and root apices and developing in a manner parallel to that of zygotic embryos. Typical treatment factors include the plant growth regulator sources and concentrations (especially the auxin), choice of explant nutrient medium composition (especially inorganic vs. organic nitrogen sources

and carbohydrate sources and concentrations), culture environment (including the physical form of the medium, e.g., liquid or semisolid; pH; humidity; light quality and quantity or absence of light; temperature; gaseous environment), and osmotic potential. Many of these factors must be adjusted (e.g., carbohydrates, nitrogen sources) or completely changed (e.g., withdrawal or reduction in auxin signal; perhaps an increase in other plant growth regulators such as abscisic acid; osmotic potential change to encourage desiccation) during maturation of somatic embryos, during which time they become competent for conversion into plantlets.^[2]

Many of the same culture factors described above for somatic embryogenesis are also manipulated to induce and optimize organogenesis, but often these factors are manipulated in different ways.^[3] For example, a high auxin signal (often specifically using 2,4-dichlorophenoxyacetic acid) is usually important to induce somatic embryogenesis, whereas a high cytokinin-to-auxin ratio (or high cytokinin with no auxin) is typically required to induce shoot organogenesis. Root initiation also typically requires a moderate to high auxin signal—but rarely use of 2,4-dichlorophenoxyacetic acid. Rather, a more “natural” source of auxin is used.^[1] Because regenerated organs are unipolar, two distinct organogenic induction signals—one to induce shoots and the other to induce roots—are required to regenerate a whole plant. In contrast, bipolar somatic embryos are induced by a single induction signal.

GENETIC COMPONENTS OF MORPHOGENESIS

One of the most exciting advances in recent years is the discovery of specific genes involved in plant regeneration in vitro. Such genes are being explored in order to increase transformation efficiency and to develop marker-free transgenic plants.^[4] Because a primary factor in optimizing somatic embryogenesis and organogenesis is phytohormone models, it is of interest that receptors for each of the major phytohormone classes have now been identified and many of the corresponding genes have been cloned.^[4,5] Examples of specific genes involved in the major plant morphogenesis pathways are summarized in [Table 1](#).

Table 1 Examples of genes involved in various plant morphogenesis pathways

Gene	Putative function	Reference(s)
<i>Somatic embryogenesis</i>		
<i>LEC2</i>	Initiates ectopic somatic embryogenesis	4
<i>WUS (PGA6), SERK, LEC1</i>	Involved in the vegetative-to-embryogenic transition	4,6,7
<i>SHR</i>	Establishes ground tissue via asymmetric cell division	8
<i>CLV, WUS</i>	Regulate stem cell fate	8,9
<i>CLV1, CLV3, STM</i>	Regulate shoot apical meristem development	8,9
<i>LEC1, FUS3, ABI3</i>	Regulate embryo maturation	8
<i>Shoot organogenesis</i>		
<i>CYCD3</i>	Involved in acquisition of competence for organogenesis	9,10
<i>SRD3</i>	Competence for shoot organogenesis	10,11
<i>SRD1, SRD2</i>	Competence for redifferentiation of shoots	10,11
<i>ESR1</i>	Enhances shoot regeneration, vegetative-to-organogenic transition	4
<i>CRE1</i>	Cytokinin receptor	4
<i>CKII</i>	Cytokinin perception	4,9
<i>CLV, WUS</i>	Preserve stem cell identity in shoot apical meristem	9
<i>KN1, STM</i>	Initiate ectopic shoot meristems, shoot apical meristem function	9
<i>SHO, MGO</i>	Modifiers of the shoot apical meristem involved in leaf founder cell recruitment, lateral organ primordia	9
<i>Root organogenesis</i>		
<i>SRD2</i>	Competence for root organogenesis	10,11
<i>PKL</i>	Transition of embryonic root cells to grow vegetatively	7
<i>RML</i>	Root apical meristem function	11,12
<i>CYCD4;1</i>	Involved in lateral root formation	13
<i>RAC</i>	Involved in adventitious root formation and auxin transduction	11
<i>Floral organogenesis</i>		
<i>LFY</i>	Switch to reproductive development, floral meristem identity	9,14
<i>AP1</i>	A-class gene involved in establishing the first floral whorl: petals	14
<i>UFO</i>	Interacts with <i>LFY</i> by providing regional specificity within floral meristems and to control B-class signals that establish the second floral whorl: sepals	14
<i>WUS</i>	Interacts with <i>LFY</i> to control C-class genes	14
<i>AG</i>	C-class gene typifying the class; interacts with B-class signals to produce the third floral whorl: stamens; C-class genes acting alone produce the fourth floral whorl: carpels	14
<i>SEP</i>	Cofactors for A-, B-, and C-class genes to convert vegetative leaves into floral organs	14

Genetic Aspects of Somatic Embryogenesis

Transgenic expression of the *LEC2* (leafy cotyledon) gene (Table 1) is sufficient to initiate somatic embryogenesis with high viability but some abnormalities persist in morphology.^[4] Several genes appear to be involved in the vegetative-to-embryogenic transition, such as *WUS* (wuschel, or *PGA6*, plant growth activator), *LEC1*,^[6] *SERK* (somatic embryogenesis receptor kinase),^[4] and *PTI* (primordial timing).^[7] *SHR* (short root) establishes the ground tissue through the first asymmetric cell division,^[8] *CLV* (clavata) and *WUS* interact to determine stem cell fate, and *CLV* and *STM* (shoot meristemless) regulate development of the shoot apical meristem.^[8,9]

LEC1, *ABI3* (abscisic acid-insensitive), and *FUS3* (fusca) are involved in somatic embryo maturation.^[8]

Genetic Aspects of Shoot Organogenesis

CYCD3 is involved in the acquisition of competence for shoot regeneration,^[9,10] as is *SRD3* (shoot redifferentiation)^[10,11] (Table 1). Shoot redifferentiation also involves *SRD1* and *SRD2*.^[10,11] The vegetative-to-shoot organogenesis transition is promoted by *ESR1* (enhancer of shoot regeneration).^[4] Two genes representing potentially independent pathways involved early in shoot organogenesis signal transduction include *CRE1* (cytokinin receptor) and *CKII* (cytokinin independent).^[4,11] The shoot apical

meristem stem cell identity is regulated by *CLV* and *WUS*,^[9] parallel to that observed in the shoot apical meristem of somatic embryos (described earlier). *STM* and *KNI* (knotted) are involved in the function of the shoot apical meristem, and overexpression leads to the formation of ectopic shoot meristems.^[9,10] Other regulators involved in shoot apical meristem organization and lateral shoot formation include multiple *SHO* (shoot organization) and *MGO* (mgoun) genes.^[9]

Genetic Aspects of Root Organogenesis

Competence to regenerate root organs is affected by *SRD2*^[10,11] (Table 1). The transition of embryonic root cells to initiate vegetative growth is controlled by *PKL* (pickle),^[7] *RML1* (root meristemless) and *RML2* play specific roles in the root apical meristem,^[11] and interact with components of the apical dominance system.^[12] The *RAC* (rooting auxin cascade) gene is involved in an early stage of auxin perception specific to the formation of adventitious roots,^[11] and *CYCD4;1* is directly involved in lateral root primordia formation.^[13]

Genetic Aspects of Floral Organogenesis

Floral organs arise as determinate structures out of the indeterminate shoot apical meristem.^[9] The concept of floral organs being specified by the A-, B-, and C-class genes is well established.^[14] *LFY* (leafy) is a key gene involved in the switch to reproductive growth and in establishing floral meristem identity^[9,14] (Table 1). *LFY* activates the key A-class gene *API* (apetala), establishing the petals or outermost whorl of the floral organ.^[14] *LFY* and *UFO* (unusual floral organs) interact to control the B-class genes, with *UFO* providing regional specificity within meristems and thereby establishing the sepal whorl. *LFY* and *WUS* interact to control the C-class genes typified by *AG* (agamous), and the C-class genes interact with B-class genes to establish the stamens in the third whorl. C-class genes also act alone to establish the fourth or innermost whorl composed of carpels (because *AG* suppresses the action of *WUS*, thereby resulting in a suppression of the B-class components). Three MADS-Box *SEP* (sepelata) genes act as cofactors with the A-, B-, and C-class genes to convert vegetative leaves into floral organs.

TECHNICAL INNOVATIONS

In the past decade, many of the technical improvements resulting in improved in vitro plant regeneration systems have been related to manipulation of the gaseous and/or physical environment of the cultures. Falling outside this

category are a few other noteworthy innovations pertaining to thin cell layer techniques and synthetic seeds.

Manipulation of the Gaseous and/or Physical Environment

Cultured plant tissues are known to interact with the culture medium and gaseous environment. Forced ventilation and use of ventilated culture vessels, for example, have facilitated optimization of in vitro morphogenesis systems, and high CO₂ treatments have permitted establishment of photoautotrophic cultures.^[15] Control of the amount of ethylene released by the cultured tissues into the head space of the culture vessel—or alternatively, inhibition of ethylene synthesis or action—have led to improved morphogenic responses.^[16]

Efforts to improve bioreactor designs to facilitate economical large-scale production of plants or plant products have continued. Key issues that must be addressed with bioreactor designs for plant cell and tissue growth include aeration and minimization of shear damage. Advances in automation and computer controls have rendered bioreactor performance more reliable.^[17] One of the most exciting developments in bioreactor design has been the temporary immersion system, which alternates immersion of the plant tissues in the liquid culture medium with exposure to the air space at timed intervals.^[18] Temporary immersion bioreactors have been demonstrated to improve yields of shoot proliferation cultures, microtubers, and somatic embryos, as well as improve the quality and vigor of the propagules with reduced frequencies of abnormalities and hyperhydricity.

Another interesting development is the use of perfluorochemicals and commercially stabilized bovine hemoglobin as gas carriers to enhance cell performance in liquid culture systems such as bioreactors. Perfluorochemicals are recyclable (can be used to deliver gases, then be recovered from the culture and recharged), and emulsion with the surfactant Pluronic F-68[®] appears to synergistically enhance effectiveness. These gas carriers have been shown to improve cell division rates, stimulate biomass production, improve yields of cellular products, and enhance morphogenic totipotency.^[19] A technical innovation with a more physical impact on the culture environment is the use of semipermeable cellulose acetate membranes to enhance citrus somatic embryogenesis and particularly to normalize somatic embryo development.^[20]

Applications of Thin Cell Layer and Synthetic Seed Techniques

Thin cell layer culture, an approach involving mainly the manipulation of explant size to induce and optimize

regeneration, has been used for many years with dicotyledonous species to study in vitro morphogenesis. Thin cell layer cultures can be manipulated for rigorously controlled programming of different morphogenic responses: callus formation, shoot organogenesis, root organogenesis, floral organogenesis, or somatic embryogenesis.^[21] In recent years the thin cell layer technique has been extended to a variety of species formerly considered to be recalcitrant to in vitro morphogenesis. Evidence is also gathering that thin cell layer techniques can be useful for recovering transgenic plants from species heretofore considered recalcitrant to genetic transformation.

There continues to be interest in developing synthetic seed technology based on artificial encapsulation of somatic embryos suitable for direct field sowing with reliable conversion into viable plants. The most important technical advances in this area involve the use of automated bioreactors to improve yields, combined with the use of computer imaging to sort out the somatic embryos possessing sufficient quality for encapsulation and subsequent conversion.^[22] Even more exciting are the advances in use of nonembryogenic (unipolar) structures for encapsulation as synthetic seed.^[23] There seems to be a lower risk of somaclonal variation using unipolar structures such as microbulbs; microtubers; rhizomes; corms; shoots; or nodes containing either apical or axillary buds, meristemoids, and bud primordia for encapsulation. Synthetic seed technology can be extended to a wider variety of genotypes.

CONCLUSION

Basic research has begun to dissect the complex genetic pathways involved in various aspects of plant morphogenesis, including all of the major pathways leading to in vitro plant regeneration. A number of candidate genes are being identified that can be expressed transgenically to enhance or even to initiate plant regeneration from cultured cells and tissues. Such genes are being explored for potential use in developing marker-free transgenic systems as well as to potentially enhance the frequencies of transgenic plant recovery.^[4] These advances, as well as advances in specific culture systems such as thin cell layers,^[21] offer the prospects of extending more efficient in vitro plant regeneration techniques to previously recalcitrant crops, and of developing more efficient genetic transformation methods. Such advances in controlling in vitro morphogenesis should play important roles at the applied level in developing new crop cultivars and reducing the cost of micropropagation, and in furthering basic research in the area of functional genomics by testing of transgenes in a wider array of plant species.

In Vitro Plant Regeneration by Organogenesis

Janet R. Gorst

Benson Micropropagation, Brisbane, Queensland, Australia

INTRODUCTION

Efficient regeneration of plants from cells and tissues through organogenesis is an important prerequisite for the successful application of biotechnology to crop improvement. In vitro regenerability is a highly variable genetic trait that can be introgressed into nonregenerating (recalcitrant) lines by conventional breeding. The availability of mutants with distinctive regenerative characteristics and the rapid developments in molecular biology have considerably advanced our understanding of the phenomenon of in vitro organogenesis in the recent past. While the last 10 years have seen remarkable progress in defining molecular mechanisms underlying plant processes, the specific area of organogenesis in vitro has not yielded many molecular secrets.

TOTI POTENCY

The concept of totipotency is central to understanding in vitro regeneration. The term is used in the context of differentiation not being an irreversible process as a cell undergoes maturation, i.e., a living plant cell with overt functional and structural specialization still carries all the information necessary to divide and undergo a morphogenetic process in the form of either organogenesis [which can be either rhizogenesis (root formation), caulogenesis (shoot formation) or, occasionally, flower formation] or embryogenesis, or to develop directly into a specialized cell type (e.g., as seen in xylogenesis). It is clear, however, from observations of regeneration in even highly regenerative explants that not all living differentiated cells of an explant participate in the regeneration process. This may be due to: 1) an inability to achieve in vitro the necessary conditions for totipotent expression; 2) genetic (physical changes to chromosomes, e.g., loss of DNA or nucleotide substitution) or epigenetic (changes in DNA expression as a consequence of development, e.g., DNA methylation or the isolation of DNA into heterochromatin) blocks that interfere with the expression of totipotency; 3) the fact that not all cells are totipotent, i.e., although all cells may appear to be the same in a particular tissue, only some possess special characteristics that enable them to

regenerate plants when isolated and cultured under inductive conditions.

The first step in the expression of totipotency, where it occurs, is for mature cells to reenter the cell cycle and resume cell division (a process known as dedifferentiation). The next step is redifferentiation, either through direct formation of organized structures (direct regeneration) or by the formation of an intervening callus stage from which organized structures may later be induced (indirect regeneration). An early appreciation of the mechanisms underlying regeneration of whole plants, or parts of plants, from cells came with the classic observations of Skoog and Miller^[1] that the direction of differentiation could be influenced by the ratio of the exogenously supplied growth regulators auxin and cytokinin. They observed in tobacco stem pith cultures that a high ratio of auxin to cytokinin led to initiation of roots, whereas a low ratio led to development of shoots. Although there are many species for which this simple manipulation will not work, in principle, this is the basis for regeneration in plant tissue culture systems. The two groups of growth regulators play a pivotal role in unlocking and realizing totipotent expression by influencing both dedifferentiation and redifferentiation. Note, however, that other medium conditions such as nitrogen, carbon source, and pH are also extremely important.

The process whereby differentiated cells respond to inductive phenomena leading to organogenesis involves two major phases—competence and determination. These phases reflect the two-stage practice of exposing cultures first to an “induction” medium and then to a “regeneration” medium during the regeneration process,^[2] although there are cultures for which both phases will occur on the same medium, particularly in the case of direct regeneration.

COMPETENCE

This is a transient state in which cells can be induced to follow an organogenic pathway^[2,3] and mechanical wounding is the most effective biological trigger for shifting cells into the competent state. Competence can be thought of as having two distinct components, one for cell division and the other for organogenesis.

Competence for Cell Division

In order to sustain cell division following wounding, exogenous auxin (+/– cytokinin) is usually required. Progress in understanding the molecular basis of the action of auxins and cytokinins in the initiation and maintenance of cell proliferation has been slow, and the complex interaction between exogenously applied growth regulators—overlaid with the unknown of endogenous synthesis—makes it difficult to differentiate the individual roles of auxin and cytokinin.

Proteins known as cyclin-dependent kinases (Cdks) govern the onset of S-phase and mitosis in all eukaryotic cells and require an activating cyclin subunit, which leads to the formation of Cyclin/Cdk complexes. In particular, homologues of a 34 kDa protein kinase known as p34 (coded for by the Cdk CDC) have been found in all eukaryotes that have been investigated. Induction of the competence of transformed protoplasts to divide in the presence of auxin and, to a lesser degree, cytokinin, was shown to be accompanied by expression of the *Arabidopsis CDC2a* gene, even if there was no subsequent cell division,^[4] and led to the proposal of a linkage between the expression of *CDC2a* and competence for proliferation. A role for the *Arabidopsis* gene *SRD2* in conferring competence for cell division has been hypothesized,^[5] and the expression of *CDC2a* in the *srd2* mutant is being undertaken. At another level of complexity, the gene *AINTEGUMENTA (ANT)* has also been implicated in cell cycle progression, but in addition it influences organ growth.^[6] Ectopic expression of the gene gives rise to transformed plants that show spontaneous callus formation and regeneration (of roots, leaves, or shoots) at wound or senescence sites. Seen as a gene that maintains meristematic competence in cells, *ANT* could give a molecular basis to the frequent observation in tissue culture that explants derived from immature tissue (such as from embryos) are much more likely to succeed in producing regenerable cultures than those obtained from mature tissue. In other words, competence in vitro may be correlated with continuing meristematic activity in vivo.

Competence for Organogenesis

A gene in *Arabidopsis (IRE1)* that acts very early in dedifferentiation confers the ability of cells to respond later to specific regeneration stimuli such as auxin and cytokinin.^[7] The work of Ozawa et al.^[5] with *Arabidopsis* mutants *srd1*, *srd2*, and *srd3*, which are defective in their ability to regenerate, identified three sequentially acquired states associated with organogenic competence. Initially there is IC (incompetent with respect to both cell proliferation and organogenesis), which requires the gene *SRD2* in order to progress to CR (competent with respect

to rhizogenesis). Finally, *SRD3* is involved in the progress from CR to CSR (competent with respect to shoot and root organogenesis).

DETERMINATION

This is a process in which cells follow a specific developmental pathway. The distinction between determination and competence can be illustrated by the work of Christianson and Warnick.^[2] They found that callus produced on *Convolvulus* explants was initially developmentally interchangeable, i.e., it was competent to follow two developmental pathways—root formation and shoot formation. Once induction of shoots began, the cells involved in shoot formation became determined, and transfer to a root-inducing medium did not affect the formation of shoots. In other words, as determination proceeds, cells become more and more committed, and the developmental potential becomes restricted unless there is a catastrophic event—such as wounding—that cuts across the determined state. The realizing of commitment is considered to be a third phase in the process of organogenesis.^[2]

In the Skoog and Miller model,^[1] caulogenesis is stimulated by exogenous cytokinin. The work of Ozawa et al.^[5] indicated that the genes *SRD1* and *SRD2* play essential roles in the caulogenesis induced by culturing competent explants on a medium containing cytokinin. Three genes, *CKI1* isolated from *Arabidopsis*,^[8] *ESR1* isolated from *Arabidopsis*,^[9] and *PkMADS1* isolated from *Paulownia*,^[10] have been identified as regulators of shoot regeneration. *CKI1* is thought to function as a cytokinin receptor in the process of cytokinin induction of shoot organogenesis. *ESR1* expression is induced by cytokinins, but transcripts of the gene accumulate only after acquisition of organogenic competence. *PkMADS1* is hypothesized to be a shoot meristem identity gene whose expression is necessary in activating the developmental pathway leading to direct regeneration of shoots. Cytokinin also induces another shoot meristem gene, *PAS-TICCINO*, but the outcome is an inhibitory one that prevents excessive cell proliferation,^[11] thus eliminating abnormal shoot development. The expression of homeobox genes in plants can be induced by cytokinin, and two such genes—*KNOTTED1* and *STM (SHOOT MERISTEMLESS)*—have been implicated in shoot formation.^[12]

The most frequent type of regeneration occurring in cultured cells is root formation, and this is stimulated by auxin.^[1] However, there is some complexity in the action of auxin, because although it stimulates root initiation, its continued presence in the culture medium can inhibit the outgrowth of roots. Experimental systems looking at the molecular basis of rhizogenesis are few and deal almost exclusively with lateral root formation and the

development of adventitious roots on stem cuttings. Lund et al.,^[13] working with a tobacco root mutant (*rac*) that fails to initiate adventitious roots in response to exogenous auxin, concluded that the *RAC* gene is involved in an auxin signal transduction pathway acting prior to the first organized divisions that lead to the formation of root meristems. During the determination phase of rhizogenesis the *LRP1* (*LATERAL ROOT PRIMORDIUM1*) gene is expressed,^[14] and during both determination and commitment certain S-adenosylmethionine synthetase-encoding genes (*SAMS*) are also up-regulated.^[15] The *Agrobacterium rhizogenes* infection system is a potentially useful tool for characterizing events in rhizogenesis. Cells infected with the bacterium show an increased sensitivity to auxin, consistent with the ability of such cells to undergo root meristem neof ormation and proliferation.

CONCLUSION

Regeneration through organogenesis represents an amazing developmental plasticity that sets plant cells apart from most animal cells. It is an extraordinarily complex phenomenon influenced by an array of internal and external factors. The molecular work to date suggests that there is certainly no single "totipotency" gene, and the existence of a conserved suite of genes that defines a group of cells as organogenic or recalcitrant in vitro is not very evident either.

In Vitro Pollination and Fertilization

Acram M. Taji

University of New England, Armidale, New South Wales, Australia

Jennifer S. Williams

University of Queensland, St. Lucia, Queensland, Australia

INTRODUCTION

Pollination followed by fertilization normally leads to the production of an embryo that, in the intact plant, is linked with normal seed development. Most angiosperms are outbreeders, as such self-pollination (selfing) is limited. Furthermore, hybridization between species and/or genera is also rare in nature. In plant breeding, however, selfing and hybridization are methods commonly used to obtain desirable crosses. If no fertilization takes place after self- or cross-pollination, plant breeders resort to special procedures such as in vitro pollination to bring about fertilization.

In vitro pollination and fertilization is a technique wherein male and female gametes are isolated and introduced to each other under conditions suitable for zygote formation. It involves pollen tube penetration of the embryo sac via manipulation of maternal tissue by methods other than the normal in situ process. Initially developed to bypass prezygotic incompatibility barriers, this technique has been used for the production of hybrids, the induction of haploid plants, overcoming sexual self-incompatibility, and in the study of reproductive processes and pollen physiology. The diversity of applications is mirrored by the diversity of species to which this technique has been applied.

IN VITRO POLLINATION AND FERTILIZATION

Indian scientists Kanta, Rangaswamy, and Maheshwari^[2] led the first successful forays into the concept of in vitro pollination and fertilization. By 1962 they established methods for the in vitro pollination and fertilization of *Papaver somniferum* (opium plant). Successful in vitro pollination and fertilization is dependent on several basic elements,^[3] including: 1) use of pollen grain and ovules at the required developmental phase; 2) sufficient pollen germination; 3) appropriate growth of pollen tubes and correct gametogenesis (sperm development); 4) pollen tube penetration into ovules; 5) successful fertilization;

and 6) appropriate nutrient media (to support pollen germination, pollen tube growth, fertilization, and embryo development).

In vitro pollination and fertilization has been most successful in species such as those belonging to the *Papaveraceae*, *Caryophyllaceae*, and *Solanaceae*, whose ovaries are large, contain many ovules, and are situated on nutrient-rich placenta.^[4] Compared to in vivo methods, in vitro pollination and fertilization offers increased control of environmental conditions, and thus enhances the accuracy and repeatability of experiments.

Types of In Vitro Pollination and Fertilization

There are three main methods of in vitro pollination and fertilization, each suitable for slightly different purposes. Successful application of a method to one species or family does not guarantee its successful use in another species or family.

In vitro stigmatic pollination and fertilization

In this method, pollen from an externally sterilized ripe anther is placed on the stigma of an emasculated flower. This technique is suitable for plants with premature ovary loss. *Nicotiana rustica*, *Nicotiana tabacum*, *Pisum sativum*, and *Zea mays* are examples of species in which this technique has been successful.^[5]

In vitro placental pollination and fertilization

In this technique, placenta from explants with unfertilized ovules are dissected from an externally sterilized flower, onto which pollen grains are placed. Because this method has worked well with certain species of *Brassica*, it is thought that in vitro cross-pollination could be successfully applied to all members of the Brassicaceae to avoid pollen/pistil incompatibility.^[4] This method has also been used successfully on members of the Caryophyllaceae and *Zea mays*. Most important, in vitro placental pollination and fertilization can sometimes be achieved with plants

(such as *Petunia axillaris*) that are completely self-incompatible in vivo.^[6]

In vitro ovular pollination and fertilization

Both cross-pollination and self-pollination can be achieved using this technique, in which pollen is applied to excised ovules from an externally sterilized flower. Selected ovules must be suitable for pollination by their own or foreign pollen. Success with this technique has been seen in *Cichorium intybus* L.^[7] and various species of Brassicaceae.^[8]

PRACTICAL APPLICATIONS

There are many practical applications of in vitro pollination and fertilization. These techniques often allow barriers to pollination and fertilization to be overcome, achieving cross-pollination/fertilization and self-pollination/fertilization where it is impossible to realize these objectives in vivo. This method has the potential to aid in the rescue of endangered species by overcoming incompatibilities, and in the creation of higher-quality commercial products through development of hybrids. It also enables further study into the process of fertilization, and the physiology of pollen.

OVERCOMING INCOMPATIBILITY BARRIERS (SELF-INCOMPATIBILITY AND INTERSPECIFIC INCOMPATIBILITY)

Incompatibility barriers can be classed as prezygotic (occurring prior to fertilization) and postzygotic (occurring after fertilization). Prezygotic incompatibility factors include those that impede effective fertilization (e.g., failure of pollen to germinate and penetrate the stigma, disintegration of the pollen tubes in the style, inadequate length of pollen tubes to effect fertilization). Circumventing prezygotic barriers by using in vitro techniques does not rule out the existence of postzygotic barriers to success in achieving the desired cross.

Postzygotic barriers occur during or immediately following syngamy (union of gametes during fertilization), and result in embryo starvation and abortion due largely to abnormal endosperm development.^[9] When used in tandem with embryo culture techniques, in vitro pollination and fertilization can overcome sufficient incompatibility barriers to produce viable seeds and whole plants. Overcoming incompatibility barriers will potentially lead to the production of better commercial plant products, and could assist in saving endangered species.

Self-incompatibility or interspecific incompatibility is often manifested in pollen/stigma or pollen/style rejection responses, which can be bypassed through use of in vitro pollination and fertilization techniques. In vitro placental pollination and fertilization enabled Zenkteler et al.^[8] to bypass pollen/stigma self-incompatibility in *Brassica campestris*. In vitro ovular pollination and fertilization was the technique used by Rangaswamy and Shivanna^[6] to overcome self-incompatibility in *P. axillaris*.

PRODUCTION OF HYBRIDS

In vitro pollination and fertilization, particularly when used in conjunction with embryo culture techniques, enables incompatibilities to be overcome, which allows interspecific, interfamilial, and intergeneric hybridization where conventional crossing techniques fail. Combining in vitro pollination and fertilization with new pollination methods, such as in vitro cut-style pollination and in vitro grafted-style techniques,^[10] has the potential to overcome even greater incompatibilities than those overcome by the use of in vitro pollination and fertilization alone. The combination of in vitro pollination and the grafted-style method (GSM) has successfully overcome hybridization barriers between several incongruent lily species.^[10]

Stylar barriers preventing hybridization (in particular, *Nicotiana* interspecific combinations) have been overcome by use of in vitro pollination and fertilization.^[9] In vitro placental pollination and fertilization enabled Zenkteler et al.^[8] to obtain hybrids between *Brassica napus* and *B. campestris*. Hybrids between *Brassica chinensis* and *Brassica pekinensis* were obtained using in vitro ovular pollination and fertilization.^[11]

INDUCTION OF HAPLOID PLANTS

Haploid parthenogenesis can be induced by pollination with pollen of unrelated species or with inactivated pollen from the same species.^[7] *Melandrium album* (used as the female plant) can be pollinated with pollen from species of *Nicotiana* to obtain 1% haploid plants.^[4]

STUDYING REPRODUCTIVE PROCESSES AND POLLEN PHYSIOLOGY

In vitro methods offer new ways to study plant reproductive processes and pollen physiology. The development of an in vitro fertilization method without the application of electrical pulses for higher plant gametes could be used

for studies of cell-cell interaction (adhesion, fusion, recognition).^[12] Haldrup and Bruun^[13] showed that in vitro pollination could be employed to study the time course of, and processes related to, pollen-tube development. Rougier et al.^[14] predicted that in vitro fertilization systems (readily available for studying the processes of zygote formation in flowering plants) may provide new tools for molecular analysis of fertilization and early embryo development. In vitro pollination has been used as a model for the study of fertilization in *Z. mays*.^[7]

CONCLUSION

The basic concept of in vitro pollination and fertilization has evolved to be applied to various components of the pistil, and to be adapted to an enormously diverse range of plant species.

In vitro pollination and fertilization is a technique that has been used for the production of hybrids, the induction of haploid plants, overcoming sexual self-incompatibility, and the study of reproductive processes and pollen physiology. Although its potential has not yet been fully explored, in vitro pollination and fertilization has already assisted in the conservation of endangered species^[15] and in the creation of new hybrids. In vitro pollination and fertilization will almost certainly result in the development of stable novel genotypes of economically superior plants, the most important of which are edible crop species. Greater genotypic variation could mean decreased disease susceptibility and increased crop survival in inhospitable climates—very desirable traits for crop improvement.

In this era of genetic engineering, in vitro pollination and fertilization represents an essential tool with which to gain a deeper understanding of the mechanisms of fertilization in plants and the physiology of pollen. In vitro pollination and fertilization undoubtedly has a role to play in the search for genes affecting pollination and fertilization in *Arabidopsis*, the recently sequenced model plant.

In the future, in vitro pollination and fertilization will be used in conjunction with myriad techniques of cell engineering to aid researchers in their quest to better understand the mysteries of plants.

In Vitro Production of Triploid Plants

Sant S. Bhojwani

University of Delhi, Delhi, India

INTRODUCTION

Most of the flowering plants are diploid with two sets of chromosomes. The plants with a higher number of chromosomes are called polyploids. Many spontaneous and induced polyploid varieties of crop plants are under cultivation because of their better vigor, improved fruit size/quality, and/or attractive flowers or foliage. The triploid plants, with three sets of chromosomes, are seed-sterile due to disturbance in gamete formation. Therefore, triploids hold great commercial potential where seedlessness is desirable or is of no serious consequence. Triploid varieties of banana, citrus, hops, and watermelon are already under commercial cultivation for their seedless fruits. Some natural triploids of tomato bear larger and tastier fruits than their diploid counterpart. Triploidy is of special significance for crops, which are grown for their vegetative parts or flowers. Some examples where triploids have proved superior to their diploid or tetraploid counterparts for a specific economic trait are high-yielding cassava (IPGRI Newsletter for Asia, the Pacific and Oceania, May–August, 2001), disease-resistant mulberry, more vigorous and ornamental petunia, and poplar with more desirable pulpwood.

The natural occurrence of triploids is very rare. On the other hand, the traditional method of artificial production of triploids is tedious and lengthy. It involves treating the diploids with colchicine to raise tetraploids, with four sets of chromosomes, followed by backcrossing the superior tetraploids with the diploids. In many cases, this is not possible due to sexual sterility of the tetraploid plants or failure of the cross. In contrast, *in vitro* regeneration of plants from endosperm, a natural triploid tissue, offers a direct, single-step approach to raising triploids. The sexually sterile triploids can be multiplied by micropropagation.

ENDOSPERM DEVELOPMENT

The angiosperms are characterized by double fertilization. During sexual reproduction, the male gametophyte delivers two sperms in the female gametophyte. Of these, one sperm fuses with the egg, which forms the well-organized diploid embryo, whereas the other sperm fuses with two

nuclei in the central cell, which gives rise to an unorganized endosperm tissue.^[2] Since the endosperm is derived from the fusion product of three haploid nuclei, it is triploid. It is the main source of nutrition for the developing embryo. In some plants (pea, orange, and watermelon) the endosperm is completely consumed before seed maturation, whereas in others (castor bean, maize, and coconut) it persists in mature seeds as a massive tissue and supports the growth of the embryo during seed germination.

ENDOSPERM CULTURE

Following the discovery of double fertilization around 1898, the embryologists regarded endosperm as a second embryo modified to serve as a nutritive tissue for the zygotic embryo. Sargant^[3] remarked that the triploid nature of the endosperm might be responsible for its formless structure. However, the *in vitro* studies have clearly demonstrated the ability of the endosperm tissue for unlimited growth and to regenerate full plants.^[4]

The work on endosperm culture was initiated in 1933, but the establishment of continuously growing tissue cultures of maize endosperm was first achieved in 1949, by LaRue.^[5] Although maize endosperm persists in mature seeds, callus cultures could be established only from immature endosperm; 8–11 days after pollination (DAP) was the best stage. This is also true for other cereals, where the bulk of the mature endosperm is dead. Thus, the age of the endosperm at the time of culture could be a critical factor in raising tissue cultures of some species.

In 1963, Mohan Ram and Satsangi^[6] demonstrated that divisions could be induced in mature endosperm cells of castor bean by treating the seeds with 2,4-dichlorophenoxyacetic acid (2,4-D) before germination. In the same year, establishment of continuously growing callus cultures from the mature endosperm of sandalwood was reported by Rangaswamy and Rao.^[7] Since then, it has been possible to initiate tissue cultures from mature and immature endosperm of many plants. A critical factor in the induction of cell divisions in mature endosperm is its initial association with the embryo. There is ample evidence to suggest that the germinating embryo contributes some factor, which is essential to trigger cell divisions in the mature endosperm. The mature endosperm from dried

Fig. 1 A five-week-old culture of decoated seed of *Exocarpus cupressiformis*. The embryo has germinated and multiple shoot buds have differentiated from the surface of the endosperm.

seeds of castor bean did not callus, but if the seeds were soaked in $\text{Ca}(\text{OCl})_2$ solution 22 hours prior to the excision of the endosperm, it exhibited callusing. The frequency of callusing increased if the seeds were allowed to germinate, and the number of cultures showing proliferation was directly related to the germination period before the

excision of the endosperm. For tomato, soaking the seeds for three days was optimum in terms of the number of cultures showing endosperm callusing. Therefore, to initiate callus cultures from mature endosperm, it is cultured along with the embryo intact, and once the endosperm callusing has initiated (after 7–8 days) the embryo is removed to ensure that it does not callus and contaminate the endosperm callus. In some plants, the embryo factor could be substituted by gibberellic acid (GA_3). Although it is now possible to induce divisions in mature endosperm of many species (castor bean, croton, jatropha, putranjiva, neem, and sandalwood), immature endosperm continues to be the explant of choice in cereals and in those species where endosperm is consumed before seed maturation (acacia, citrus, cucumber, and mulberry).

The maize endosperm callus grew best on a medium containing yeast extract. However, in most other systems an auxin (generally 2,4-D), a cytokinin, and a rich source of organic nitrogen (yeast extract or casein hydrolysate) are required for optimal growth. The callus can be multiplied for unlimited period by periodic subcultures.

PLANT REGENERATION

By 1964 the cellular totipotency of plant cells had been well established, but the endosperm cells were still

(Based on Ref. 21.) (View this art in color at www.dekker.com.)

regarded as recalcitrant for plant regeneration. In 1965 Johri and Bhojwani,^[8] working with *Exocarpus cupresiformis*, first reported the differentiation of well-organized shoot buds from the mature endosperm. Histological studies confirmed the origin of the shoots from the peripheral cells of the endosperm (Fig. 1). As expected, the shoots were triploid. Since then, shoot/embryo/plant regeneration from the endosperm tissue has been reported for at least 24 species (Table 1).

In the cultures of mature endosperm, shoot differentiation may occur directly from the endosperm or after callusing. However, in immature endosperm cultures, it is always preceded by a callus phase. Plant regeneration from the callused endosperm of acacia, citrus, and sandalwood occurred via somatic embryogenesis.

For shoot bud differentiation from endosperm tissue, a cytokinin is always essential. Whereas *Scurrula pulverulenta* and *Taxillus vestitus* differentiated shoots in the presence of a cytokinin alone, *Dendrophthoe falcata* and *Leptomeria acida* required an auxin in addition to a cytokinin. The immature endosperm of mulberry (17–20 DAP) exhibited good callusing on a medium containing 5 μM 6-benzylaminopurine (BAP) and 1 μM α -naphthaleneacetic acid (NAA). Further addition of coconut milk and yeast extract improved the callusing response. The initial association of the embryo was promotive for endosperm callusing. The callus differentiated multiple shoots when transferred to a medium containing BAP or thidiazuron. However, maximum regeneration occurred when BAP was added in conjunction with NAA^[21] The endosperm callus of citrus initiated on a medium con-

taining 2,4-D (2 mg hr l⁻¹), BAP (5 mg hr l⁻¹), and casein hydrolysate (1000 mg hr l⁻¹) differentiated globular embryos upon transfer to a medium with GA₃ (1 mg hr l⁻¹) as the sole hormone.^[13] Further development of the embryos and plant regeneration required doubling the salt concentration and raising GA₃ concentration to 15 mg hr l⁻¹. In *Taxillus vestitus*, injury to the endosperm enhanced shoot bud differentiation (Fig. 2).

Most of the organs and plants regenerated from endosperm are triploid. Full triploid plants of endosperm origin have been developed for apple, kiwifruit, mulberry, neem, and sandalwood. The triploids of mulberry and sandalwood have been established in soil.

CONCLUSION

There is enough experimental evidence to suggest that endosperm cells are totipotent, and the technique of endosperm culture holds great potential in raising triploids of crop plants. Endosperm culture from crosses of selected diploid parents is likely to give better triploids. Triploid plants of *Petunia axillaris* derived from cultured microspores were much more ornamental than their parental anther-donor diploids.^[29]

In Vitro Tubерization

Yasunori Koda

Hokkaido University, Sapporo, Japan

INTRODUCTION

Various plants such as potato, yam, and Jerusalem artichoke develop tubers as organs for reproduction. When nodal stem segments of these plants are cultured aseptically *in vitro* under appropriate conditions, *in vitro* tubers are formed synchronously on lateral shoots that emerge from the nodes. Tubers formed *in vitro* are usually called microtubers. The culture system has provided a useful mechanism for various basic studies related to storage organ formation. In this article, *in vitro* potato tuberization is mainly described, with regard to the factors affecting the process, the mechanism, and a simple method of induction.

TUBERIZATION IN THE FIELD

After the first report by Barker on potato tuberization *in vitro*,^[1] the culture system has been used in various basic studies. The nature of tuberization in the field is described first, since there are several analogies between tuberization *in vitro* and in the field. Tuberization in field-grown plants is controlled mainly by photoperiod. Short days stimulate the process, whereas long days prevent or retard it. The response to photoperiod interacts with many other factors. Both high temperature and high levels of reduced nitrogen in the soil inhibit tuberization. Plants from physiologically old mother tubers form tubers irrespective of photoperiod, so aging makes the photoperiod requirement for tuberization redundant. As to the genotype, late-maturing cultivars have a shorter critical photoperiod than the early-maturing cultivars. In other words, tuberization occurs earlier in the early-maturing cultivars under the natural field conditions from summer to autumn. The differences in their tuberizing ability seems to be due to the balance between two endogenous factors, one being inhibitive and the other promotive. The inhibitive factor is gibberellin (GA) and promotive one seems to be jasmonates (jasmonic acid, JA, and related compounds).^[2] GA that is necessary for formation and elongation of stolon strongly inhibits tuberization, and reduction of GA level is a prerequisite to tuberization.

Potato tuberization is initiated by expansion of cells at the subapical region of a stolon, i.e., a kind of lateral

shoot. The swelling at this early stage is mainly caused by radial expansion of cells. Subsequently, vigorous thickening growth due to expansion and division of cells occurs, and starch accumulates. The initial cell expansion is attributed to both an increase in osmotic pressure in the cells due to the accumulation of sucrose and changes in cell wall architecture that increase extensibility of the wall. The direction of cell growth (elongation or expansion) is controlled by the orientation of cortical microtubules (MTs). Characteristic reorientation of MTs, from perpendicular to parallel with respect to the axis of the stolon, is found when a slight swelling of the stolon occurs. Jasmonic acid (JA) is capable of inducing both reorientation of MTs and expansion of cells.^[2] After the commencement of the swelling, cytokinins are accumulated in the expanded region, leading to cell division.

FACTORS AFFECTING IN VITRO TUBERIZATION

Various factors affecting *in vitro* tuberization are summarized in Table 1. Each factor exhibits the opposite effect on shoot growth. Longer duration of culture period tends to stimulate tuberization. The low tuberizing ability of late-maturing cultivars seems to be due partly to higher endogenous GA.^[3] Application of an inhibitor for GA biosynthesis, such as ancymidol, uniconazol, or paclobutrazol at concentrations below 10 μM , stimulates *in vitro* tuberization in late-maturing cultivars. JA is also capable of inducing microtubers in these cultivars, but it induces only smaller tubers.

Sucrose at a high concentration (more than 6%) is indispensable for *in vitro* tuberization. Although the supplied sucrose is rapidly hydrolyzed into glucose and fructose, these monosaccharides cannot replace sucrose,^[4] indicating that sucrose is not a mere regulator of osmotic pressure. Cytokinins (benzyladenine, kinetin, and zeatin, etc.) at a concentration of 10 μM can promote tuberization.

Culture conditions, such as vessel size, headspace gas exchange, and culture density, affect *in vitro* tuberization and yield of microtubers. Although a large-scale bioreactor with forced aeration is favorable for good yield, the

Table 1 Various factors affecting in vitro tuberization and shoot growth

Factors		Tuberization	Shoot growth
<i>Environmental</i>			
Photoperiods	Short days	Promotive	Inhibitive
	Long days	Inhibitive	Promotive
Temperature	Cool (20–22°C)	Promotive	Inhibitive
	Warm (25°C)	Inhibitive	Promotive
<i>Nutritional</i>			
Sucrose	High (8%)	Promotive	Inhibitive
	Low (3%)	Inhibitive	Promotive
Reduced nitrogen		Inhibitive	Promotive
<i>Genotypic</i>			
Early-maturing cultivars		Promotive	Inhibitive
Late-maturing cultivars		Inhibitive	Promotive

system itself affects the cost of seed tuber production. A vessel that contains a smaller amount of medium (e.g., a 500 ml bottle containing 50 ml medium) can produce enough microtubers. When the bottle is sealed tightly with aluminum foil, many lenticels are formed on the surface of the microtubers, reducing their storability. Lenticle formation seems to be mediated by ethylene production, because an application of silver thiosulfate (ethylene antagonist) to the medium or sealing the culture vessels with air-permeable membrane can reduce lenticel formation. The density of shoots in the culture also affects microtuber production; usually, the larger the density, the higher the rate of production.

MICROTUBER DORMANCY

Prolonged or highly variable dormancy is a significant obstacle to the efficient use of microtubers as seed tubers. The dormancy seems to be induced by endogenous abscisic acid (ABA) and/or ethylene.^[5] Microtubers that developed in the presence of fluridone (an inhibitor for synthesis of carotenoid including ABA) or silver nitrate (ethylene antagonist) exhibit a loss of dormancy and sprout on the mother shoots (precocious sprouting). On the other hand, GA can release tubers from dormancy. Varying photoperiodic treatments and light intensities during the microtuber induction affect the duration of dormancy. The lower the light intensity, the longer the dormant period. An 8-hour photoperiod instead of continuous darkness reduces dormancy.^[6] Although several exogenous chemicals could break dormancy, chemical treatments sometimes affect the growth of plants developed from microtubers. Rindite and bromoethane have a practical use as dormancy-releasing reagents.^[6] The duration of dormancy can be manipulated by various methods,

but development of cultivar-specific protocols is necessary to control dormancy.

A SIMPLE METHOD FOR IN VITRO TUBERIZATION

An in vitro tuberization system can be established easily from tubers using the procedure shown in Fig. 1. This

Fig. 1 Schematic diagram showing the procedure to establish an in vitro tuberization system from potato tubers.

method enables one tuber to produce many nodal segments as materials for culture, and is also applicable to bioassay for tuber-inducing activity. Surface-sterilization of tubers and tissue plugs is necessary to avoid microbial contamination, and relative humidity in the dark room should stay below 30% in order to raise healthy etiolated shoots. After surface-sterilization, nodal segments of the shoots are planted on agar-solidified Murashige–Skoog (MS) medium (3% sucrose) and cultured at 25°C for 2 to 3 weeks to obtain lateral shoots. If some tuber-inducing compound such as JA is applied to the medium, tubers are formed on the laterals. To produce microtubers routinely, two culture steps are usually employed (Fig. 2). The first step is called *in vitro* layering, which involves shoot propagation by recycling segments of shoots back to the

shoot culture. Vigorously growing shoots are selected and subcultured every four to six weeks in liquid medium, under long-day conditions (16 h photoperiod), at 25°C. Viruses can be eliminated by meristem culture at any time during this step. To induce *in vitro* tuberization, the propagated shoots are transferred to fresh liquid medium that contains 8% sucrose and are cultured in the dark, or under short-day conditions, at 20–22°C. Many microtubers are formed on the lateral shoots within a week, and the tubers continue to grow for another seven to eight weeks. The final fresh weight of the microtubers is usually between 0.2–1.0 g. Recycling smaller microtubers back into propagation of shoots is a preferable option for mass production.^[7] Since somaclonal mutation scarcely occurs during these steps, this method enables long-term conservation of disease-free germplasm.^[8] The *in vitro* layering system is also applicable to the conservation of potato viruses. For *in vitro* tuberization in other plants such as yam (*Dioscorea* spp) and Jerusalem artichoke (*Helianthus tuberosus*), a similar method can be employed.

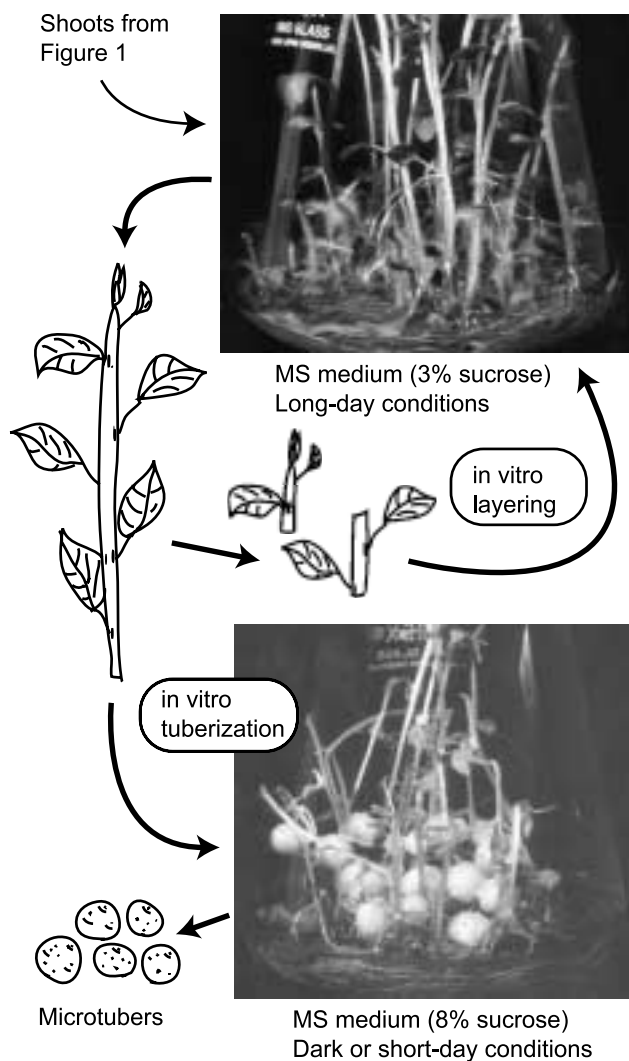

Fig. 2 Schematic diagram showing the procedure for successive microtuber production.

MICROTUBERS AS SEED TUBERS

The degree of periderm (skin) development affects the storability of microtubers. Greening of microtubers by light irradiation improves the storability. Microtubers retain their viability for three years under low temperature and high relative humidity storage conditions. Each microtuber produces a single shoot when planted in the field. Early growth of the plant is much slower than that from true tubers, but the plant produces many branches and grows vigorously thereafter. Interestingly, the plant's final yield of tubers is comparable to that of the plant grown from a true tuber.

CONCLUSION

Besides practical use for production of disease-free seed tubers, the *in vitro* tuberization system is applicable to experimental tools for various basic studies, such as studies on the mechanism of tuberization, carbohydrate metabolism, starch synthesis, and the transformation of plastids (from amyloplasts to chloroplasts). Furthermore, *Agrobacterium*-mediated gene transformation is easily carried out using this system.^[9] Several attempts have been made to improve protein quality and to introduce foreign carbohydrate in tubers. Perhaps in the near future, this method will be applied to produce various useful seed tubers for molecular farming.

Insect Dietary Needs: Plants as Food for Insects

Spencer T. Behmer

Department of Entomology, Texas A&M University, College Station, Texas, U.S.A.

INTRODUCTION

Insects comprise more than half of all living macroscopic organisms, and about half of all insects feed on plants. Plant-feeding as a lifestyle is, however, found in only 8 of the 30 insect orders—Coleoptera (beetles), Diptera (flies), Hemiptera (sucking bugs), Hymenoptera (sawflies, wasps, ants, and bees), Lepidoptera (butterflies and moths), Orthoptera (grasshoppers, katydids, and crickets), Phasmida (stick and leaf insects) and Thysanoptera (thrips). Like all other animals, plant-feeding insects eat to acquire the nutrients necessary for growth, reproduction, and general maintenance, and while the qualitative nutritional requirements of all insects are generally quite similar, plant-feeding insects do have some special requirements. An additional issue for plant-feeders is that the nutrient content of plants and plant parts are considerably variable. In some instances, plant-feeding insects have developed mutualistic relationships with microorganisms, which has allowed them to feed on plants, or plant tissues, that lack or contain low levels of essential nutrients.

INSECT NUTRITIONAL REQUIREMENTS

Plant-feeding insects, like other insects and animals, have the ability to biosynthesize some nutrients, although most of the nutrients they need are provided by their host-plants. Nutrients that cannot be synthesized endogenously are classified as being essential, while those that can be produced by using other dietary components are termed non-essential. Much of our understanding of nutrition in plant-feeding insects comes from rearing studies using artificial foods. The most common approach is to omit a specific nutrient from the diet and then measure the effect of this deletion on insect growth and/or reproduction. Once essential nutrients have been identified, the effect of replacing these nutrients with analogs can be measured. Finally, radiolabeled precursors can be used to determine which nutrients are generated endogenously.

AMINO ACIDS

Amino acids, the building blocks of protein, are often considered the most limiting nutrients for plant-feeding

insects. There are 20 amino acids that are regularly found in plant proteins, and of these 10 are considered essential (Table 1). Plant-feeding insects use amino acids to build proteins, which can be used for structural purposes, as enzymes, for transport and storage, or as receptor molecules. Individual amino acids also serve important physiological functions. For example, tyrosine is essential for hardening of the cuticle, tryptophan is used in the synthesis of visual screening pigments, glutamate operates as a neurotransmitter, and for some plant-feeding insects proline is an important energy source.^[1]

Plant proteins are the dominant source of amino acids, although plants also contain a small pool of free amino acids (usually about 5% of the total). An individual plant will contain a range of different proteins, but the value of any particular protein varies depending on its digestibility and amino acid content, particularly the number and balance of essential amino acids. Ribulose biphosphate carboxylase is likely to be a particularly important dietary protein because it makes up about 50% of the soluble protein in young leaves.^[2] Protein composition and quality also vary between and within plant species as a result of genetic and environmental factors, as well as within an individual plant as a result of differences in leaf age (e.g., protein content is usually high in young leaves but tends to be lower in old leaves) or plant part (e.g., nitrogen concentration is lowest in xylem and phloem but highest in flower buds and seeds). In general, the absence of any single essential amino acid from the diet prevents growth, and in some instances non-essential amino acids (e.g., proline for the silkworm, *Bombyx*) may be required.^[1] Even though some amino acids are non-essential, optimal growth usually only occurs when there is a good mixture of non-essential amino acids in the diet.

CARBOHYDRATES

Carbohydrates, which contain the elements carbon, hydrogen, and oxygen in a 1:2:1 ratio, respectively, are the major source of metabolic energy for plant-feeding insects. Carbohydrates are generally split into two groups: sugars (e.g., glucose, fructose, and sucrose) and non-sugars (e.g., starch, dextrin, and cellulose).

Table 1 Essential and non-essential amino acids for plant-feeding insects. Amino acids that cannot be synthesized by insects are called essential, and these must be obtained from the diet or generated from non-essential amino acids by endosymbionts

Essential	Non-essential
Arginine	Alanine
Histidine	Asparagine
Isoleucine	Aspartate
Leucine	Cystine
Lysine	Glutamate
Methionine	Glycine
Phenylalanine	Histidine
Threonine	Proline
Tryptophan	Serine
Valine	Tyrosine

The ability of a plant-feeding insect to use a particular carbohydrate depends upon the type of digestive enzymes present in the salivary glands and midgut. Most plant-feeding insects can use sugars, starch, and dextrin, but not cellulose.^[3]

Strictly speaking, carbohydrates are not essential nutrients because insects can convert fats and amino acids to carbohydrates via gluconeogenesis. Nonetheless, carbohydrates are considered important, and growth is enhanced when they are provided in the diet. For example, the desert locust, *Schistocerca*, grows best on a diet containing 20% digestible carbohydrates, while the flour beetle, *Tenebrio*, exhibits optimal growth on diets containing 70% carbohydrate.^[1] *Tenebrio* fails to develop, however, if the carbohydrate concentrations drop below 40%.

LIPIDS, VITAMINS, AND MINERALS

Lipids are found in both plants and animals, where they operate as electron carriers, substrate carriers in enzymatic reactions, components of biological membranes, and sources and stores of energy, and their common property is insolubility in water. Sterols, fatty acids, fat-soluble vitamins, and carotenoids are examples of lipids that are either essential or considered important for plant-feeding insects.

Sterols serve as structural components in cellular membranes and as precursors for steroid hormones (e.g., molting hormone), and are essential nutrients for all insects, in fact all arthropods. Cholesterol (Fig. 1) tends to be the dominant tissue sterol in plant-feeding insects despite the fact that plants rarely contain it at appreciable levels. To date hundreds of different sterols have been identified in plants, with

Fig. 1 All plant-feeding insects require a dietary source of sterol, and cholesterol, with a double bond at position 5 (Δ^5), is the dominant tissue sterol found in insects. Plants, however, rarely contain cholesterol at appreciable levels. The arrows on the four plant sterols indicate structural differences from cholesterol. Of the four plant sterols shown, only sitosterol supports normal growth and development in grasshoppers.

sitosterol being the most common; so plant-feeding insects produce cholesterol by metabolizing the sterols found in their host-plants.^[4] Some plant-feeding insects, however, have strict limitations on which plant sterols can be metabolized to cholesterol. Grasshoppers, for example, cannot use sterols with double bonds in certain positions (Fig. 1).^[4] Some plant-feeding insects, such as the cactus fly, *Drosophila pachea*, can only use the phytosterols found in the plants on which they specialize.^[5]

Most plant-feeding insects also have a dietary requirement for polyunsaturated fatty acids. Generally plant-feeding insects grow well when linoleic or linolenic acid is present in the diet (Fig. 2).^[3] The effect of omitting fatty acids from the diet varies from species to species. For example, in the Lepidoptera and Hymenoptera, adults fail to develop properly if linolenic acid is omitted from their larval diet,^[1] although this does not appear to be the case for the caterpillar *Heliothis subflexa*.^[6] Fatty acids also seem to play a role in

Fig. 2 Most plant-feeding insects require a dietary source of polyunsaturated fatty acids with double bonds in the 3 and/or 6 position. Linoleic and linolenic acid each have a chain length of 18 carbons, but they differ in the number of double bonds contained within the chain (2 and 3, respectively).

reproduction because some beetles suffer reduced fecundity and produce slow growing larvae when it is omitted from the diet. The Diptera, with the exception of mosquitoes, do not seem to require polyunsaturated fatty acids.^[1]

Vitamins are organic compounds, and plant-feeding insects, like other animals, need them in small amounts. Typically, vitamins are split into two groups based on their solubility in water. The B vitamins, including thiamine, riboflavin, nicotinic acid, pyridoxine, pantothenic acid, folic acid, and biotin, are water soluble. Primarily, they function as cofactors of the enzymes catalyzing metabolic transformations, but they also serve additional roles (e.g., biotin is part of the enzyme pyruvate carboxylase, and folic acid is necessary for nucleic acid biosynthesis).^[3] *Myo*-inositol and choline are components of some phospholipids and are usually required in larger quantities than vitamins. Choline can be produced from methionine, though, so the amount of choline a plant-feeding insect needs will vary depending on the levels of methionine in the diet.^[1] Ascorbic acid, which is also known as vitamin C, is required by most plant-feeding insects.

Plant-feeding insects also require two fat-soluble vitamins. The first of these, β -carotene (provitamin A), is a functional component of visual pigments and is involved in the normal pigmentation of plant-feeding insects. It is, however, produced only by plants and microorganisms, and when carotenoids are absent from the diet, insects often appear rather drab and dull, and melanization is reduced.^[1] Vitamin E (α -tocopherol)

is the other lipid-soluble vitamin needed by most plant-feeding insects. Its presence boosts fecundity, while its absence negatively affects sperm production.^[1]

Mineral elements are found in most plant-feeding insects because they are constituents of plants. However, sodium, potassium, calcium, magnesium, chloride, and phosphate are considered essential because they each play an important role in metabolic processes. As with other animals, plant-feeding insects require iron because it is the central element in cytochromes.^[1] Zinc and manganese are also required because they play a part in hardening the cuticle of mandibles.^[3]

NUTRIENT POOR FOODS AND ENDOSYMBIONTS

While most plant-feeding insects eat leaves, those in the order Hemiptera have specialized mouthparts that enable them to feed from individual plant cells. For example, some treehoppers (Membracidae) feed from leaf mesophyll, aphids (Aphididae) and planthoppers (Fulgoroidea) feed on phloem, and spittlebugs (Cercopidae) feed on xylem. Some plant-feeding insects have also become specialists on wood (e.g., beetles in the family Bostrycidae), while others specialize on detritus (e.g., crickets). Generally speaking, sap, wood, and detritus are not particularly nutritious, so insects feeding on these substrates use endosymbionts, which reside in the alimentary canal and/or intracellularly,

to overcome nutritional deficits.^[7] The majority of the endosymbionts in plant-feeding insects are bacteria, although yeast is found in planthoppers and in some wood-boring beetles.^[1,7] The endosymbionts of aphids and wood-boring beetles produce essential amino acids from non-essential amino acids, while the endosymbionts of wood-feeding insects digest and metabolize cellulose. Endosymbionts, particularly yeast, may also supply sterols.^[3]

CONCLUSIONS

Much of the success of insects as a group has been attributed to their ability to feed on a wide range of foods, and this certainly seems the case for plant-feeding insects because they are found on every plant and virtually every plant part (leaves, stems, flowers, roots, vascular tissues, etc.). Compared to their predaceous relatives, however, the food of plant-feeding insects is nutritionally poor. For example, it has a much lower protein/carbohydrate ratio and is generally lower in sodium. Additionally, many plants contain defensive compounds that are toxic or interfere with digestion.^[2] Nonetheless, plant-feeding insects are quite adept at regulating the intake of important nutrients,^[8] and they employ a range of pre- and post-ingestive mechanisms to reduce the intake of harmful chemicals and their toxicity, respectively.^[2,8] Nutrient regulation is a critical component in determining the individual success of any insect, including economically important pest species, and a more comprehensive

understanding of insect nutrition might lead to the development of novel control methods that exploit insect nutritional requirements. Such an approach would be advantageous because it would be target specific and environmentally friendly.

INTRODUCTION

Interactions between insects and other pests can be divided into two broad categories (Fig. 1). The first of these comprises interactions whereby insect pests have an effect on other organisms. These may be beneficial (e.g., pollination) or detrimental (e.g., disease transmission) to the organism concerned. The other major class of interaction involves impacts of other organisms on insect pests. Similarly, these interactions may harm the insect (e.g., predation, parasitism, and pathogenesis) or provide some kind of benefit (e.g., gut symbiosis).

INSECT PEST IMPACTS ON OTHER ORGANISMS

Pest interactions with plant pathogens are of huge economic importance, as many insects are vectors of plant diseases. Although insect vectored diseases are inimical to host plants, resulting in cosmetic damage and yield loss, the insect vectors are highly beneficial to the virus itself. For many viruses, insect vectors are the sole means of transmission, making them integral to the persistence of the virus. The potato-colonizing aphid *Macrosiphum euphorbiae* (Thomas) (Homoptera: Aphididae) is responsible for transmission of the virus responsible for potato leaf roll disease (e.g., Ref.^[1]). This is a persistent virus, as an aphid individual will remain infective for the duration of its life as a result of viral circulation within the vector. In other cases, for example, potato virus Y, the virus is nonpersistent and transmission will result immediately after feeding begins on a new host plant.

Nonviral pathogens such as phytoplasma are also transmitted by insects. For example, the plant-pathogenic chrysanthemum yellows phytoplasma infects a

variety of dicotyledonous plants, causing stunting and phloem hyperplasia, and is transmitted by several species of leafhoppers in the family Cicadellidae. Similarly, European stone fruit yellows phytoplasma is transmitted in a persistent manner by the psyllid *Cacopsylla pruni* Scopoli (Homoptera: Psyllidae).

Multispecies interactions involving insect pests, weeds, and pathogens are also known. Lettuce necrotic yellows rhabdovirus is transmitted from sow thistle *Sonchus* spp., which is an alternative host of the virus as well as the aphid vector *Hyperomyzus lactucae* (L.) (Homoptera: Aphididae).

Insects can also indirectly lead to the spread of plant diseases by producing substances that favor survival of fungal pathogens. For example, honeydew produced by aphids can facilitate growth of fungal diseases such as sooty molds that inhibit growth of the host plant by blocking photosynthesis, and cause damage to fruit. Again, the insects in this example are beneficial to a species of pathogen, but harmful to the host plant.

Insects may, however, act in a way that is beneficial to plants. For example, milkweed *Asclepias syriaca* (Gentianales) is pollinated by a pest insect, the European skipper *Thymelicus lineola* (Ochsenheimer) (Lepidoptera: Hesperiiidae). In this case, the European skipper would presumably derive some type of nutritional benefit in terms of nectar or pollen.

THE IMPACT OF OTHER ORGANISMS ON INSECTS

The impact of weeds on insect pests is of major ecological and economic importance. Pests may use weeds facultatively as an alternative host as in the case of the mite, *Halotydeus destructor* (Tucker) (Acarina: Penthalidae), which will reproduce on capeweed

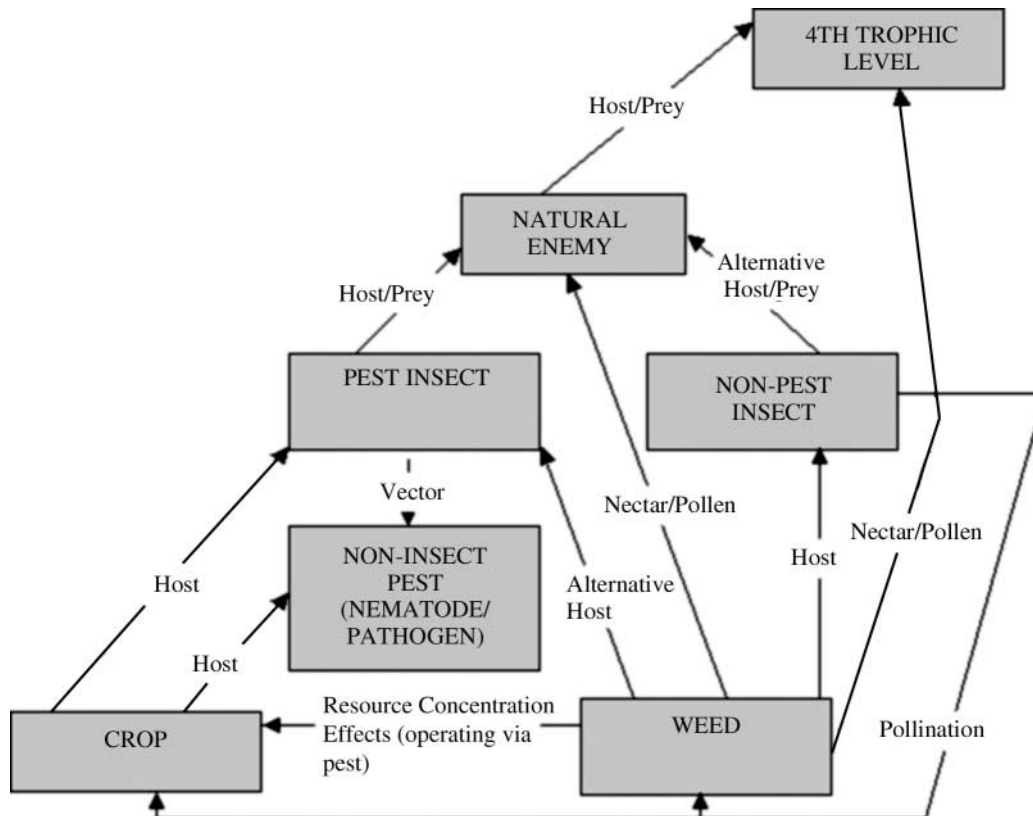

Fig. 1 Summary of major interactions between insects and other pests (weeds, pathogens, and nematodes) with arrows depicting the direction of benefits. See text for explanation.

Arctotheca calendula (L.) as well as damage desirable species within pastures. Weeds may also constitute alternative hosts that are essential for local survival of insect pest populations. For example, lightbrown apple moth *Epiphyas postvittana* (Walker) (Lepidoptera: Tortricidae) uses broadleaved weed species in the floor of vineyards when the leaves and fruits are absent from the vines during winter months.

In some cases, a weed may provide a specific resource that is otherwise limiting within a crop habitat. In the case of lepidopterans, for example, noncrop vegetation can provide nectar to adults and exacerbate larval damage to the nearby crop.^[2] Weeds can, however, benefit pest management by making crop plants less apparent against the soil background. This type of effect is especially well known for aphids, which are unlikely to land on bare soil, but may land on green plant surfaces even if they are not a suitable host. Such “resource concentration” effects are widely acknowledged to be an important explanation for the common observation that severity of pest damage is lessened in polycultures of crops containing weeds.^[3] Weeds may also constitute a “trap” for pests when they are attractive oviposition substrates but do not allow subsequent pest development.^[4] This form of interaction offers good scope for preventing damage to crops as is the

case when *Cucurbita pepo* L. is planted in the vicinity of melon (*Cucumis melo* L.) crops to reduce melon fly (*Bactrocera (Dacus) cucurbitae* Coquillet) (Diptera: Trypetidae) attack.

Weeds may influence pests indirectly via higher trophic levels. There are many cases of weeds providing resources for the natural enemies of pests: foods (e.g., nectar, pollen), populations of alternative hosts/prey, or moderated microclimate.^[5] In some instances, however, such resources may benefit the fourth trophic level (parasites or predators of natural enemies).^[6]

Entomopathogenic fungi, viruses, nematodes, and bacteria can all cause considerable harm to insects, and consequently, many of these organisms are used in biological control. These pathogens can directly reduce pest populations; however, if they infect natural enemies of the pest, they may indirectly lead to an increase in pest numbers. Although entomopathogenic fungi show promise as a potential alternative to insecticides, care must be taken, as metabolites secreted by these organisms may be toxic to humans. Nonpest insects may also act as vectors for the transmission of fungi, such that an insect natural enemy may reduce pest densities directly through predation/parasitism, and indirectly via fungus transmission.^[7,8]

Interactions involving viruses can also be a major cause of insect pest mortality. For example, the single-embedded nuclear polyhedrosis virus of *Trichoplusia ni* (Hubner) (Lepidoptera: Noctuidae) can be introduced to cabbage seedlings at the time of transplanting, and results in 95–97% mortality of Lepidoptera larvae, compared with 4.5% in untreated plots. A variety of baculoviruses are also used for control of Lepidoptera and other insect pests.^[7]

Entomopathogenic nematodes are parasites of many lepidopteran, dipteran, and coleopteran pests of commercial crops. Many nematodes have symbiotic relationships with bacteria such that the bacterium (e.g., *Photorhabdus*) is introduced into the insect via the nematode, then secretes chemicals that kill the insect and converts its tissues into suitable food for the bacteria and nematode.^[9] This mutualism and the ease with which nematodes may be cultured make them very suitable as biological control agents in the future.

A number of species of bacteria infect insect pests. One notable example is *Bacillus thuringiensis* (Bt), which can be cultured and sprayed across a crop in a similar manner to insecticides. An endotoxin of this species is lethal to pest Lepidoptera larvae, and a gene for its production has been used in a variety of transgenic crops.^[10]

Despite the numerous instances described above where other pest species have negative effects on insects, interactions with other organisms may also be beneficial to the insect. Many pest insects have mutualistic relationships with gut microbes that facilitate digestion. For example, the gut symbionts *Buchnera* spp. Munson et al. (a type of gamma-Proteobacterium) interact positively with aphid digestion, thereby producing a benefit for both species.^[11]

An interaction where plants may have potentially beneficial impacts on insects involves production of sex pheromones. Many insects require host-plant chemicals as “building blocks” for pheromone synthesis, and the host plant can therefore have a marked influence on sex-pheromone behavior of phytophagous insects.^[12]

CONCLUSIONS

Insects interact with pests from other phyla in a variety of ways. Many pathogens have evolutionary strategies that are so intimately tied to those of their insect vectors that transmission in their absence is impossible. These insect/pathogen interactions have received considerable attention, as they are highly detrimental to agriculture. Virus transmission is responsible for a large proportion of the economic damage caused by aphids, and nonviral (e.g., bacterial) pathogens can

destroy entire crops. However, interactions with pathogens may also be harmful to insects, and are frequently exploited in biological control. A number of entomopathogenic organisms are readily available commercially and can be applied to crops as a living insecticide.

Therefore, the interactions involving insects and other pests outlined above underlie a variety of agricultural problems, yet they also provide a variety of potential solutions. Examination of these interactions may lead to further improvements in biological or cultural pest control, and may simultaneously expose complex symbioses or multitrophic level interactions.

Insect Life History Strategies: Development and Growth

Jeffrey C. Miller

Oregon State University, Corvallis, Oregon, U.S.A.

INTRODUCTION

The growth and survival of individuals, family units, and populations perpetuate the species. Adaptations to specific modes of growth and survival lead to the evolution of life history traits. Furthermore, combinations of life history traits involving physiological, morphological, behavioral, and ecological characteristics result in suites of adaptive tactics providing for the expression of certain features that may occur in coincidence or opposition with other features. Combinations and tradeoffs in tactics used to achieve growth and survival are repeated to some degree among species that capitalize on essential resources exhibiting similar attributes regarding spatial and temporal characteristics. For instance, many species capable of rapid colonization of ephemeral habitats exhibit short generation times and relatively high reproductive potential. Such traits exhibited in combination with other traits, such as weak interspecific competitive abilities, provide an adaptive suite of traits generally referred to as life history strategies. The life history characteristics that in sum create the suite of traits involved in life history strategies can be considered in at least eleven component areas: type of metamorphosis, location of life stages, acquisition of food resources, developmental rates, phenology, reproductive potential, dispersal and colonization, competitive behavior, defensive mechanisms, living in extreme environments, and group living and domiciles. Each of these components of life history strategies will be discussed in the context of adaptive suites and tradeoffs in risks and benefits relating to growth and survival.

METAMORPHOSIS

Three principle processes occur in the developmental pathway from the egg, to the immature stage, to adulthood. The most primitive process is ametabolous development. This process involves three life stages: egg, immature, and adult, where sequential molts of immature individuals (instars) do not result in an appearance or ecology that differs to any significant degree from that of the adult, and adults that are reproductively mature may continue to molt. The primitively wingless insects, such

as, silverfish, firebrats, and jumping bristletails are some of the more notable groups characterized by ametabolous development. In contrast, the hemimetabolous (including paurometabolous) insects also develop through three life stages, but the immature stages (nymphs or naiads) are distinguished by external wing buds, no pupal stage, and adults that are reproductively mature and do not continue to molt. Fully developed wings are present following the molt from the final instar to the adult. Typically, the ecology of immatures and adults that exhibit hemimetabolous development is very similar. Hemimetabolous development is characteristic of many insect groups exhibiting a diverse array of habits. For instance, aquatic insects such as dragonflies, damselflies, mayflies, and stoneflies. Also, numerous terrestrial plant-chewing and plant-sucking insects exhibit hemimetabolous development, such as grasshoppers, earwigs, walking sticks, true bugs, bark lice, aphids, whiteflies, mealybugs, and scales. The holometabolous insects develop through four distinct life stages: egg, larva, pupa, and adult. The immature stages, unlike in ametabolous or hemimetabolous development, exhibit a morphology and ecology typically very different from the adult stage. The transition from immature to adult occurs most dramatically in the pupal stage when the larva with internal wingbuds transforms into the reproductively mature adult with fully developed external wings. Holometabolous development is characteristic of the groups comprising a majority of insect biodiversity, such as beetles, butterflies, moths, lacewings, fleas, caddisflies, true flies, sawflies, wasps, bees, and ants.

Regardless of which developmental process is followed by an insect species, the major function in the immature stage is acquisition of food for growth, while the major function of the adult stage is reproduction and dispersal. Uncommonly, the immature stages are the primary dispersal agents and select life history tactics are associated with this condition, as discussed under colonization. The fact that most insect species exhibit holometabolous development suggests that holometabolous development facilitates resource partitioning between immatures and adults, which reduces competition between the life stages and in turn enhances the exploitation of specialized niches, resulting in higher levels of speciation.

LOCATION OF LIFE STAGES

The sites for development of eggs, immatures, the pupa, and adults may involve many types of environments and microhabitats. For instance, herbivorous insects may occur on the surfaces of plants or within plant organs. The location of the various life stages is relevant to life history strategies because specialized adaptations are necessary to mediate physical and biological conditions encountered in the variety of microhabitats throughout the environment. Adaptations may be needed for defense against soil microbes, extracting nitrogen from a low nitrogen source like plant sap, or tolerance of temperature extremes. The life history of a typical geometer moth illustrates the complexity of a holometabolous life cycle where each of the four life stages occurs in a different microenvironment: Eggs are placed on the plant; caterpillars feed on leaves; pupation occurs in the soil; and the adult is free-flying and feeds on nectar or does not feed at all. In general, immatures of herbivorous insects function in the role of seed-, root-, crown-, or stem-borers, leaf-miners, leaf-chewers, or phloem- or xylem-feeders. The type of food consumed may be a specific resource or a generalized set of resources. An insect herbivore that is a specialist feeder may be either a taxonomic specialist, which means the insect feeds on only one plant species or a few species within the same genus, or a plant part specialist, which means the insect feeds only on seeds or roots, etc. In extreme cases, a generalist insect herbivore might feed on a hundred or more plant species across several plant families. The acquisition of suitable food resources and the condition of being a food specialist or

Fig. 1 Caterpillars represent a major group of herbivorous insects; they are the larval life stage of Lepidoptera and exhibit holometabolous development. The caterpillar will molt into the pupal stage, from which the adult butterfly or moth will emerge. (Photo by Jeffrey C. Miller.) (View this art in color at www.dekker.com.)

generalist can involve many types of life history traits regarding morphology, physiology, and behavior (Fig. 1).

FOOD RESOURCES

Numerous specialized morphological adaptations and numerous life history traits are associated with the behavioral and physiological adaptations involved in avoiding starvation, locating food, and food acceptability. Among the tactics employed to mitigate starvation are cannibalism, oosorption (females are able to reabsorb nutrients from eggs still in the reproductive tract), protein reclamation from muscle degeneration, and development through an extra (supernumary) molt. One of the dominant themes regarding food resources is the condition of specialist and generalist feeding habits and vegetation as apparent and unapparent plants.^[8] Specialist feeders have a low probability of randomly finding food; therefore, they must possess traits that place them in the proper habitat at the proper time for exploitation of their respective food resources. For specialists the proper habitat can be discovered by detecting certain cues such as unique form and color, or unique and often toxic chemicals characteristic of apparent plants. In addition to serving as cues in the process of host plant location, certain otherwise toxic plant chemicals may serve as phagostimulants and as a protein source for nutrition and defense mechanisms. On the other hand, generalist feeders may have a higher probability of encountering a seemingly random but acceptable food resource, but do not derive notable chemically based defensive properties from the unapparent plants, because the foliage is devoid of acutely toxic compounds. The timing of life stages to coincide with the availability of required food resources is an issue of phenology and is discussed after developmental rates.

DEVELOPMENTAL RATES

The rate of development depends on three main factors: temperature, nutrition, and genetics. Temperature is critical to insect development and is the focus of mathematical models capable of predicting insect developmental rates. The temperature-dependent growth models require information regarding two key variables in insect life history traits: 1) temperature thresholds (upper and lower) for development and 2) heat-unit requirements above the lower developmental threshold needed to complete development of each life stage.^[9] Typically, insects inhabiting temperate latitudes exhibit a lower developmental threshold in the range of 5–15°C. One of

the tradeoff considerations regarding temperature-dependent growth and life history traits is that a low lower developmental threshold might allow for a rapid accumulation of heat-units and, therefore, rapid growth rates. However, a low lower developmental threshold may also compromise tolerance regarding the upper developmental threshold, which, if exceeded, will result in death due to an intolerance of heat. Likewise, a higher value for the lower developmental threshold may confer a cold intolerance and a slower rate of heat-unit accumulation that could result in a slower growth rate. As with other life history traits, the genetically based developmental thresholds are, to one degree or another, characteristic of family units, populations, and species. The ability of an insect to thermoregulate, increase body temperature through rapid muscle contraction or basking in the sun, involves life history traits that allow certain species to defy environmental temperatures that otherwise would preclude an activity such as feeding or flight. Because temperature is a dominant factor in determining growth rates, it is also the case that temperature is influential in determining the seasonal occurrence of life stages and therefore the phenology of various events that must occur in synchrony, such as the timing of egg hatch with the occurrence of bud break and leaf maturation.

PHENOLOGY

Three aspects of phenology are particularly relevant to life history strategies: 1) diapause, 2) overwintering, and 3) voltinism. The onset of diapause and overwintering are often coincidental in nature.^[10] That is, particularly among temperate zone insects, overwintering life stages will be in a state of diapause that was triggered in part by declining photoperiod in the autumn. The gradual conclusion of the diapause condition is triggered by a cold period followed by warming above the lower developmental threshold. A combination of factors, including developmental threshold values, heat-unit requirements, diapause conditions, and the temperatures characteristic of the habitat, will determine how many generations an insect population may exhibit within one year. Univoltine species cycle through only one generation per year and typically exhibit relatively narrow variance in the seasonal occurrence of the various life stages, whereas, multivoltine populations may cycle through many generations per

year and exhibit a wide variance in the presence of various life stages and have overlapping generations. Among other considerations, a consequence of voltinism in combination with the length of time necessary to complete a generation is the effect on potential reproductive potential expressed by the population or species.

Insect Life History Strategies: Reproduction and Survival

Jeffrey C. Miller

Oregon State University, Corvallis, Oregon, U.S.A.

INTRODUCTION

Insect herbivore life history traits related to development and growth are integral to understanding the life history traits regarding reproduction and survival. In fact, the relationships cannot fully be appreciated unless the adaptive nature of each life history trait is considered in the context of natural selection and its affects and effects concerning variation across temporal and spatial scales, predictable and unpredictable aspects in environmental constancy and heterogeneity, variation in genetics, the fitness value of a given combination of alleles, and the high diversity of combinations in life history traits. This article on insect life history strategies concentrates on adaptations regarding reproductive potential, dispersal and colonization, competitive behavior, defensive mechanisms, living in extreme environments, and group living and domiciles.

REPRODUCTIVE POTENTIAL

The total number of offspring, the timing of delivery of offspring, and sex ratio are central themes in life history strategy analysis.^[1-3] In fact, the concept of *r*- and *K*-selection^[4] is predicated on the dynamics of birth and death rates that on balance represent the reproductive capacity of a given population or, in a very general application, the species. Species that exhibit a high fecundity (total egg production per female) may also exhibit short generation times and may be multivoltine. The annualized reproductive capacity of such a species is extremely high. On the other hand, the rates of mortality in such a species may also be extremely high, resulting in highly volatile population densities. Other life history traits that may be associated with highly fecund species are rapid colonizing ability (discussed shortly), generalist food requirements, intense intraspecific competition for limited resources, and inferior interspecific competitive ability.^[5,6] Conversely, species exhibiting lower levels of reproductive potential may be slower to colonize newly available habitats, but once they do they may retain their presence by being more specialized in food requirements and superior interspecific competitors (Fig. 1).

Many insect species may control the sex ratio of their offspring through various mechanisms where the female can regulate the fertilization of her eggs with sperm stored in a special pouch called the spermatheca. One sex determination mechanism is arrhenotoky, also known as haplo-diploidy, where haploid offspring are males and diploid (fertilized eggs) offspring are females. Some species of weevils and all of the Hymenoptera are arrhenotokous. The ratio of female to male offspring has the direct consequence of altering the dynamics of population growth rates. Some species do not possess males during any part of their life cycle or only during certain generations in a multivoltine life cycle. For instance, aphids develop through a sexual generation from the fall through winter and into the spring; however, in late spring and during the summer, many species will develop through numerous parthenogenetic generations that lack males. In the case of aphids, other life history traits are associated with the alternation of sexual generations, such as shifts in specific host plant affinities between generations. During the summer, asexually produced females are wingless, the parthenogenetic females give birth to live young, and summer populations typically occur in large aggregations on plants. Each of the individual features illustrated by the complex aphid life cycle contributes to an extremely high reproductive potential due to a mix of life traits that in combination contribute to rapid population growth. On the other hand, aphid life history strategies are associated with considerable risk regarding mortality due to predation. A diverse complex of predators, parasitoids, and diseases, each with their own life history strategies, may at times counterbalance the high reproductive potential inherent in aphid populations and thereby regulate aphid numbers to very low population densities. An effective defense against natural enemies is dispersal, an action allowing escape and affecting survival in other ways as well.

DISPERSAL AND COLONIZATION

The movement of individuals is critical for the exchange of genes among and between populations, which in turn is essential for adaptation to changing environments and for placing an individual in a certain life stage into a suitable

Fig. 1 Ants are excellent examples of how insects exhibit an array of life history strategies involving defensive behavior, domiciles, herbivory by farming, dispersal, competition, and surviving in extreme environments. (Photo by Jeffrey C. Miller.) (View this art in color at www.dekker.com.)

habitat at an appropriate time of the year. Long distance movement, including migration, in insects is a mode of active dispersal generally controlled by flight. Migrations are not a prevalent feature in life history strategies of herbivorous insects but are well known in a few species, such as the monarch butterfly, the milkweed bug, and some species of noctuid moths.^[7] However, aerial passive dispersal over distances measured in kilometers is a relatively common behavior. Aerial passive dispersal is strongly influenced by wind currents, thus the insect must be buoyant and may be incapable of flight. For instance, certain Lepidoptera disperse in the larval stage. The caterpillars typically are hairy or spin silk for buoyancy and have generalist feeding requirements, and the females are flightless but highly fecund, whereas the male is winged and capable of flight.^[8] Flightlessness is an obvious condition of adult insects exhibiting aptery and brachyptery with the activity of dispersal dependent on a passive mode; however, the feature of flightlessness is not necessarily a fixed trait. Species may possess various states of wingedness that are expressed through a suite of polymorphic conditions that in some cases are sexually determined. The expression of sexually dimorphic traits, polymorphic features, differences in colonizing abilities, and reproductive potential also interrelate with considerations of competitive behavior and defensive mechanisms.

COMPETITIVE BEHAVIOR

Insect herbivores compete within and among species for limited, essential resources. Therefore, life history traits exist that either enhance the competitive edge of one species over another or provide a means for one species to minimize competition for limited, essential resources such as mates, oviposition sites, food, and shelter. Two of the primary tactics employed by insects to gain a competitive

advantage are 1) the use of chemical markers and 2) the expression of aggressive behavior. Numerous insect species mark parts of the habitat with pheromones. An example of habitat marking is the placement of a pheromone with a newly deposited egg, which has the effect of deterring oviposition by other females of the same species at or near the same place. Pheromones are also prevalent in mating behavior, trail maintenance, colony integrity, and warning signals. Interestingly, the pheromones that may alleviate intraspecific or interspecific competition for food among herbivorous species may serve as a cue in aiding natural enemies of the herbivores in prey location. The expression of aggressive behavior is manifested in life history traits such as cannibalism and various degrees of combat, from pushing and shoving to biting and stinging to the death of one or both of the combatants. Many herbivorous insects are cannibalistic, that is, they will kill and in some cases consume individuals of their own species. Cannibalism is most commonly encountered in species exhibiting a solitary lifestyle. For instance, caterpillars are immature Lepidoptera, a group that is virtually herbivorous in nature, and yet individual caterpillars will fight with and consume other caterpillars of the same species, or different species, when they encounter one another on their host plant. Aggressive behavior also provides an important component of defensive mechanisms.

DEFENSIVE MECHANISMS

Numerous life history traits are involved in defense mechanisms, such as, as previously mentioned, flight for escape, mimicry for appearing to be another species that possesses a threatening or toxic defense, aposematic coloration for warning predators of toxic compounds, crypsis for camouflage and for hiding out in the open, startle behavior for scaring off a potential attacker, feigning for appearing to be dead, expulsion of liquids for repelling an attacker, spines and poison glands, alarm pheromones, domicile construction, and guarding behaviors for protection of progeny or a colony. Each of these features, and many more, may be found occurring in combination with one another in an insect species.^[9] In general, the adaptive nature of any particular suite of defensive mechanisms is dependent upon the intensity of the selective pressure exerted by a given mortality factor. For instance, a species of beetle, such as the Colorado potato beetle, whose larva is a specialist feeder on the foliage of potato, which is a toxic plant, may gain protection from enemies by sequestering the plant allelochemicals that otherwise confer protection to the plant against generalist herbivores. The ability to sequester toxic compounds will have limits and may be

genetically determined and, thus, subject to variability within the population, as in monarch butterflies where certain individuals lack the cardiac glycosides responsible for the aposematic coloration of the adult. If the ability to sequester the toxic compound has an energetic cost, perhaps measured relative to reproductive potential, then individuals that are not capable of sequestering the toxic compounds are at risk, but they might gain a benefit if predation is not a primary mortality factor. Other defensive mechanisms involve mimicry and crypsis, which are expressed through morphological characters and coloration, traits that can vary based on selective pressures and genetically based polymorphisms. As mortality due to predation changes in time and space within the environment so will the gene frequency regulating the expression of each particular state of the polymorphism. Each genotype within the polymorphic suite of traits can exhibit a different fitness value depending on the presence and absence of predators. Thus, the tradeoffs in benefits and risks can have the consequence of changing the trend of directional selection. The principle of tradeoffs in benefits and risks in life history strategies is also well illustrated by considering adaptations to extreme environments.

EXTREME ENVIRONMENTS

Specialized morphological features and character reduction are two common types of adaptations to extreme environments. Some examples of these are a lack of color in certain species living in habitats devoid of light, such as caves; a lack of sight, as in certain soil-dwelling blind ground beetles; extremely dorso-ventrally flattened bodies typical of many leaf-mining caterpillars; and exaggerated features, such as the enlarged antennae associated with cave-dwelling crickets or the fossorial legs present in the soil-dwelling nymphs of cicadas. Similarly, insects in arid environments will exhibit specialized traits such as an extremely waxy cuticle, high numbers of Malpighian tubules, or physiological means for excreting uric acid instead of ammonia. Each one of these traits provides a selective advantage due to benefits regarding water conservation. Overall, growth and survival in extreme environments will depend on a combination of life history traits involving other physiological mechanisms and behavioral activities regarding the timing of dispersal to avoid harsh environmental conditions, phenology of life stages and diapause or aestivation, reproductive potential to compensate for high mortality, food resource requirements, and developmental biology, which determines growth rates and voltinism. One additional feature in life history strategies relates to the mitigation of adaptations to

extreme environments through the behavior of group living and the activity of domicile construction.

GROUP LIVING AND DOMICILES

Insects may occur as solitary individuals, in groups consisting of a few to hundreds of individuals, or in a family unit consisting of thousands of individuals. Some of the benefits of group living are protection from natural enemies, cooperation for brood care, and in some cases construction of nests, as occurs with social insects such as termites, bees, and ants.^[10] However, one of the risks of group living, whether it is as a simple aggregation of aphids on the exterior of a leaf or as a social unit inside a nest, is the supply of adequate food reserves. Among the social insects, the means for gathering and storing large quantities of food involves specialized life history traits including morphological features such as enlarged foreguts or hindguts, pollen baskets, physiological processes resulting in caste differentiation, behavioral mechanisms such as feeding via trophallaxis, and sanitation. Also, social insects are noted for their communal construction of domiciles; however, living within a domicile is not restricted to the social insects. Numerous species of herbivorous, nonsocial insects live within structures of some sort. For instance, gall-making insects, notably certain beetles, flies, wasps, and aphids, may stimulate their host plant to create a gall that includes a supply of nutritive tissue as well as a place to house the immatures and provide a barrier to guard against the outside environment. Although the benefits of a gall are obvious, one of the risks is that a predator capable of invading the gall space can readily consume its otherwise defenseless prey.

CONCLUSION

The subject of insect life history strategies is a well-studied topic on the basis of empirical data, concepts, and models. Basically, the topic focuses on considerations of variability in the environment, variability in genetics of the organisms responding to the variable environments, and the relative advantages and disadvantages of various combinations of life history traits across spatial and temporal components of the environment.

Insect/Host Plant Resistance in Crops

C. Michael Smith

Kansas State University, Manhattan, Kansas, U.S.A.

INTRODUCTION

The development of plants with resistance to insects is a proven method for managing insect pest populations. Many insect-resistant crop varieties have played vital, integral roles in sustainable systems of agricultural production. Resistant varieties are nonpolluting; ecologically, biologically, and socially acceptable; and economically feasible as a means of pest control. In the eighteenth and nineteenth centuries, insect resistant varieties of cereals and fruits were first developed and cultivated in Europe and North America. When the grape phylloxera, *Phylloxera vitifolae*, destroyed the French wine industry during the late 1880s, resistant rootstocks from the United States were grafted to French scions, and the industry recovered.

TERMINOLOGY

Plant resistance to insects is the sum of the inheritable genetic qualities that result in a plant of one variety or species being less damaged than a susceptible plant lacking these qualities under a similar pressure of herbivory.^[1] Resistance is measured on a relative scale, and the degree of resistance is based on comparison to susceptible plants that lack resistance in the same experiment.^[2] Variation in insects, test plants, and the environment may affect the expression of resistance, often resulting in pseudoresistance in normally susceptible plants. The effect of each variable should be determined before concluding that a plant is resistant.^[3]

Associational plant resistance to insects occurs when mixtures of plant species slow pest insect population development on normally susceptible plants growing in association with resistant plants^[4] or plants infected with fungal endophytes that produce alkaloids that kill or delay the development of pest insects.^[5] Searches for resistance can be directed at selection for either allopatric resistance (plants evolving in the absence of insect pressure—no previous evolutionary contact) or sympatric resistance (plants evolving in the presence of insect pressure).^[6]

FUNCTIONAL CATEGORIES OF RESISTANCE

Painter^[7] defined the negative effects on insect biology of chemical and morphological plant defenses in resistant plants as antibiosis. These defenses may be overcome by the expression of virulence genes in an insect pest population after prolonged exposure to high levels of antibiosis. Populations expressing virulence are known as insect biotypes. Many biotypes are parthenogenic (reproduce asexually) aphid species, or Dipteran and Heteropteran species with high reproductive potentials that infest large cereal (rice and wheat) monocultures. Biotypes have been identified by phenotypic plant reaction for many years, but DNA marker techniques are beginning to be employed for more accurate identification of biotypes.

Resistance is also manifested as antixenosis, where chemical or morphological plant factors result in pest insect selection of alternate host plants.^[8] The resistant plant may also be able to withstand or recover from insect damage and yield as much or more biomass than a protected susceptible plant. In this case, resistance is expressed as tolerance to the pest insect. An advantage of tolerance is that although the pest population level is not reduced, an ample food source for pest predators and parasites is provided, and synergizes the beneficial effects of these biological control agents. Frequently, resistant plants exhibit multiple resistance categories.

In addition to enhancing biological control, even moderate levels of resistance combined with insecticides can greatly reduce insecticide use costs and the amount of insecticide residues. This effect has been demonstrated in many different agricultural systems.^[9] In some cases, insect-resistant varieties offer producers genetically incorporated insect control for the cost of the seed alone. Insect-resistant varieties provide a substantially greater rate of return on investment than do insecticides. The current global economic value of all insect-resistant crop plants, based on increased crop yields and reduced insecticide use, is approximately \$2.7 billion per year^[9] (Table 1).

Table 1 Approximate annual value of resistance genes deployed in all arthropod-resistant crops produced globally

Crop plant	Pest arthropod	Geographic location(s)	Value (US\$ × 1,000)
Cotton (<i>Bt</i>)	<i>Helicoverpa zea</i>	Southeast U.S.	1,350
	<i>Heliothis virescens</i>		
Rice	<i>Nilaparvata lugens</i>	South/Southeast Asia	1,125
	<i>Nephotettix cincticeps</i>		
Sorghum	<i>Schizaphis graminum</i>	Midwest/Southwest U.S.	85
	<i>Blissus leucopterosus</i>		
Wheat	<i>Aceria toschiella</i>	North America	170
	<i>Mayetiola destructor</i>	Southeast U.S.	19
	<i>Diuraphis noxia</i>	Western U.S./South Africa	14
	<i>Cephus cinctus</i>	North America	17

INSECT RESISTANCE TRANSGENES

Two changes occurred in the development of insect-resistant varieties near the end of the twentieth century. First, *Agrobacterium* transformation systems and biolistic projectile devices were used to transfer genes encoding insecticidal crystal (cry) toxins from the soil bacterium *Bacillus thuringiensis* (Bt) into crop plants. After ingestion, crystals are solubilized in the alkaline environment of the insect gut, where active toxic fragment(s) are released by insect digestion, bind to specific receptors on the midgut cells of susceptible larvae, and then cause osmotic lysis of those cells, and insect death. Several crop plants have also been transformed with transgenes expressing insect digestive enzyme inhibitors of both plant and insect origin.

Before the development of Bt transformants, numerous studies determined that insects became virulent to the cry toxin gene after prolonged exposure to high doses of Bt, similar to how high doses of conventional pesticide or high levels of conventional gene expression lead to virulence in target insects. One early research study indicated that Bt corn was toxic to larvae of the monarch butterfly, *Danaus plexippus*. Subsequently, the U.S. National Academy of Sciences reviewed a series of several other experiments and concluded that the risk to monarchs from Bt corn is not significant. One Bt corn event grown on a very small U.S. hectare was shown to be toxic to monarch larvae and is being eliminated from production.

To obtain their maximum longevity, Bt insect-resistant transgenes in corn and cotton are deployed with non-Bt plant refuges that enable the survival of pest moths from susceptible larvae to mate with moths produced from larvae virulent to Bt. Shifting the mortality of larvae heterozygous for virulence from 50% to 95% provides a tenfold delay in time before the development of virulence.^[10]

Although numerous transgenic crop plants have been developed, only the production and marketing of trans-

genic corn, cotton, and potato varieties have proceeded in North America and Asia. However, because these are essentially insecticidal plants, their deployment strategy has proven complex, and their production and use have met with strong opposition by environmentalists, primarily in Europe. Estimates are that recommended insecticide use against one insect pest of corn, *Ostrinia nubilalis*, dropped approximately 30% after the commercialization of Bt corn in North America.

DNA RESISTANCE MARKERS

The second major shift in the development of insect-resistant plants is the adaptation of genotypic screening techniques to identify insect resistance genes. This change involves isolating DNA from resistant and susceptible parents, amplifying complementary DNA with molecular markers from known chromosome locations, separating the DNA amplification products by electrophoresis, and identifying primers that differentially amplify the DNA of resistant and susceptible parents and their progeny in a polymorphic (informative) pattern. DNA markers have several advantages over phenotypic markers. They can be codominant and detect heterozygous patterns of inheritance, where morphological markers behave in a dominant/recessive manner and do not. The allelic variation of DNA markers is greater than for morphological markers. Finally, molecular markers are unaffected by the environmental fluctuations that have been shown to have a significant effect on morphological markers. DNA markers can be used to map resistance genes inherited as dominant traits at single loci, or as quantitative traits, located at multiple loci and linked to several minor genes contributing to insect resistance.

The chromosome location of many constitutive insect resistance genes has been identified in a wide number of crop plants using molecular markers.^[11] However, the

only insect resistance gene cloned to date is Meu1 from wild tomato, *Lycopersicon peruvianum*, which confers resistance to the potato aphid, *Macrosiphum euphorbiae*, and the root knot nematode, *Meloidogyne incognita*.^[12] Meu1 is a member of the nucleotide-binding site and leucine-rich region (NBS-LRR) family of disease and nematode resistance genes.

EXPRESSED RESISTANCE GENES

While research on constitutive herbivore resistance genes is only beginning, progress is also being made in the identification of unique mRNA transcripts expressing induced insect resistance genes that are produced by several species of plants. In essence, tissue damage caused by components of insect saliva contacting plant tissues activates an octadecanoid signaling cascade that leads to biosynthesis of signals such as jasmonic acid, salicylic acid, ethylene, and abscisic acid that in turn activate the production of many different types of insect antifeedant compounds. Chewing insects elicit plant responses different from those induced in response to feeding by piercing/sucking insects.^[13] In addition, the end result of hypersensitive responses to insect feeding is often the production of enzymes that lead to cell wall thickening in resistant varieties, hindering insect feeding and digestion. In cereal plants, induced disease and nematode resistance gene loci occur in clusters^[14] and there is evidence that insect resistance genes occur in a similar manner.^[15]

CONCLUSION

Insect-resistant crops play an important role in world sustainable agricultural systems, and will become more prominent as world food needs increase. Resistant varieties have proven to be ecologically and socially acceptable to consumers, and economically feasible for producers. Although there have been many successes in deploying insect-resistant genes in improved varieties, it is not completely clear how plants recognize the attack and feeding by different insects. However, chemical and mechanical stimuli perceived by plants during insect feeding contribute to plant recognition of feeding. Very limited information exists about the molecular aspects of plant response to insects, but a partial understanding is emerging. The continued use and refinement of molecular marker techniques to genotype constitutive and induced insect resistance genes in plants should continue to provide the necessary information to determine the molecular bases of plant genetic defenses against insects.

The use of functional genomics will enable the sequencing of additional insect resistance genes in many plants, and will help develop refined genetic maps of these genes. A more complete understanding of pest resistance genes will reduce the possible development of virulent, resistance-breaking insect biotypes and lead to more rapid development of crop varieties with greater and more diverse levels of insect resistance.

Insect–Plant Interactions

Sujaya Rao

Oregon State University, Corvallis, Oregon, U.S.A.

INTRODUCTION

Insects and plants have evolved together for millions of years, and their relationships are both antagonistic and mutualistic. Antagonistic associations arise because the energy trapped in plants during photosynthesis is used by approximately half of the species of insects. Insects of the six largest orders (Orthoptera, Hemiptera, Lepidoptera, Coleoptera, Diptera, and Hymenoptera) derive most or all of their food directly from plants.^[1] However, despite extensive herbivory by insects, plants continue to flourish, in part because of defenses that they have evolved against insect attack. As a result, no insect species feeds on all plants, and no plant species is eaten by all insect herbivores. Certain insect species have, however, evolved effective means to overcome plant defenses, and in turn new plant defenses have evolved. Coevolution has also resulted in the development of mutualistic interactions that benefit both plants and insects in diverse ways. This review will outline plant–insect interactions that are beneficial to insects, those that are beneficial to plants, and certain mutualistic interactions.

INTERACTIONS OF BENEFIT TO INSECTS

Feeding

Insects profit by using plants as sources of food. All parts of a plant may be eaten by phytophagous insects: roots, sap, stems, leaves, buds, pollen, nectar, fruits, seeds, and decaying plant tissue. Monophagous insects feed on one or a few plant species, whereas polyphagous insects include a wide range of plants in their diet. Plants provide insect herbivores with nutrients necessary for growth and development, such as water, nitrogen, carbohydrates, amino acids, lipids, minerals, and vitamins.^[2] Plants also serve as sources of sterols required for production of hormones.

Plant growth is affected negatively when photosynthetic tissue is eaten, phloem sap is drained, or uptake of water and minerals is affected as a result of feeding by chewing and sucking insects. Chewing insects feed either externally or internally, as borers or miners. Sucking insects imbibe juices and cause weakening and yellowing

of plants. These influences result in stunted growth, lowered production of seeds, weakened competitive abilities, or plant death. In addition, damage to flowers, fruits, and seeds directly affects population growth of plants. Further, some insects inject toxins or disease organisms such as viruses during feeding, which can have additional detrimental impacts on host plants. Certain insect species such as leafcutter bees transport pieces of leaves to line their nests, whereas leafcutter ants use parts of leaves as a substrate for growing fungi in their nests.

Several species of phytophagous insects induce the production of abnormal growths called galls in their host plants. Galls are found in buds, leaves, stems, flowers, or roots, and their shapes and locations are often characteristic of the plant and insect species concerned. They provide insects with a rich source of food and protection from predators and the elements.^[3]

Oviposition

Plants provide sites for oviposition that enable immatures to commence feeding soon after egg hatch. Egg laying is a critical step in the life cycle of insects, since survival of progeny is highly dependent on recognition of suitable host plants by gravid females. Newly emerged larvae are often limited in their dispersal abilities, and hence host selection is a function of the ovipositing females. Eggs are often attached to plants and may be laid singly or in groups on any plant part. In certain insect orders such as Hemiptera, several species conceal their eggs by insertion into plant tissues.

Additional Benefits

Not all interactions beneficial to insects are detrimental to plants. Plants provide insect herbivores with shelter from natural enemies and the elements, rain and sunlight. Plants can also act as sites for mating.

INTERACTIONS OF BENEFIT TO PLANTS

Despite the great number of phytophagous insect species that exist, plants continue to dominate the landscape. This suggests that plants are a formidable evolutionary barrier

that many insects are not able to overcome.^[4] Plants possess morphological or chemical defenses (discussed below) that enable them to escape insect attack.

Carnivorous Plants

Certain plant species use insects to supplement their nutrition. These carnivorous plants are found in nitrogen-poor soils, particularly in acid bogs and heavy volcanic clays, and their root systems are not extensive. Carnivorous plants trap and digest insects. Trapping mechanisms include sticky exudates that entangle insects, such as in sundews; structural modifications, such as the pitcher on pitcher plants; or modified leaves such as those in the Venus flytrap.^[5] Trapped insects are digested by enzymes secreted from various glands, and amino acids—the nitrogenous compounds in insects that are beneficial to the plant—are absorbed by special tissues in the plant.

MUTUALISTIC INTERACTIONS

Different species or guilds of species that have coevolved to the extent that they benefit each other are considered mutualistic. Mutualistic interactions between insects and plants have evolved on several occasions. Many angiosperms, or flowering plants, are dependent on insects for pollination. More specialized mutualistic interactions have evolved such as those between neotropical species of acacia trees that produce secretions attractive to an aggressive ant species, which in return protects the trees from insect herbivores.^[6]

A lesser-known mutualistic interaction that has gained attention in recent years exists between plants and the natural enemies of herbivorous insects. Natural enemies, parasitoids and predators of insect herbivores, cue in on stimuli associated with plants in habitats where their hosts are likely to occur. Predators and parasitoids benefit by reduction of the time spent in searching, whereas plants that provide appropriate cues for attracting natural enemies benefit by the reduction in herbivory.^[7] Although undamaged plants attract natural enemies, the influence is enhanced when plants are damaged by herbivores.

FACTORS AFFECTING INSECT-PLANT INTERACTIONS

Insect species use a restricted range of taxonomically related plant species. Distinct food preferences are to a large extent attributable to an insect's ability to identify acceptable host plants on the basis of plant-related traits, amid a multitude of nonhosts. Host location by herbivo-

rous insects is a complex process involving a hierarchy of cues, some acting from a distance and some at close range.

Host plant selection in insects includes host habitat finding, host finding, host recognition and acceptance, and host suitability. Plant-related factors can influence each of these steps. Differential colonization of plant varieties by the same insect species may be due to differences in morphological or chemical traits. Plant traits such as architecture, thickened cell walls, or trichomes (small hairs on plant surfaces) impede surface penetration or herbivore movement, and thereby influence insect herbivores directly. Such traits can benefit herbivorous insects indirectly when they exert negative impacts on predators and parasitoids, thereby providing enemy-free space. As a result, parasitoids and predators are more successful in locating and accessing their hosts or prey on certain plant species than on others. Chemical traits in plants that have negative impacts on insect herbivores include secondary plant metabolites produced by plants.^[8] These include alkaloids such as caffeine and nicotine, pyrethrum, tannins, and diverse other compounds that are difficult to handle and hence deter herbivory. Plants also produce compounds that function as protein inhibitors or insect growth regulators, and thereby affect metabolism and development.

Insects and plants have evolved chemical messenger systems involving diverse allelochemicals (Fig. 1). An allelochemical is a chemical involved in an interaction between organisms belonging to different species. When plant compounds evoke a reaction in a receiving herbivorous insect that is favorable to the plant but not the insect, the compound is called an allomone. Allomones include toxic plant compounds mentioned above that serve as defenses against herbivory. In chemically-mediated

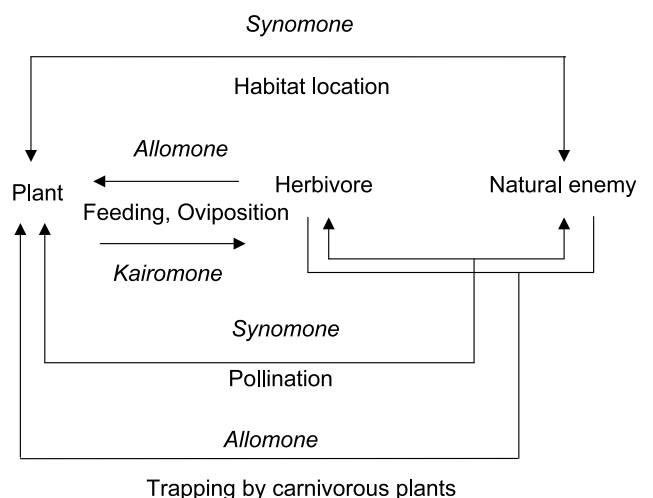

Fig. 1 Allelochemicals in plant-insect interactions (the direction of arrows indicates beneficiaries in the interactions).

interactions where the receiver benefits but not the emitter, the chemical involved in the relationship functions as a kairomone. In plant-insect interactions, examples of kairomones include phytochemicals that attract herbivorous insects to their host plants. When plants produce chemical cues that draw natural enemies to habitats of their hosts, the chemicals involved in the interactions function as synomones, because the emitter and receiver of the chemical both benefit from the interaction.^[9]

Plant-related allelochemicals are used extensively by insects for location of appropriate host plants for feeding or oviposition purposes. Typically volatile compounds from plants serve to draw insects from a distance, whereas more stable compounds serve as short range cues for arrestment and ultimate acceptance of the plant. Attraction of an insect to a plant may be due to the presence of specific compounds such as allyl isothiocyanate in cruciferous plants, the presence of specific blends of compounds, or the absence of deterrent compounds.

Some insects are able to overcome the detrimental effects of chemical defenses in plants by detoxification, sequestration, or excretion. In addition, certain species that sequester toxic phytochemicals use these compounds to their advantage in their relationships with conspecifics or members of other species. For example, moths of *Utetheisa ornatrix* sequester pyrrolizidine alkaloids acquired from their food plants during larval development. The alkaloids are involved in mate selection and are also transferred to eggs, providing protection against predation.^[10]

FUTURE CHALLENGES

The examples presented here provide some insights into the diversity of interactions between plants and insects. Coevolutionary processes in nature continue to modify these relationships. In addition, human practices bring about further changes in associations between plants and insects. For decades, plant-insect interactions have been exploited in conventional plant breeding programs for development of cultivars that are resistant to attack by insect pests, but little attention has been directed toward impacts on natural enemies. With biotechnology advances, evolutionary changes in plant-insect interactions are

likely to be expedited. Evaluation in risk assessment programs of the impacts of genetically modified plants on herbivorous insects and their natural enemies is critical, and it presents a tremendous challenge due to the complexity and diversity of plant-insect interactions.

Insects as Vectors of Disease Agents

Alexander H. Purcell

INTRODUCTION

Vectors are organisms that can introduce a pathogen such as a bacterium or virus into a plant to cause an infection. Insects, mites, and nematode vectors focus the movement of plant pathogens among immobile plants. Many insects or other arthropods may contain plant pathogens but cannot transmit these to plants and thus are not vectors. Some of our most important plant diseases require mobile vectors. Almost all plant viruses and all wall-free, plant pathogenic bacteria known as mollicutes have recognized or suspected vectors. See elsewhere for insect vector transmission of bacterial plant pathogens.

Much research on vector transmission seeks to understand the transmission process so as to explain why only certain kinds of insects or mites can serve as vectors and to identify what factors are required for transmission.^[1] Because insecticides applied to kill vectors frequently fail to control the diseases caused by the vector-borne pathogens, a good understanding of the relationships between vectors and the pathogens that they transmit is important.

Vector transmission processes are usually complex, even for the seemingly simple mechanical transfer of plant viruses to plants on the tips of vectors' stylet-like mouthparts (similar to a hypodermic needle) during feeding. In many other cases, the plant parasites transmitted by insect vectors must multiply and circulate throughout the body of the vector to be transmitted. The most fundamental characteristic by which to classify or categorize vector transmission is that of transmission efficiency (also called vector competence), or how often a vector transmits a pathogen over time or per transmission opportunity. Transmission efficiency can increase or decrease over time after a vector first acquires a pathogen, usually by feeding, but some pathogens are transmitted from a mother vector to her offspring via her eggs or embryos. Generally, vector acquisition of pathogens increases with time spent feeding on infected plant sources of the pathogen. Transmission is called nonpersistent if the rate of transmission drops to near zero within a short time

(hours). Nonpersistent transmission of viruses also differs from other types of vector–pathogen relationships in that acquisition generally decreases rather than increases with sustained feeding on infected plants. Semipersistent transmission persists for, at most, a few days after acquisition. Persistent transmission describes situations in which the vector can transmit over many days, in some cases, for weeks or months.

LATENT PERIOD

Vectors that increase their transmission rates over time have a latent period: the time between a vector's acquisition of the pathogen and its first transmission to plants. Some vectors never transmit a pathogen until days or weeks after they first acquire it. In contrast to these long latent periods, some vectors need no latent period; transmission can occur immediately after acquisition. (See [Table 1](#) for examples.)

The nonpersistent transmission of viruses by aphids illustrates the importance of how vector transmission characteristics contribute to the spread of plant disease and why some control strategies for these viruses differ from those for other aphid-transmitted viruses. Potato virus Y (PVY) and other potyviruses are transmitted by a wide variety of aphids (family Aphididae; [Fig. 1](#)) in a nonpersistent manner (relatively low vector specificity). The optimum time for an aphid to acquire PVY is after only a few minutes of feeding. The most convincing experimental evidence points to the tips of the vector stylets ([Fig. 2](#)) as the critical region where the virus is transferred from vector to plant during feeding. A bridging polypeptide molecule links virus particles to the aphid's stylet tips.^[2] A virus can genetically code for its own linking molecule (“helper factor”) or provide a helper factor to aid the aphid transmission of another virus. How the virus detaches from the vector mouthparts is not understood.^[3] The nonpersistent nature of the transmission of PVY fits in well with the flight behavior of its aphid vectors to promote virus spread in crops. Alighting aphids typically make a few probes on the first plant on which

Fig. 1 The slender needlelike mouthparts of the feeding aphid barely protrude from the larger surrounding sheath touching the plant surface. (Photo by and courtesy of Marvin Kinsey.)

they land and then fly short distances to other plants until they settle to feed continuously and reproduce. Because the aphids rapidly lose infectivity, they do not often disperse the virus over long distances. Most virus spread in such cases is from plant to plant within a field, making sanitation to eliminate seed transmission or other ways that introduces virus into a crop a key control method.^[4] The aphid vectors' rapid transmission of virus without a latent period and during exploratory feeding probes makes reducing of virus spread by killing incoming aphids with insecticides ineffective.

PLANT VIRUSES

Virus Vector Groups

Most vectors of plant viruses are sucking insects in the order Homoptera^[5] (considered the order Hemiptera by most recent classifications). Their small stylets allow vectors to introduce virus into plant cells or vascular tissues with minimal feeding damage. Aphids (Aphididae) transmit the greatest variety of plant viruses.

Next in importance are the whiteflies (Aleyrodidae), followed by the leafhoppers (Cicadellidae) and planthoppers (Fulgoroidea). Some viruses have mealybug vectors (Pseudococcidae), and various other hemipteran families have virus vector species. Only a few viruses are transmitted by thrips (Order Thysanoptera), but their economic impact is internationally important. However, some important viruses require leaf beetle (Chrysomelidae) or weevil (Curculionidae) vectors. Viruses transmitted by beetles (order Coleoptera) seem to be best able to withstand, perhaps even require, the severe tissue damage caused by beetle vector feeding that inoculates the virus into plants. The microscopic bud or gall mites in the family Eriophyidae are the most important of the noninsect arthropods that are virus vectors.

Persistent Transmission of Viruses and Other Pathogens

Numerous viruses and other disease agents are transmitted by an infectious vector for many days or even weeks. For example, the beet curly top virus (BCTV)

Fig. 2 X-rays capture the location of radioactive isotope-labeled virus (cluster of tiny black spots) on the very slender probing stylets of an aphid. (Photo by and courtesy of R.Y. Wang.)

has only one known vector, the beet leafhopper (*Circulifer tenellus*).^[5] Infectious beet leafhoppers transmit the virus after a latent period of only a few hours and continue to transmit for days to weeks. The length of time that they continue to transmit depends on how long they feed on a virus-infected plant to acquire this geminivirus. Beet curly top virus is an example of a persistently transmitted virus that is circulative but does not multiply within the vector.^[5] This virus also requires a longer feeding period for vector transmission. Like BCTV, the aphid-borne, persistently transmitted viruses that cause the internationally important diseases barley yellow dwarf and potato leafroll (luteoviruses) can be controlled by effectively timed applications of insecticide that kill aphids shortly after they fly into the crop.^[4] Most lengthy latent periods result from the requirement of the pathogens to multiply within the vector to attain the numbers needed to complete the vector transmission process by reaching the salivary glands in sufficient numbers. Some viruses and bacteria multiply within numerous types of organs and tissues within the vector that probably are not required for transmission, and a consequence is that some of these plant pathogens are harmful to the vector. Reoviruses (rice dwarf, for example) multiply within both their insect vectors

and plant hosts. Multiplication and circulation of the pathogens within the body cavity (hemocoel) of the vector insures that the pathogen will remain within the vector after molts that occur as the vector develops. Nonpersistently or semipersistently transmitted viruses are no longer transmitted once the vector has molted its exoskeleton.

NONVIRAL PATHOGENS

Vectors and Fungi

Insect feeding damage can cause wounds that promote the invasion of fungi that damage plants or their fruit.^[5] A variety of sucking insects that feed on fruits can introduce the fungus *Nematospora corylii*, which causes yeast spot disease of bean, coffee, cotton, and a variety of other crops. The feeding of a sucking insect, the grape phylloxera, causes lesions on the roots of grapevines that are invaded by soil fungi that deteriorate the roots.^[6]

Dutch elm disease is a representative example of a disease caused by a beetle-transmitted fungus, *Ophiostoma ulmi*. The fungus colonizes the wood of living elms or recently killed trees or cut logs, which are also

where the bark beetle larvae develop beneath the elms' bark. Fungal spores of *O. ulmi* are sticky and attach to the newly emerging adult bark beetles. After flying to other elms, the beetles introduce the spores into feeding wounds on small twigs or into the tunnels excavated under elm bark by the bark beetles for egg laying.^[5] The fungus spreads into the tree's vascular system. Elms weakened by the Dutch elm disease are more attractive for new beetle attacks. Control requires vigilant sanitary measures of quickly removing and destroying diseased elms to eliminate the fungus and reduce the numbers of developing bark beetles.^[7]

Trypanosomes and Nematodes

Sucking insects can also vector trypanosomes (flagellated protozoa) that infect various plants, causing especially serious diseases of palms and coffee. Other insect-vectored trypanosomes cause mild or symptomless infections of milkweeds and tomatoes.^[8] Wood-boring beetles (Cerambycidae) serve as vectors of nematodes that cause pine wilt disease. Immature nematodes multiply within plant tissues and enter the spiracles of the newly molted adult beetles. The nematodes crawl out of their beetle transporters after the beetles have flown to other trees and excavated

egg-laying chambers in the trees' trunks to lay eggs (Table 1).

CONTROL OF PLANT DISEASES CAUSED BY VECTOR-BORNE PATHOGENS

The principal methods to control crop disease spread by vectors limit vector acquisition of the pathogen or prevent infective vectors from transmitting to susceptible crops. The impact of insecticides for vector control on disease spread depends on the vector transmission characteristics of the pathogen, as previously discussed. Sanitation is most often used to prevent vector acquisition. This requires the removal of diseased plants or insuring that new plants are free of the targeted pathogen by using certified propagating materials. Physical isolation of crops from exposure to vectors can be used in greenhouses or by growing crops in regions where the vector populations are very low. Varying planting dates can be used to avoid peak periods of vector activity if these can be reliably predicted and do not cause unacceptable losses in yields or quality. Using resistant varieties of plants is a highly effective control if genetic resistance is available. Molecular methods of producing new varieties promise to increase the availability of resistant

Table 1 Representative examples of diseases caused by vector-borne pathogens

Type of pathogen	Vector	Type of transmission (see text for explanation)
<i>Virus</i>		
Lettuce mosaic potyvirus	Aphids (many species)	Nonpersistent
Barley yellow dwarf luteovirus	Aphids (few species)	Persistent days to weeks, circulative, not propagative in vector
Lettuce necrotic yellows baculovirus	Aphids (many species)	Persistent, circulative, propagative in vector
Maize rough dwarf reovirus	Planthoppers (very few spp.)	Persistent, circulative, propagative, and transovarial in vector
Maize streak geminivirus	Leafhoppers (<i>Cicadulina</i> spp.)	Persistent, circulative, nonpropagative
Southern bean mosaic sobemovirus	Leaf beetles (<i>Chrysomelidae</i>)	Semipersistent to persistent, noncirculative (?)
<i>Bacteria</i>		
<i>Xylella fastidiosa</i> (numerous diseases)	Xylem sap-feeders (sucking insects in several families)	Noncirculative but persistent, propagative in vector
Aster yellows phytoplasma	Leafhoppers (several spp.)	Persistent, circulative, propagative
<i>Trypanosomes</i>		
Hartrot of palm	Shield bugs (<i>Pentatomidae</i> : <i>Linctus</i> spp.)	Persistent, circulative
<i>Fungi</i>		
Yeast spot of bean, coffee, etc.	Hemipteran fruit or seed feeders	Noncirculative but persistent
Dutch elm fungus	Bark beetles	Persistent, carried externally by adults
<i>Nematodes</i>		
Pine wilt nematode	Long-horned beetles	Persistent, nematodes infest spiracles of adults

varieties against diseases now lacking satisfactory sources of resistance.

Integrated Pest Management

Marcos Kogan

Oregon State University, Corvallis, Oregon, U.S.A.

INTRODUCTION

In the context of integrated pest management (IPM), a pest is any living organism whose life system conflicts with human interests, economy, health, or comfort. Pests belong to three main groups: 1) invertebrate and vertebrate animals; 2) disease-causing microbial pathogens; and 3) weeds or undesirable plants growing in desirable sites.

The concept of pest is entirely anthropocentric. There are no pests in nature, in the absence of humans. An organism becomes a pest only if it causes injury to crop plants in the field or to their products in storage or, outside an agricultural setting, if it affects structures built to serve human needs. This article focuses on the impact of pests on plants.

BACKGROUND

Since the beginnings of agriculture some 10,000 years ago, humans competed with other organisms for the same food resources. Primitive tools to fight pests were probably limited to handpicking and methods such as flooding or fire, although at times of despair agriculturists resorted to magic incantations or religious proclamations.^[1] But as early as 2500 B.C., Sumerians used sulfur to control insects and by 1000 B.C., Egyptians and Chinese were using plant-derived insecticides to protect stored grain.^[2] Real progress in the fight against agricultural pests occurred upon advances in biological sciences, resulting in a better understanding of arthropod pests and the relationships between microbial pathogens and plant diseases. Until the middle of the twentieth century, insect pest control ingeniously combined knowledge of pest biology and cultural and biological control methods. Trichlorodiphenyltrichloroethane (DDT) in the early 1940s ushered in an era of organo-synthetic insecticides. Initial results were spectacular and many entomologists foresaw the day when all insect pests would be eradicated. This optimistic view was premature, as insects quickly evolved mechanisms to resist the new chemicals, requiring more frequent applications, higher dosages, or the replacement of old insecticides with more powerful ones. This cycle has become known as the insecticide tread-

mill.^[1] At the end of the 1950s, scientists around the world became aware of the risks associated with the application of powerful insecticides, as resistance rendered one chemical after the other useless and as beneficial organisms were indiscriminately killed along with target pest species. Such killing of insect parasitoids and predators caused the resurgence of pests at even higher levels. In addition, populations of other plant-eating species, usually balanced by the pests' natural enemies, exploded in outbreak proportions, causing upsurges of secondary pests and pest replacements. As a result of mounting concern about resistance, resurgence, and upsurges of secondary pests, the concept of integration emerged—an attempt to reconcile pesticides with the preservation of natural enemies.^[3]

INTEGRATION

The next phase in the evolution of IPM was the expansion of the term “integrated” to include all available methods (biological, cultural, mechanical, physical, legislative, as well as chemical) and to span all pest categories of importance in the cropping system (invertebrates, vertebrates, microbial pathogens, and weeds). Because of the multiple meanings, integration in IPM was conceived at three levels of increasing complexity. Level I integration refers to multiple control tactics against single pests or pest complexes; level II is integration of all pest categories and the methods for their control; level III integration applies the steps in level II to the entire cropping system. At level III, the principles of IPM and sustainable agriculture converge.^[4]

THE ECOLOGICAL BASES OF IPM

Ecology offered the tools to describe how populations expand and contract under natural conditions; how biotic communities are organized and how their component organisms interact; how abiotic (nonliving) factors (climate, soil, topography, hydrology) shape biotic communities; how biodiversity stabilizes ecological systems; and, perhaps most significantly, how to understand the effects of

disturbances in the dynamics of biotic communities.^[5,6] Thus, IPM relied upon a solid ecological foundation.^[4,5,7]

THE TOOLS OF PEST MANAGEMENT

Management of pests in an IPM system is accomplished through selection of control tactics singly or carefully integrated into a management system. These tactics usually fall into the following main classes: 1) chemical; 2) biological; 3) cultural/mechanical; and 4) physical control methods (these four methods apply to all pests); 5) host plant resistance (applicable to invertebrate and microbial pests); 6) behavioral; and 7) sterile insect technique, a genetic control method (relevant only to insects).

Chemical Control

Chemical pesticides are used to kill or interfere with the development of pest organisms. Pesticides are called insecticides, acaricides, nematocides, fungicides, or herbicides if the target pests are insects, mites, nematodes, fungi, or weeds. Pesticides are useful tools in IPM if used selectively and if the pest population threatens to reach the economic injury level (described later). Much care is necessary to handle pesticides and avoid their potentially negative effect on the environment.^[8]

Biological Control

Biological control refers to the action of parasitoids, predators, and pathogens in maintaining another organism's population density at a lower average than would occur in their absence.^[9] In IPM practice, biological control includes intentional introduction of natural enemies to reduce pest population levels (classical biological control), the mass release of biocontrol organisms (inundative biocontrol), or the timely inoculation of natural enemies (augmentative biocontrol).^[10]

Cultural Control/Mechanical

Cultural practices become cultural controls when adopted for intentional effect on pests. Thus, tillage and other operations for soil preparation have a direct impact on weeds and on soilborne insect pests. The manipulation of the crop environment to favor natural enemies is called habitat management, and is of growing interest as a form of conservation biological control.^[10,11]

Physical Control

Fire, water, electricity, and radiation are some of the main physical forces used in IPM. Flooding in paddy rice cul-

tivation is a major adjuvant method in many parts of the world.

Host Plant Resistance

This means of control is based on breeding crop plants to incorporate genes whose products cause plants to be unsuitable for insects feeding on them (antibiosis) or impair insects' feeding behavior (antixenosis).^[12] Resistance is the only effective method for control of plant viral diseases. Techniques of genetic engineering have opened new opportunities to expand plant resistance in IPM, but the approach is not without risks and should be adopted cautiously, within a strict IPM framework.^[13]

Behavioral Control

Behavioral control uses chemicals (allelochemicals) to interfere with normal patterns of mainly sexual (mating) and feeding behaviors of arthropods. Sex pheromones are used for mating disruption.^[14,15] Feeding excitants or deterrents are used to disrupt normal feeding behavior or to attract and kill insects.^[16]

Sterile Insect Technique

This genetic control method disrupts normal progeny production of the target species by the mass release of sterile insects.^[17]

THE SCALE OF IPM SYSTEMS

Most IPM programs focus on single fields because of local variability in physical, crop, and pest conditions. Some pests, however, are highly mobile and require a regional approach for their control. Furthermore, certain control tactics are effective only if deployed over large areas. Mating disruption for control of the codling moth in apple and pear orchards in the western United States used an areawide approach that required a minimum operational unit of about 160 ha. Advancement of IPM to higher levels of integration will require planning and implementation at the landscape or even ecoregional levels. Advanced technologies of geographic information systems (GIS) and remote sensing are essential for development of such programs. Such planning is still at its infancy in IPM.

DECISION SUPPORT SYSTEMS FOR IPM IMPLEMENTATION

IPM uses objective criteria for making decisions about the need for a control action and selection of the most

Fig. 1 Fundamental decision-making concepts for insect pest management: economic threshold (ET) and economic injury level (EIL). Illustrated is an insect pest population with two peaks in one year. The first peak remains below ET and no treatment is needed; the second peak exceeds ET. If a treatment is applied, the population crashes (curve A); if a treatment is not applied, the population exceeds EIL and an economic crop loss occurs (curve B). (View this art in color at www.dekker.com.)

appropriate tactics. In arthropod pest control the criteria are based on assessments of the extant pest population in the field, its damage potential (if not controlled), and the relative costs of treatment and crop value. The main parameters are the economic injury level (EIL) and economic threshold (ET). ET is the population level that will trigger a control action. Fig. 1 describes these parameters. To use ETs it is necessary to monitor pest populations in the field using well-defined sampling methods, which vary with the pest species. Although useful, the concept of EIL is less effective as a decision-making support tool for weed management and is partially applicable for microbial disease management.^[18]

CONCLUSION

It is difficult to assess the global impact of IMP. It is safe, however, to state that the concept drastically changed the approach to pest control among progressive growers, the chemical industry, research establishments, and policy makers. One of the few economic analyses of the impact of IPM was done in Brazil on soybean production costs. The study suggested that technologies available in 1980 (date of the study), if adopted throughout the entire

production area (8.5 million ha), would have resulted in savings of US\$216 million annually. Most major agricultural crops have benefited from the adoption of IPM, although IPM is in its infancy and major advances are still to be expected as modern technology comes to be incorporated into the management of all pests.

Dodds & Associates, Washington, D.C., U.S.A.

INTRODUCTION

Intellectual property (IP) refers to creations of the human mind. Intellectual property may be inventions, artistic works, designs, names, images, and so on. The basic means to protect intellectual property are patents, copyrights, trademarks, and trade secrets. Plant Breeder's Right is a specific type of protection for new sexually propagated plant varieties.

Even if the intellectual property rights are largely national rights, there are several international treaties, the most important being the TRIPS agreement (Trade Related Aspects of Intellectual Property Rights), regulating the contents of the national intellectual property laws. In addition to international treaties, there are international organizations such as WIPO (World Intellectual Property Organization) and UPOV (International Union for the Protection of New Varieties of Plants) administering certain intellectual property practices.

In the following article we will briefly go through various means for protection relevant to plant sciences. Thereafter, we will deal with the current issues of intellectual property and modern plant sciences, and lastly we will briefly discuss the development of intellectual property legislation and international treaties affecting it.

MEANS TO PROTECT INTELLECTUAL PROPERTY

The basic means to protect intellectual property are patents, copyrights, trademarks, trade secrets, and Plant Breeder's Rights. There are variations in the national laws, and some countries provide broader protection than others. For example, a concept of plant patent is specific for the protection system of the United States. A basic understanding of these mechanisms is essential for anyone whose research may lead to an invention.

Patents

Historically, a patent was a grant made by a sovereign that would allow for the monopoly of a particular in-

dustry, service, or goods. Over time, the concept has been refined from a public policy perspective and has evolved to an agreement between the government and the inventor/creator.

In return for the right to exclude others from the practice of the invention, the government requests the inventor to fully disclose the enablement of the invention; furthermore, the monopoly is now limited by time and clearly is only applicable in the territory under the jurisdiction of the government.

A patent, as stated above, is an agreement between the government and the inventor, and in the United States a fundamental right is provided in Article I, Section 8, of the Constitution. Congress is empowered to "...promote the progress of science and useful arts by securing for limited times to authors and inventors the exclusive right to their respective writings and discoveries."

In exchange for a limited-term right (usually 20 years) to exclude others from making, using, or selling the invention, the inventor must provide a complete and accurate public description of the invention and the best mode of "practicing" it. This provides others with the ability to use that information to invent further, thus promoting technology development for the benefit of society.

This right to exclude means that a patent is a "negative right" since a patent holder may only exclude others from using, manufacturing, copying, or selling his or her invention.

Copyrights

A copyright is a type of intellectual property protection for "authors" of original works. Basically, a copyright protects an original work and allows the author an exclusive right to reproduce the work, prepare derivatives, distribute copies of the work, and perform the copyrighted work publicly.

Historically, copyrights have been important in protecting the rights of artists and authors. Today, copyrights are becoming more and more important in protecting the rights of database creators. Copyrights may be relevant means of protecting, for example, GIS databases or databases containing gene sequences.

Trademarks

A trademark is a word, phrase, symbol, or design, or a combination of those, that distinguishes the source of one's goods or services from those of others. A trademark can be valid only when it is used in connection with the goods or services in commerce. Trademarks are important means for distinguishing a product or a technology; for example, plant seeds may be trademarked.

Geographical Indications

Geographical indications are defined in the TRIPS agreement as a type of intellectual property. A geographical indication is a sign used on goods that have a specific geographical origin and possess qualities or a reputation that are due to that place of origin. In the United States, geographical indications are treated as trademarks.

Most commonly, a geographical indication consists of the name of the place of origin of the goods. Agricultural products typically have qualities that derive from their place of production and are influenced by specific local factors, such as climate and soil.

Trade Secrets

Trade secrets are the cheapest way to protect one's intellectual property: Having a trade secret simply requires that the intellectual property is kept secret. A trade secret could, for example, be composition of a culture medium or a method to transform a plant species.

The positive aspect of trade secrets in addition to their cheapness is that there is no expiration date. However, the negative side is that once the secret is out the protection is gone.

Plant Breeder's Rights

The TRIPS agreement obliges the member countries to provide protection for plant varieties either through patents or by an effective *sui generis* system or a combination of them. The most common *sui generis* system is Plant Breeder's Rights (PBR). PBR allows the developers of new plant varieties to control multiplication and sale of the reproductive material of a new variety.

Several countries have joined UPOV, established in 1961 and last revised in 1991. UPOV sets forth the minimum requirements that the national protection should grant.

In the United States the right is called Plant Variety Protection (PVP), and it is granted for sexually reproduced or tuber-propagated plants. The term of protection is 20 years for most crops and 25 years for trees, shrubs, and vines.

Plant Patent

Plant patent is a specific type of patent granted in the United States to an inventor who has invented or discovered and asexually reproduced a distinct and new variety of plant species. The provision excludes tuber-propagated plants or plants found in an uncultivated state. Plant patents are issued for 20 years.

CURRENT ISSUES

Patenting Life

The intellectual property system is a dynamic system that needs to be reevaluated in the course of developing technologies and trade practices. The emergence of modern biotechnology more than 20 years ago prompted the U.S. Supreme Court to reevaluate the concept of patentability. In 1980 the Court gave the famous decision^[1] stating that a genetically modified bacteria qualifies as patentable subject matter and that "everything under the sun made by man is patentable." Five years later, the Board of Appeals and Interferences of the U.S. Patent and Trademark Office held that genetically modified plants are patentable.^[2]

However, as recently as 2001, the U.S. Supreme Court still discussed whether utility patents may be issued for plants.^[3] The ruling was that newly developed plant breeds fall within the terms of utility patent. Therefore, a sexually reproduced plant variety may receive a double protection by PVP and by utility patent.

The issue of patentability of transgenic plants is not resolved in Europe yet. The European Patent Office (EPO) acts under European Patent Convention (EPC). EPC prohibits patenting of plant varieties. In 1995 the EPO Board of Appeal held that a transgenic plant was a new plant variety and therefore not patentable. However, cells from the transgenic plant were held to be "microbiological products" and therefore patentable.^[4]

The European Biotechnology Directive entered into force on July 30th, 2000. The Directive confirms that biological material *per se* is not unpatentable. Inventions having the required novelty, inventive step, and industrial applicability shall be patentable even if they comprise biological material or utilize a process by means of which biological material is produced, processed, or used. Therefore, an isolated gene or gene sequence may be patentable provided that its function is known and a suitable industrial application is derived from that product.

According to the Directive, plant and animal varieties are not patentable, but the definition of plant variety is so narrow that most transgenic plants do not fit into it. The European Commission is soon going to release legislation

for so-called Community Patent that would cover all the member countries. The Community Patent would follow the standard of the Biotechnology Directive and therefore basically allow patenting of transgenic plants.

Traditional Knowledge

Traditional knowledge refers to the knowledge, innovations, and practices of indigenous and local communities around the world. Traditional knowledge has been transmitted orally from generation to generation and tends to be collectively owned. Among many other things, agricultural practices, including the development of plant species and animal breeds, may be traditional knowledge. This kind of traditional knowledge is based on genetic resources. The relationship between genetic resources, traditional knowledge, and intellectual property rights is one of the most important issues on the agenda of several international organizations.

The Convention of Biological Diversity (CBD) constitutes the central instrument concerning biodiversity at the international level. CBD affirms the sovereign rights of states to exploit their own resources pursuant to their own environmental policies.

The Convention also provides a broad framework for member states' policies concerning access, development, and transfer of technologies and acknowledges the necessity for all parties to recognize and protect intellectual property rights in this field. It points to the need for equitable sharing of benefits arising from the use of traditional knowledge, innovations, and practices relevant to the conservation of biodiversity and the sustainable use of its components.

The Food and Agricultural Organization (FAO) adopted the International Treaty on Plant Genetic Resources (ITPGR) in 2001. The objectives of the Treaty are the conservation and sustainable use of plant genetic resources for food and agriculture and the fair and equitable sharing of the benefits arising out of their use, in harmony with the Convention of Biological Diversity, for sustainable agriculture and food security. The contracting parties agree to establish a multilateral system to facilitate access

to plant genetic resources for food and agriculture and to share the benefits arising from the utilization of these resources in a fair and equitable way.

The issues related to traditional knowledge are also closely related to IP protection in the developing world. People in many developing countries are asset-poor but knowledge-rich, and poor communities seldom gain from that knowledge. As it might be difficult for indigenous people to invest in conventional IP protection, let alone litigations to protect their IP, new IP protection and contract models may be needed to protect such knowledge and to bring the benefit to the poorest.

CONCLUSION

Even if the concept and means for intellectual property are old, the issues emerging with the rapid development of life sciences together with ethical concerns have made it necessary to reevaluate the concept. Presently there are several international organizations trying to create harmonized guidelines for protection of intellectual property in industrialized countries as well as in developing countries. A detailed overview of the current issue of intellectual property rights in agricultural biotechnology is given in recent review.^[5] Especially interesting issues are those related to the protection of traditional knowledge.

International Treaties Relevant to the Management of Plant Genetic Resources

H. David Cooper

Convention on Biological Diversity, Montreal, Quebec, Canada

N. Murthi Anishetty

Food and Agriculture Organization of the United Nations, Rome, Italy

INTRODUCTION

Over the last two decades the management of plant genetic resources has become increasingly subject to political debate, and thus international treaties have become more relevant to those working in this area. While the focus has been largely on issues of access to and transfer of genetic resources, benefit sharing, and intellectual property rights, the most relevant treaties have important implications for all aspects of the management of plant genetic resources.

The main international treaties relevant to the management of plant genetic resources are the Convention on Biological Diversity (CBD; Nairobi, May 1992) and the International Treaty on Plant Genetic Resources for Food and Agriculture (Rome, November 2001). These legal instruments have comprehensive provisions for the conservation and sustainable use of, and access to, plant genetic resources, and for the sharing of benefits derived from their use. These and other relevant agreements are briefly reviewed in [Table 1](#).

THE FAO GLOBAL SYSTEM ON PLANT GENETIC RESOURCES

International cooperation on plant genetic resources has been developed primarily in the framework of the Food and Agriculture Organization of the United Nations. The International Board for Plant Genetic Resources was set up at FAO in 1974. Its successor body, the International Plant

Genetic Resources Institute (IPGRI), is one of the 16 international agricultural research centers (IARCs) of the Consultative Group on International Agricultural Research (CGIAR) which collectively house the world's most important network of ex situ collections (see article by Anishetty and Robinson, p. XXX). In 1983, the FAO Conference established the Commission on Plant Genetic Resources as an intergovernmental forum to address all issues related to plant genetic resources and adopted the International Undertaking—a nonbinding agreement which recognized plant genetic resources as the heritage of mankind.^[4] Although qualified by recognition of national sovereignty over genetic resources, the system developed within the framework created by the Undertaking was essentially one based on free access to genetic resources. In 1989, FAO recognized Farmers' Rights as "rights arising from the past, present and future contributions of farmers in conserving, improving and making available, plant genetic resources, particularly those in the centres of origin/diversity." In 1994, most of the collections held by the IARCs were brought under the auspices of FAO as part of the international network of ex situ collections and are held "in trust" for the world community. In 1995, the Commission was broadened to become the Commission on Genetic Resources for Food and Agriculture (CGRFA). The Global Plan of Action for the Conservation and Sustainable Use of Plant Genetic Resources for Food and Agriculture (PGRFA) was adopted in 1996 by the International Technical Conference, Leipzig, and subsequently endorsed by the FAO Conference and the Conference of the Parties of the CBD. These and other elements of the FAO "global system" are listed in [Table 2](#).

THE CONVENTION ON BIOLOGICAL DIVERSITY

The CBD, adopted by a diplomatic conference in Nairobi, 1992, is one of the three Multilateral Environmental Agreements to have emerged from the United Nations

This article draws upon the material in Cooper (2003): International treaties relevant to the management of plant genetic resources, Chapter 57, in CIP-UPWARD (2003), Conservation and Sustainable Use of Agricultural Biodiversity: A Sourcebook. International Potato Centre—User's Perspectives With Agricultural Research and Development, Los Baños, the Philippines. 3 Volumes, updated and expanded. The views expressed in this article are the author's own and do not necessarily reflect the position of the Convention on Biological Diversity or the Food and Agricultural Organization of the United Nations.

Table 1 International agreements

Agreement ^a	Scope and key provisions
Convention on Biological Diversity (Nairobi, 1992; EIF: 29-12-93; 188 Parties). http://www.biodiv.org ; http://www.cbd.int	Objectives: Conservation and sustainable use of biodiversity, and the fair and equitable sharing of the benefits arising out of the utilization of genetic resources, including by appropriate access to genetic resources and technology transfer. (Refer to text.)
International Treaty on Plant Genetic Resources for Food and Agriculture (Rome, 1996; EIF: 29-06-04; 56 Parties) http://www.fao.org/ag/cgrfa/itpgr.htm	Objectives: Conservation and sustainable use of plant genetic resources for food and agriculture and the fair and equitable sharing of the benefits arising out of their use, in harmony with the Convention on Biological Diversity, for sustainable agriculture and food security. (Refer to text.)
Cartagena Protocol on Biosafety (Protocol to the CBD; Montreal, 2000; EIF: 11-09-03; 105 Parties). http://www.biodiv.org/biosafety/default.aspx	Objective: “(. . .) the safe transfer, handling and use of living modified organisms resulting from modern biotechnology that may have adverse effects on the conservation and sustainable use of biological diversity, taking also into account risks to human health, and specifically focusing on transboundary movements.”
Convention on Trade in Endangered Species (CITES) (166 Parties). http://www.cites.org	Objectives: Protection of wildlife against overexploitation and prevention of international trade of species threatened with extinction. Bans international trade in an agreed list of endangered species. Regulates and monitors trade in species that might become endangered.
International Plant Protection Convention (Rome, 1952; Revised 1979, EIF: 04-04-91, 117 Parties; Revised 1997, Revision not EIF). http://www.ippc.int	Purpose: To secure common and effective action to prevent the spread and introduction of pests and plant products and to promote measures for their control. Standards set under the IPPC are recognized by the WTO Agreement on the Application of Sanitary and Phytosanitary Measures.
WTO Agreement on Trade-Related Intellectual Property Rights Annex to the Final Act Embodying the Results of the Uruguay Round on Multilateral Trade Negotiations (Marrakesh, 1994; EIF: 0101-95; 147 members). http://www.wto.org	Provides for minimum standards on intellectual property rights such as patents, trademarks, and copyrights.
International Union for the Protection of Plant Varieties (UPOV) (1961, latest revision: 1991; 55 members). http://www.upov.org	Provides a model law for plant breeders' rights.

^aIn parentheses the following information is given: date of adoption of the text of the agreement; date of entry into force; number of parties as of 1-08-04. Further information is provided in Refs. [1–3].

Conference on Environment and Development process. Its objectives (Article 1) are “. . . the conservation of biological diversity, the sustainable use of its components and the fair and equitable sharing of the benefits arising out of the utilization of genetic resources, including by appropriate access to genetic resources and by appropriate transfer of relevant technologies. . . .” The Convention applies to biodiversity at three levels: genes, species, and ecosystems.^[1] The Conference of the Parties meets regularly (currently every 2 years) to develop guidance and various programs of work and to review implementation of the Convention.

The Convention requires Parties to develop national strategies, plans, or programs for the conservation and sustainable use of biological diversity and, as far as is possible and as appropriate, to integrate them into sectoral and cross-sectoral plans, programs, or policies (Article 6).

The Convention includes specific measures for the conservation of biological diversity, including genetic resources, *in situ* (Article 8) and *ex situ* (Article 9). Article 8(j) includes a specific provision to protect the relevant knowledge, innovations, and practices of indigenous and local communities.

Access to Genetic Resources and Benefit Sharing

In its Article 15, the Convention reaffirms national sovereignty over natural resources and establishes that the right to determine access to genetic resources rests with national governments and is subject to national legislation. At the same time, the Convention requires Parties to facilitate access and “not to impose restrictions that run counter to the objectives of the Convention.”

Table 2 Key elements of the global system for plant genetic resources in the framework of FAO

Component	Function/description
International Treaty on Plant Genetic Resources for Food and Agriculture (adopted 1996). See Table 1.	On its entry into force will provide main binding legal framework for international collaboration on PGRFA, effectively replacing the nonbinding 1983 International Undertaking. Commission on Plant Genetic Resources for Food and Agriculture (established 1983; mandate extended 1995). Intergovernmental global forum.
Global Plan of Action for the Conservation and Sustainable Use of PGRFA (adopted 1996; endorsed by FAO Conference; CBD CoP)	Agreed plan encompassing 20 priority activities in four areas: in situ conservation and development; ex situ conservation; the utilization of PGR; institutions and capacity building. Now a “supporting component” of the Treaty, under Article 14.
Report on the State of the World’s PGRFA (First report 1996; second report planned for 2006)	Provides a periodic assessment on all aspects of PGRFA conservation and use, to identify gaps, constraints, and trends. Now a “supporting component” of the Treaty, under Article 17.
World Information and Early Warning System	Collects and disseminates data on PGRFA and related information and technologies; identifies hazards. Now a “supporting component” of the Treaty, under Article 17.
Network of international ex situ collections (agreements with IARCS 1994)	Holds international collections, including IARC collections, in trust for the international community with material available according to a standard MTA. Expected to be incorporated into the Treaty as a “supporting component” under Article 15, when the IARCs sign the appropriate agreements with the Governing Body of the Treaty.
International Code of Conduct on Germplasm Collecting and Transfer (adopted 1993)	Suggests procedures for requesting and issuing collecting permits. Provides guidance for requesting and issuing collecting permits to collectors, sponsors, and users of PGRFA to respect PGR and local traditions.

Article 15 introduces two key concepts: access shall be on “mutually agreed terms” (MAT) and subject to “prior informed consent” (PIC).

Mutually Agreed Terms

For access to be on MAT, both supplier and recipient must agree to the terms, thus providing an opportunity for the providing country to negotiate a share of the benefits derived from the use of the genetic resources. Usually, this implies a contractual arrangement, executed on a bilateral basis. The contract often takes the form of a “Material Transfer Agreement” (MTA) setting out the agreed terms on which the genetic material is transferred. The MTA may specify the permitted or prohibited uses of the genetic resources provided, including whether or not it may be commercialized; any rights which may or may not be taken out over the resource or its derivatives; and the benefits that are to be shared.

Prior Informed Consent

Unless the Party determines otherwise, access is also subject to PIC. This means that the responsible authority of the providing country can decide to grant or refuse

access following a request from the applicant. In the application, the applicant may be required to provide information concerning the genetic resources required and the purpose for which they are required, as well as any proposal for benefit sharing. As part of the PIC procedure, the responsible authority may consult with indigenous and local communities, or other stakeholders, concerned.

Some 25 countries have already developed laws and other policy measures to regulate access to genetic resources and benefit sharing, and a similar number are planning or considering such measures.^a

^aRegional groups, national governments, or state governments that already have laws or regulations concerning access to genetic resources and benefit-sharing include the Andean Pact (Bolivia, Colombia, Ecuador, Peru, Venezuela); Australia (the States of Western Australia and Queensland); Brazil (at the Federal level and the States of Acre and Amapa); Bulgaria; Cameroon; Costa Rica; the Gambia; Guyana; India; Kenya; Malaysia (the State of Sarawak); Malawi; Mexico; Nicaragua; Panama; the Philippines; Switzerland; South Africa; Uganda; Vanuatu; and the United States of America (within Yellowstone and other national parks). In some cases there is specific legislation or regulations governing access and benefit sharing; in other cases the laws are only “enabling” in nature, in that they charge a competent national authority to examine the issue and develop specific guidelines or regulations in the future. For further information and updates consult <http://www.biodiv.org/programmes/socio-eco/benefit/measures.aspx> or <http://www.grain.org/brl/>.

The Conference of the Parties has adopted a number of programs of work for the implementation of the Convention including a program of work on Agricultural Biodiversity, which is of relevance to the management of genetic resources (Decision V/5; Nairobi, May 2000). The Conference of Parties has also adopted a Global Strategy for Plant Conservation with 16 outcome-oriented targets for 2010 (Decision VI/9; The Hague, April 2002). Of most relevance to plant genetic resources management is target 9: “70 per cent of the genetic diversity of crops and other major socio-economically valuable plant species conserved, and associated indigenous and local knowledge maintained.”

In 2002, the Conference of the Parties adopted the Bonn Guidelines on Access to Genetic Resources and the Fair and Equitable Sharing of the Benefits Arising out of their Utilization (Decision VI/24; The Hague, April 2002), which provide guidance on the development of national legislation and on contracts for benefit sharing, including measures that might be taken by Parties to encourage users of genetic resources to comply with the Guidelines.

Recently, the Conference of the Parties, responding to an invitation contained in the Johannesburg Plan of Implementation of the World Summit on Sustainable Development, initiated a process to elaborate and negotiate the nature, scope, and elements of an international regime on access and benefit sharing (Decision VII/19; Kuala Lumpur, February 2004). This will be carried out by the Convention’s Intergovernmental Working Group on Access and Benefit Sharing. The Working Group will also address measures to support compliance with PIC and MAT (“user measures”), including an international certificate of origin, and the disclosure of origin of genetic resources and associated traditional knowledge in applications for intellectual property rights.

THE INTERNATIONAL TREATY ON PLANT GENETIC RESOURCES FOR FOOD AND AGRICULTURE

The International Treaty on Plant Genetic Resources for Food and Agriculture was adopted by the FAO Conference on 3 November 2001 after 7 years of negotiations in FAO’s CGRFA. Most of the negotiations focused on developing a multilateral system of access and benefit sharing for major food crops, and on dealing with issues identified as “outstanding” by the diplomatic conference that adopted the Convention, namely: access to *ex situ* genetic resources not covered by the Convention, and farmers’ rights.^[2] The Treaty entered into force on 29 June 2004.

The Multilateral System for Access and Benefit Sharing

As recognized both by the FAO’s CGRFA and the Conference of the Parties of the CBD, a purely bilateral approach to access and benefit sharing is not well suited for the genetic resources of major food crops. This is because, for several reasons, agriculture in all countries depends largely on PGRFA that originated elsewhere; future advances in crop improvements, which are needed for sustainable agriculture and food security, require continued access to a wide genetic base without major restrictions; and because of movements of people and resources over past millennia as well as modern collecting efforts, the genetic resources of major crops already are widely distributed *ex situ* both in genebanks and in production areas, and thus attribution of country of origin is often very difficult.^[5]

Thus the new International Treaty creates a “Multilateral System for Access and Benefit Sharing,” which, for a list of certain plant genetic resources for food and agriculture “established according to criteria of food security and interdependence,” guarantees facilitated access in return for benefit sharing. The list comprises most major food crops (including cereals such as rice, wheat, maize, sorghum and millets; grain legumes such as beans, peas, lentils, chickpeas, and cowpeas; roots and tubers such as potato, sweet potato, cassava, and yams), plus a list of forages (32 genera).

The Treaty provides for facilitated access to material in the Multilateral System for the purposes of food and agriculture research, breeding, and training in this area. A Party is obliged to provide access to PGRFA listed in the Multilateral System on these terms: 1) when requested to do so by another Party, a legal or natural person under the jurisdiction of a Party, or by an international institute that has signed an agreement with the governing body; and 2) when such PGRFA has been acquired under these same terms. Article 13 of the Treaty provides that benefits arising from the use, including commercial use, of plant genetic resources for food and agriculture under the Multilateral System shall be shared fairly and equitably through the exchange of information, access to and transfer of technology, capacity-building, and the sharing of the benefits arising from commercialization. There are special provisions for monetary benefit sharing in the case of commercialization of a product that is a PGRFA and that incorporates material accessed from the Multilateral System: “recipients shall pay to [a] mechanism (. . .), an equitable share of the benefits arising from the commercialization of that product, except whenever such a product is available without restriction to others for further research and breeding, in which case the recipient who commercializes shall be encouraged to make such

payment.” The Treaty also provides for special terms of access to material maintained by the International Agricultural Research Centers (Article 15).

The establishment of a multilateral system is made by the Parties “in the exercise of their sovereign rights.” By agreeing to the terms of the Treaty, countries are, in effect, agreeing that for access to a defined subcategory of PGRFA, PIC would not be required on each and every occasion, but rather that a multilaterally determined set of MATs would apply.

Other Provisions of the International Treaty

This focus on access and benefit sharing notwithstanding, the Treaty has a comprehensive scope. The Treaty calls for an integrated approach to the exploration, conservation, and sustainable use of plant genetic resources for food and agriculture (Article 5), and includes specific provisions on surveying, inventorying, and collecting PGRFA as well as on in situ and ex situ conservation. Explicit reference is given to “on farm” conservation by farmers, as distinct from in situ conservation of wild PGRFA. This is an example of greater specificity in the Treaty as compared to the CBD. The Treaty’s Article 6 requires Parties to develop and maintain appropriate policy and legal measures that promote the sustainable use of plant genetic resources for food and agriculture. Measures for sustainable use include those aimed at improving the use of plant genetic resources through plant breeding by farmers and professional breeders alike, as well as promoting diversity at all levels. Article 7 of the Treaty calls for integration of these activities into agricultural and rural development programs and policies. This complements Article 6 of the CBD for the integration of National Biodiversity Strategies and Action Plans (NBSAPs) into sectoral and intersectoral policies.

Article 9 of the Treaty states that Parties are to “recognize the enormous contribution that the local and indigenous communities and farmers of all regions of the world, particularly those in the centres of origin and crop diversity, have made and will continue to make for the conservation and development of plant genetic resources which constitute the basis of food and agriculture production throughout the world.” The Treaty provides for three substantive elements of Farmers’ Rights including 1) protection of traditional knowledge relevant to plant genetic resources for food and agriculture; 2) the

right to equitably participate in sharing benefits arising from the utilization of plant genetic resources for food and agriculture; and 3) the right to participate in making decisions, at the national level, on matters related to the conservation and sustainable use of plant genetic resources for food and agriculture.

The Treaty provides for a funding strategy (Article 18), the objectives of which are “to enhance the availability, transparency, efficiency, and effectiveness of the provision of financial resources to implement activities under the Treaty.” Further, the Governing Body shall periodically establish a target for such funding to mobilize funding for priority activities, plans, and programs, taking the Global Plan of Action into account. The Treaty includes provisions for regular communication between the Governing Body and the Conference of the Parties of the CBD (Article 19). The Conference of the Parties has welcomed the Treaty (Decision VI/9; The Hague, 2002).

The first meeting of the Governing Body of the Treaty is expected to take place in 2005. A number of important decisions will be taken by Parties at this first meeting, including the development of a standard MTA for material in the Multilateral System, the funding strategy, and procedures to promote compliance with the Treaty. The CGRFA, acting as the interim committee for the Treaty, is preparing for this first meeting.

Interphase Nucleus, The

Paul Fransz

University of Amsterdam, Amsterdam, The Netherlands

INTRODUCTION

Most cells of a multicellular organism contain the same genetic information, yet their gene expression pattern, morphology, and function may differ considerably. Cell identity is determined by the nuclear program and established by a complex molecular interplay between DNA sequence and proteins involved in higher order chromatin structure. The organization of the nucleus, therefore, plays a crucial role in cell type and stage-specific processes. The nucleus is a complex organelle showing a high degree of compartmentalization. The linear organization of several eukaryotic genomes is completed, but we know very little about the higher order chromatin structure. Our knowledge of the functional organization of the interphase nucleus is also still very limited. Most of what we know about nuclear architecture comes from microscopic studies with animal cells. Apart from chromatin, a number of subnuclear structures have been characterized, including the nucleolus, splicing-factor compartments, and many different small nuclear foci. The molecular mechanism underlying the nuclear architecture is currently being unravelled in animals, plants, and yeast. Here, the organization of the interphase nucleus in plants is discussed with respect to chromosome structure and function.

CHROMOSOMES OCCUPY NUCLEAR TERRITORIES

The interphase nucleus is the organelle that accommodates the chromosomes and, thus, the majority of the genetic information that makes up a eukaryote organism.^[1] In addition, nuclear processes involve maintaining and passing the genetic information by repairing, replicating, and transcribing the DNA sequence. The haploid genome of higher eukaryotes varies between 10^8 (*Caenorhabditis elegans* and *Arabidopsis thaliana*) and 10^{11} (*Amphiuma* and *Fritillaria*) base pairs. One of the main questions in studies of interphase nuclei is how the eukaryote genome, spanning up to several meters of DNA, fits into a nucleus with a diameter of only a couple of microns. In order to understand nuclear organization it is essential to study individual chromosomes, which occupy the major part of

the nucleus as discrete domains. In 1888, Boveri was the first to suggest that interphase chromosomes occupy nuclear territories. One century later, this theory was demonstrated in human cells by chromosome painting using fluorescence in situ hybridization (FISH) with chromosome-specific DNA probes.^[2] Chromosome painting appeared impossible in plants with large genomes such as wheat, *Vicia faba* or *Pisum sativum*, probably because the complex molecular organization of their genomes includes abundant dispersed repetitive sequences. However, alien chromosomes present in monosomic or disomic addition lines can be successfully visualized by FISH using the alien genomic DNA as probe. This technique is also known as genomic in situ hybridization (GISH).^[3] In interphase nuclei of cereals with large genomes, GISH reveals elongated chromosome territories. Plants with small genomes, such as *Arabidopsis* contain less repeats and have a higher gene density. The low repeat content allows the use of large genomic DNA probes to visualize chromosome-specific regions up to an entire chromosome territory.^[4] Differential chromosome painting can monitor position and size of the homologous chromosome territories and subchromosomal regions at subsequent cell cycle stages (Fig. 1).

Although chromosomal territories are discrete nuclear regions, close association of different chromosomes may occur. Long before the FISH technique was developed, fusion of interphase chromosomes was suggested by cytogeneticists who analysed plant species such as the crucifers, which contain nuclei with discrete, heterochromatic chromocenters. The FISH technology identified the subchromosomal regions involved in homolog association. In polyploid wheat, but not in its diploid progenitors, homologous centromeres associate in the xylem cells of developing roots.^[5] Similarly, in parenchyma cells of *Arabidopsis*, chromocenters with homologous rDNA repeats associate nonrandomly. Between 10% (chromosome 5) and 75% (chromosome 2) of the homologs associate at their chromocenters.^[6] Moreover, correct alignment of homologous regions occurs in 6% ($n = 114$) of the nuclei (Fig. 2A). In comparison association of homologous chromosome territories in mammalian cells was found for gene-dense, small chromosomes. These observations suggest a physical interaction between homologous chromosome territories in somatic cells.

Fig. 1 Different cell cycle stages of *Arabidopsis* parenchyma cells after in situ hybridization with 118 individually labeled BAC DNA clones covering the long arm. (From Ref. 4.) (View this art in color at www.dekker.com.)

CHROMOSOME ARRANGEMENT

Each chromosome consists of several distinct domains such as the centromere region, telomere, heterochromatin, and euchromatin. The chromosome territory is likely organized in such a way that each chromosomal subregion occupies a specific position corresponding to its function. The pericentromeric heterochromatic regions are generally positioned towards the periphery of the nucleus. The location of telomeres, however, appears variable. Organisms with large genomes (haploid genome size >3000 Mb) generally exhibit a Rabl orientation with telomeres and centromeres at opposite nuclear poles, whereas organisms with relatively small genomes show non-Rabl patterns (Fig. 3).^[7] The orientation of chromosomes during interphase may depend on factors other than

genome size, such as position or size of the nucleolus and chromosome size. In *Arabidopsis*, for example, the telomeres are clustered around the nucleolus (Fig. 3C). Furthermore, the genome of *Crepis capillaris* (1C = 2000 Mb), which shows a Rabl configuration, is smaller than 3000 Mb, but the chromosomes ($1n = 3$) are longer than in maize (2540 Mb, $1n = 10$), which shows a non-Rabl pattern. The Rabl orientation in wheat (1C = 16000 Mb) and rye (1C = 7500 Mb) corresponds with the elongated chromosome territories in these species. Human chromosomes (1C = 3000 Mb) generally do not show a Rabl orientation, but a polar orientation of chromosome domains with the major heterochromatin segments towards the nuclear periphery has been suggested based on 1) the observation of late-replicating (G band) DNA near the nuclear periphery and 2) electronmicroscopical studies showing a tendency for perinuclear positioning of heterochromatin domains.

CHROMOSOME ORGANIZATION

Several models of higher-order chromatin structures have been proposed based on microscopic investigation of human interphase chromosomes. The basic unit of chromatin is the nucleosome, which consists of the core histone proteins H2A, H2B, H3, and H4, around which approximately 150 bp of DNA is wrapped. The nucleosomes form a 10 nm fiber, which is visible under the electron microscope as a beads-on-the-string arrangement. Higher-order structures of chromatin are formed in the presence of histone H1. A chromatin structure, termed the solenoid, has been proposed, which consists of a 30 nm fiber, in which nucleosomes are packaged into a helical coil with six nucleosomes per turn and histone H1 positioned along the central axis of the coil.

Fig. 2 FISH images of *Arabidopsis* nuclei hybridized with 18 BACs from chromosome arm 4S (see diagram on the left) show aligned chromosome arms (A) and a megabase-sized loop (arrow) covering the entire arm 4S in one of the homologs (B). (View this art in color at www.dekker.com.)

Fig. 3 Telomere position (red) in barley (A), tomato (B), and *Arabidopsis* (C), which have an average chromosome size of 4900 Mb, 950 Mb, and 130 Mb, respectively. The centromere in barley is shown in green opposite to the telomeres, while in tomato and *Arabidopsis* the centromeres are in the heterochromatin islands. (Fig. 3A is kindly provided by Zuzana Jasencakova.) (View this art in color at www.dekker.com.)

Further winding of nucleosomes into higher organization levels of chromatin generates irregular folding patterns that are difficult to interpret. Structures such as the scaffold or the matrix have been proposed that may form a supportive skeleton keeping the higher-order chromatin loops together. However, the existence of these supportive structures is a matter of debate, because they have been demonstrated only with severe extraction techniques.

In *Arabidopsis*, nuclei chromosomes have a relatively simple organization. Each chromosome consists of a heterochromatic chromocenter from which euchromatic loops emanate.^[6] Chromocenters contain all major tandem repeats and the majority of the dispersed repeats. In contrast, euchromatin loops are gene-rich and range in size from 200 kb up to an entire chromosome arm (Fig. 2B). Together, chromocenter and loops form a chromosome territory (Fig. 4). This chromocenter-loop organization

suggests a clear functional differentiation within a chromosome territory. Most of the DNA in chromocenters is heavily methylated, while the tails of histone H3 are methylated at lysine position 9. In contrast, the euchromatin loops contain less methylated DNA and are rich in histone H4 acetylated at lysine positions 5 and 8, and histone H3 methylated at lysine position 4. These modifications of DNA and histones imply that chromocenters represent transcriptionally silent domains, whereas euchromatic loops contain potentially active gene regions.

The model reflects the simple linear organization of the *Arabidopsis* chromosomes, which contain only 15% heterochromatin, confined to the pericentromeric and the subtelomeric 45S ribosomal regions. The majority of the chromosome consists of gene-rich euchromatin. In comparison, wheat and rye contain more than 95% heterochromatin. Their chromosomes are not likely to have a similar

Fig. 4 The chromocenter-loop model for the organization of *Arabidopsis* chromosomes. Each chromosome consists of a heterochromatic chromocenter from which euchromatin loops emanate. The loops may span 0.2 kb up to an entire arm of 3 Mb. (View this art in color at www.dekker.com.)

simple chromocenter-loop organization. Based on the genomic sequence, the content of the average chromosome territory of *Arabidopsis* is estimated at 25 Mbp of DNA with 5200 genes. This is in contrast with the average human chromosome territory, which contains five times more DNA (130 Mbp) but only approximately 1700 genes. Megabase-sized loops have been demonstrated indirectly for the histocompatibility complex locus on human chromosome 6. Whether these loops are equivalent to the loops found in *Arabidopsis* and whether the chromocenter-loop model also accounts for other eukaryotes remains to be investigated.

CONCLUSION

The description of territories, euchromatin loops, and heterochromatin domains may suggest a rigid, non-flexible nuclear architecture. However, the interphase nucleus and the chromatin structure appear to be highly dynamic. Advanced 3D-fluorescence microscopy has recently provided new tools for studying the dynamics of chromatin. By tagging chromatin proteins with GFP, it is possible to track specific chromosome sites in real time and measure the kinetic properties of protein complexes.^[8] Nuclear components are shown to be transient complexes of nucleic acids and proteins that associate and dissociate dependent on internal or external stimuli. We soon will be able to visualize in detail chromatin remodelling in differentiating cells. More and more we tend to consider the nucleus as a membrane-bound bag filled with DNA, RNA, and protein complexes and lacking a solid skeleton. The flexible, higher-order structure of chromatin is controlled by a complex interplay between DNA and protein complexes. Modulation of chromatin structure and function takes place via covalent modification of histone tails by acetylation, methylation, phosphorylation, or ubiquitination.

These modifications affect the composition of chromatin-associated protein complexes and alter the activity of the gene regions.^[9] Several chromatin modifiers have been identified and their effect on gene expression demonstrated in different species. For example, methylation of histone H3 at lysine position K9 by histone methyltransferase SUV39 forms a stable mark that is recognized by heterochromatin protein (HP1). This results in binding of HP1 and subsequent spreading of heterochromatin into native chromatin. The same basic molecular mechanism has been reported for yeast, animals, and plants. The characterization of proteins and protein complexes is currently being

established, which will eventually lead to the identification of the factors that are responsible for the higher order organization of chromatin in interphase nuclei.

Interspecific Hybridization

D. S. Brar

International Rice Research Institute, Los Banos, Laguna, Philippines

INTRODUCTION

Genetic variability for agronomic traits is a prerequisite for any plant breeding program. To introduce such variability, plant breeders usually employ intervarietal hybridization. However, in several cases, useful variability for certain traits is either limited or lacking in the cultivated species. In these situations, breeders look for diverse sources and resort to interspecific hybridization. The wild relatives of crop plants are an important reservoir of useful genes and offer enormous potential to introduce such genes into cultivated species. Interspecific hybridization has been one of the important plant breeding methods to broaden the gene pool of crops. Numerous examples are available of the production of interspecific hybrids and their utilization in genetics and breeding research. Several pre- or postzygotic barriers hinder the production of interspecific hybrids and the transfer of genes into crops through interspecific hybridization. However, several techniques of chromosome manipulation, tissue culture, (embryo rescue, anther culture, somatic cell hybridization), molecular markers, and molecular cytogenetics can be employed to overcome these barriers.

Interspecific hybridization has provided a wealth of information on genomic relationships among species, nucleo-cytoplasmic interactions, synteny among distant genomes, the nature of reproductive barriers, mechanisms controlling chromosome pairing, chromosome elimination, nuclear restitution, and alien-gene introgression into the genomes of cultivated species. Numerous examples are available on the transfer of useful genes into crop plants through interspecific hybridization. Notable examples include the transfer of resistance to diseases and pests; leaf and stem rust, Hessian fly, green bug in wheat; crown rust and mildew in oat; mosaic virus and blank shank in tobacco; grassy stunt virus in rice; powdery mildew in barley; black arm in cotton; aphid in lettuce; mosaic virus in okra; bacterial wilt and root knot nematode in tomato; late blight and virus A, X, Y in potato; nematode resistance in sugarbeet; wider adaptation to warmer and drier region in peas; hardiness in grapes; cytoplasmic male sterility in wheat and cotton; high protein content in wheat; and highly soluble solids and increased salt tolerance in tomato.

CYTOGENETICS OF INTERSPECIFIC HYBRIDS AND THEIR DERIVATIVES

Interspecific hybrids and their derivatives exhibit peculiar features such as hybrid inviability, hybrid sterility, hybrid breakdown, limited recombination, and linkage drag.^[1,2] Factors such as genomic disharmony, nuclear instability, unfavorable nuclear-cytoplasmic interactions, the presence of deleterious genes, chromosome elimination, allocyly, and centromeric affinity account for limited progress in introgression of useful genes through interspecific hybridization^[3] (Table 1). As an example, Fig. 1 shows production of interspecific hybrids through embryo rescue between distantly related species of *Oryza*.

Hybrid Sterility

Hybrid sterility may be due to differences in structure and number of chromosomes, lack of chromosome homoeology resulting in a variable number of univalents, and production of unbalanced gametes. There are numerous reports of sterile interspecific hybrids and their derivatives. This kind of sterility could be due to gene substitutions and/or cryptic structural differences. Crosses between species with similar genomic constitutions (*Oryza sativa* × *Oryza glaberrima*; *Oryza sativa* × *Oryza longistaminata*) are highly sterile.

Allocyly or Genomic Disharmony

The parental genomes in interspecific crosses generally show disharmony resulting in meiotic instability, aneuploidy, and unbalanced gametes, and thus to increased sterility and reduced grain yield. Differences in the cell-cycle rhythm of parents, genomic ratio, presence of telomeric heterochromatin, and the cytoplasm donor may contribute singly or collectively to disharmony of the two genomes.

Nuclear Instability

Nuclear instability refers to any deviant nuclear behavior producing a nucleus (or nuclei) of abnormal structure,

Table 1 Techniques for overcoming barriers to interspecific hybridization

Barrier	Technique for overcoming barrier
Prefertilization	
Failure of pollen germination	<ul style="list-style-type: none"> • Mechanical removal of pistil followed by pollination of the exposed end of the style • Use of recognition pollen
Slow pollen tube growth	<ul style="list-style-type: none"> • Use of recognition pollen, growth hormones • In vitro fertilization

Hybrid sterility	<ul style="list-style-type: none"> • Chromosome doubling (amphiploid production) • Backcrossing with the recurrent parent
Hybrid breakdown	<ul style="list-style-type: none"> • Growing larger F₂ populations • Inducing premeiotic chromosomal exchanges in hybrids through mutagenesis and/or tissue culture
Limited alien recombination	<ul style="list-style-type: none"> • Inducing homoeologous recombination through genetic manipulation of chromosome pairing system • Inducing chromosomal exchanges through tissue culture and/or irradiation
Low recovery of alien recombinants	<ul style="list-style-type: none"> • Selection of recombinants with alien chromosome segments in early generations using molecular markers and in-situ hybridization techniques • Selection of lines with smaller alien segment substitutions for enhanced transmission to the progenies

karyotype, or behavior. Nuclear instability and mitotic abnormalities in coenocytic endosperm affect seed fertility and endosperm development in triticale. Nuclear instability in triticale endosperm often begins with the formation of a chromatin bridge at anaphase. Restitution nuclei result in degenerated endosperm. The probable cause of nuclear instability may be the higher DNA content in rye. Unlike wheat chromosomes, rye chromosomes have large telomeric segments of heterochromatin. Late-replicating DNA (mostly telomeric heterochromatin) in rye chromosome may cause bridge formation at anaphase. Such bridges may cause the production of abnormally polyploid endosperm nuclei leading to sterility. First-division restitution (FDR), second-division restitution (SDR)

in potato, and indeterminate meiotic restitution (IMR) in lily are common features of interspecific crosses.

Hybrid Breakdown and Reversion to Parental Types

The phenomenon of hybrid breakdown refers to situations where the F₁ is fertile but segregants in the F₂ or later generations are weak or sterile. The phenomenon of hybrid breakdown is not well understood; probable causes include centromeric affinity, cryptic structural hybridity, gene substitution, and unfavorable nuclear-cytoplasm interactions.

Fig. 1 Production of interspecific hybrids through embryo rescue between distantly related species of *Oryza*. (View this art in color at www.dekker.com.)

Limited Recombination

Reduced chromosome pairing and lack of recombination between genomes of alien and cultivated species are key factors limiting alien gene transfer. The extent of recombination depends on the genetic homoeology of two genomes, which may be different for different chromosomes or chromosome segments. Until precise methods for inducing or enhancing homoeologous recombination

and allosyndetic pairing become available, it will be difficult to transfer alien genes into commercial varieties.

Presence of Deleterious Genes and Linkage Drag

Breeders in general are reluctant to use wild species for the improvement of cultivated species because of linkage

drag, wherein some undesirable characters of wild parents are transferred along with useful genes. Some interspecific derivatives (such as Transec) have not been used extensively in wheat breeding because they are associated with lowered yield. Similarly, the Agatha strain of wheat (possessing rust resistance from *Agropyron*) shows undesirable association with yellow flour color. A number of available wheat lines with substituted chromosomes of *Aegilops*, *Agropyron*, and *Secale* have disease and pest resistance or high protein. However, only a few of them are widely used in cultivar improvement because of linkage drag.

ALIEN GENE TRANSFER

Major advances have been made in understanding genomic relationships, genetic control of chromosome pairing, and characterization of alien chromatin in interspecific derivatives. Methods have been developed for incorporating complete alien genomes (amphiploids), single chromosomes (alien addition/substitution), small chromosome segments (alien translocations), or a few alien genes from wild into cultivated species. Numerous examples are available of alien gene transfer into crop plants.^[2,4,5]

Synthetic Amphiploids

A majority of the interspecific hybrids show sterility to varying degrees. Fertility can be restored by doubling the chromosome number of F₁ hybrids (amphiploid production). The other option is to backcross with the recurrent parent until fertile progenies (introgression lines) with stable chromosome number become available. Several amphiploids of hybrids involving cultivated species and wild relatives have been produced during the last 45 years, especially since the discovery of colchicine. With the exception of triticale, however, none has become a new crop.

In amphiploids such lack of genomic harmony causes meiotic instability and several other undesirable features resulting from nuclear-cytoplasmic interactions. However, they are important for extracting desirable derivatives involving crosses of natural × synthetic allopolyploids.

Extracted Allopolyploids

Several amphiploids in wheat, cotton, tobacco, and *Brassica* have been used to extract stable allopolyploids through intercrosses of synthetic × natural allopolyploids. Triticale is the classic example for demonstrating the

usefulness of extracted polyploids. The hexaploid triticales extracted from the progenies of 8x triticale × 6x triticale and 6x wheat × 6x triticale are cytologically more stable. They are superior to the primary triticales in meiotic stability, grain yield, and grain quality.

The production of amphiploids, alien chromosome addition and substitution lines, and backcross (introgression) progenies are important genetic stocks for transferring alien genes to crop plants. Once these stocks are available, they can be further manipulated by directed chromosome engineering.

Characterization of Alien Chromatin in Interspecific Derivatives through C-Banding and In Situ Hybridization

Several methods are available to characterize alien chromatin in interspecific hybrids and their derivatives. Morphological traits, isozyme, molecular markers, C-banding, fluorescence in situ hybridization (FISH), and genomic in situ hybridization (GISH) have been employed to characterize parental genomes, extra alien chromosome, translocated chromosome segments, and introgressed genes. Fiber FISH can further enhance the precision for characterization of homoeologous pairing in interspecific hybrids and their derivatives. C-banding has been employed to characterize changes in karyotype and alien chromosome translocations.^[6] Several kinds of molecular markers, BAC and YAC, including repetitive DNA; total genomic DNA; and species-specific markers, have been used in characterizing alien chromatin in a great number of interspecific derivatives.

RESEARCH PRIORITIES AND OUTLOOK ON INTERSPECIFIC HYBRIDIZATION

With advances in tissue culture, genomics, and molecular cytogenetics the outlook for interspecific hybridization in crop improvement seems more promising. Following are some priorities for future research on interspecific hybridization.

Map-Based Cloning of Gene(s) Controlling Chromosome Pairing

Isolate *Ph* gene(s) and introduce into other crops that lack a similar system to promote homoeologous recombination. As in the case of wheat, there is a need to identify pairing controlling genes in crops such as *Brassica*, cotton, rice,

soybean, legumes, and millets to enhance alien gene transfer from different species.

Identifying and Introgressing Chromosome Regions in Wild Species Carrying Novel Alleles for Enhanced Yield Potential

Molecular analyses of mapping populations derived from interspecific crosses have revealed novel QTLs-yield-enhancing loci. Molecular-marker technology should be used to identify and introgress such novel alleles from wild species into cultivated species.

Physical Mapping Using Alien Chromosome Addition Lines and Radiation Hybrids

Partial hybrids or alien addition lines have been produced through chromosome elimination from oat \times maize crosses. Such cytogenetic stocks and radiation hybrids should be developed in other systems. Species-specific DNA sequences, retroelements, chromosome-specific markers, and GISH could be used in the physical mapping of genomes of crop plants.

Identifying Agronomically Important Gene-Rich Chromosome Regions

Identify gene-rich regions in different species. Physical mapping of such genes would provide useful information on the possibility for map-based cloning and introgression into genomes of cultivated plants. Genes in the proximal region of chromosomes may be difficult to introgress because of limited recombination. New methods of tissue culture or transposons should be used to transfer such genes into elite germplasm.

Enhancing Chromosomal Exchanges through Tissue Culture among Genomes of Cultivated and Distantly Related Species

Induce chromosomal exchanges between genomes of species that otherwise lack chromosome pairing. Tissue culture of interspecific (sexual and somatic) hybrids and alien addition lines is suggested to achieve this.

FISH-Assisted Selection for Alien Recombinants

Advances in GISH/FISH have made it possible to characterize lines carrying alien chromatin. Emphasis should be given to develop protocols to select interspecific deri-

vatives in early generations based on GISH, important for the recovery of recombinants and to enhance the selection efficiency of alien gene introgression.

Characterizing Genomic Relationships and Microsynteny among Species

Conventional cytogenetic techniques have provided a wealth of information on the genomic homoeology and evolutionary relationships of different species. Molecular cytogenetic techniques involving molecular markers, GISH, FISH, and fiber-FISH should be used to understand precisely the nature and extent of cryptic structural differences, microsynteny, and homoeologous pairing during early meiotic divisions among distant genomes to enhance the efficiency of alien gene introgression.

Producing Haploids from Interspecific Crosses through Chromosome Elimination

Chromosome elimination through species crosses has proven to be a valuable mechanism to produce haploids in wheat, barley, and oat. Haploid-inducing systems need to be identified in other crops such as *Brassica*, cotton, rice, and legumes. This would be an important complementary approach to produce haploids where anther culture response is limited to only specific genotypes.

Broadening Gene Pool of Crops for Tolerance to Major Biotic and Abiotic Stresses

An integrated approach using tissue culture, molecular markers, and molecular-cytogenetic techniques should be used to monitor alien chromatin and introgress useful genetic variability from wild species into crop plants through interspecific hybridization.

Isoprenoid Metabolism

Russell K. Monson
Todd N. Rosenstiel

University of Colorado, Boulder, Colorado, U.S.A.

INTRODUCTION

Plants synthesize a wide range of molecules with complex structural and functional attributes from the branched, five-carbon monomer precursor known as the isoprene unit. Isoprenoid molecules range in size from those with 5 carbon atoms (the hemiterpenes) to those with more than 40 carbon atoms (the polyterpenes). The various isoprenoid groups have a broad range of functions in plants, including those associated with herbivore deterrence, metabolic electron transport, and hormonal activity. Isoprenoid compounds are used in numerous ways to support human activities, including their use as food flavoring agents (e.g., mint essential oils), perfumes (e.g., monoterpenes), pharmaceuticals (e.g., the antitumor compound, taxol), and insecticides (e.g., pyrethrins). Isoprenoid compounds also have important roles in ecological interactions, including their role in plant–insect interactions (e.g., as antiherbivore agents and as attractants for pollinators and parasites alike) and as allelopathic agents. Recently, it has become clear that the loss of volatile isoprenoid molecules from plants has important ramifications for atmospheric processes. These molecules cause much of the active photochemistry that occurs in the lower atmosphere, including those reactions that lead to tropospheric ozone production and the oxidation of methane, a potent greenhouse gas.^[1,2]

BIOSYNTHESIS OF ISOPRENOID PRECURSORS

All isoprenoids are biosynthesized from just two 5-carbon (C_5) metabolic precursors: isopentenyl diphosphate (IPP) and its allylic isomer, dimethylallyl diphosphate (DMAPP) (Table 1). Until recently, the biosynthesis of these precursors in plant cells was thought to occur exclusively via the well known mevalonic acid pathway, as occurs in yeast, fungi, and animal cells. However, several results inconsistent with the mevalonate pathway led to the discovery of an additional non mevalonate pathway of isoprenoid biosynthesis operating in certain bacteria, green algae, and plants.^[3] The discovery and partial elucidation of the deoxyxylulose phosphate (DOXP)

pathway represents one of the most exciting advances in basic plant physiology to occur near the closure of the 20th century.

In plant cells, IPP synthesis not only results from two independent biochemical pathways, but these pathways occur in distinct cellular compartments (Fig. 1). The mevalonate route to isoprenoids appears to reside solely in the cytosol-endoplasmic reticulum (ER) compartment where sterols, sesquiterpenes (C_{15}), triterpenes (C_{30}), and polyterpenes are synthesized. Hemiterpenes—such as isoprene (C_5), monoterpenes (C_{10}), diterpenes (C_{20}), and tetraterpenes (C_{40}) as well as the side chains of plastoquinone and α -tocopherol—are synthesized in plastids from IPP formed predominately via the DOXP pathway. A third cellular compartment, the mitochondrion, also participates in isoprenoid biosynthesis by using IPP from the cytosol-ER pathway to make the prenyl side chain of ubiquinone, a component of this organelle's electron transport chain. This extensive subcellular partitioning of biochemical pathways and products highlights the significant role of compartmentation in plant isoprenoid metabolism. However, the compartmental separation of the two different IPP biosynthetic pathways is not absolute because plastids may supply IPP to the cytosol for use in biosynthesis and vice versa. For example, the first two C_5 units of the sesquiterpenes of chamomile are formed via the DOXP pathway, whereas the third unit is derived from both biosynthetic routes.^[4] Although crosstalk between the two pathways appears to be small (<1%), elucidation of the nature of the metabolites exchanged between the compartments and regulation of this process remains a significant challenge to plant biochemists.

The biochemical steps involved in the formation of IPP via the mevalonic acid pathway have been firmly established and are known to result from the stepwise condensation of three molecules of acetyl coenzyme A. As in the situation of animals, numerous studies indicate that 3-hydroxy-3-methylglutaryl-CoA reductase (HMGR), a key enzyme in this pathway, also catalyzes a rate-determining step in sterol formation in plants. Although accumulated evidence suggests that the activity of the plant HMGR is highly regulated, it remains unclear how differential regulation of HMGR activity in the cytosol facilitates the production of distinct isoprenoid families.

Table 1 Primary groups of isoprenoid compounds and examples of functional roles in plants

Type of compound	Number of C atoms	Role in plants
Hemiterpenes (isoprene)	5	Possible thermal protectant
Monoterpenes	10	Antiherbivore; pollinator attractant
Sesquiterpenes	15	Antiherbivore; antimicrobial; abscisic acid
Diterpenes	20	Phytol side-chain of chlorophyll; gibberellins; phytoalexins
Triterpenes	30	Phytosterols of membranes; antiherbivore
Tetraterpenes	40	Carotenoids
Polyterpenes	>40	Plastoquinone and ubiquinone electron carriers

The DOXP pathway of IPP formation in plastids begins with pyruvate and glyceraldehyde 3-phosphate. In this pathway, pyruvate reacts with a thiamine pyrophosphate (TPP) cofactor to yield a two-carbon molecule, hydroxyethyl-TPP, which condenses with glyceraldehyde 3-phosphate. TPP is released to form a five-carbon intermediate, 1-deoxy-D-xylulose 5-phosphate (for which the pathway receives its name), which is rearranged and reduced to form 2-C-methyl-D-erythritol 4-phosphate and subsequently is transformed to yield IPP. The enzymes and corresponding gene sequences of the first five steps in

the new pathway are now fairly well documented.^[5] However, the genes, enzymes and reactions involved in the final steps leading to IPP and DMAPP formation remain unknown.

The identification of the regulatory steps of the DOXP pathway is an issue of major importance for both theoretical and applied reasons. So far, efforts have focused on the first two enzymes of the pathway (1-deoxy-D-xylulose 5-phosphate synthase, DXS; and 1-deoxy-D-xylulose 5-phosphate reductoisomerase, DXR) and preliminary results indicate both enzymes may contribute to regulating

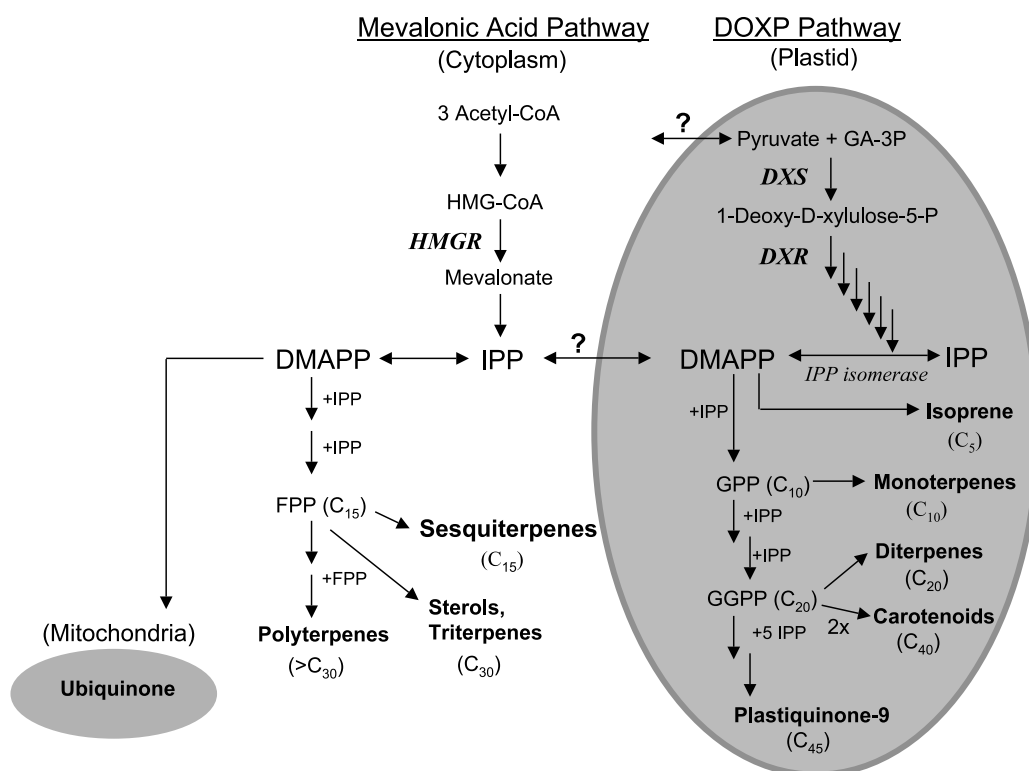

Fig. 1 Compartmentation of isoprenoid biosynthesis in higher plants between the cytosol (mevalonic acid pathway) and plastids (DOXP pathway). The role of cytosolic IPP in the formation of mitochondrial ubiquinones is also indicated. Abbreviations used: DMAPP, dimethylallyl diphosphate; IPP, isopentenyl diphosphate; GPP, geranyl diphosphate; FPP, farnesyl diphosphate; GGPP, geranylgeranyl diphosphate; HMGR, HMG-CoA reductase; DXS, deoxyxylulose phosphate synthase; DXR, deoxyxylulose phosphate reductoisomerase. (View this art in color at www.dekker.com.)

plant isoprenoid production. Transgenic manipulation of the DOXP pathway holds much promise for the production of commercially important isoprenoids. In one unique example, overexpression of DXR in peppermint led to a dramatic increase in total essential oil accumulation.^[6] Similar successes in the genetic engineering of isoprenoid metabolism have been achieved in the area of isoprenoid vitamins, including α -tocopherol (vitamin E) production in oilseeds and enhanced β -carotene in rice and rapeseed. Because the DOXP pathway is uniquely restricted to plants and certain bacteria (particularly human pathogens), selective inhibition of the DOXP pathway might be the basis for the development of new herbicides as well as novel antibiotics and antimalarial agents.^[7] Despite rapid advances in our understanding of the novel DOXP pathway, significant uncertainties remain. Because constraints on precursor flow will ultimately limit the effectiveness of transgenes for isoprenoid synthesis, information about the flux controls on IPP and DMAPP formation as well as the source of carbon precursors supplying the DOXP pathway is sorely needed.

THE ISOPRENE RULE AND FORMATION OF ALLYLIC DIPHOSPHATE ESTERS

In 1910, the German chemist Otto Wallach was awarded the Nobel Prize in Chemistry for elucidation of the isoprene rule. Simply stated, the isoprene rule revealed that isoprenoid molecules in plants are synthesized by repetitive head-to-tail condensations of a five-carbon, alkene monomer. This rule was modified in the 1930s by Leopold Ruzicka to give the biogenetic isoprene rule, which stated that an isoprenoid molecule is one that is derived from an isoprenoid precursor, even if it undergoes subsequent chemical modification that results in a product with obscure connections to its isoprene origins. Ruzicka was awarded the Nobel Prize in Chemistry in 1939. Thus, the history of isoprenoid chemistry in plants has a rich award-winning legacy.

The head-to-tail condensation of IPP by prenyltransferase enzymes forms three types of allylic diphosphate ester compounds—geranyl diphosphate (GPP), farnesyl diphosphate (FPP) and geranylgeranyl diphosphate (GGPP)—which are subsequently converted into a broad range of terpenes by various terpene synthase enzymes. In the first step of allylic diphosphate ester compounds, IPP is converted to dimethylallyl diphosphate (DMAPP) by IPP isomerase. In the presence of a divalent metal cation, the allylic double bond of the DMAPP molecule forms a resonance-stabilized carbocation that can subsequently react with a second IPP molecule to form GPP (C_{10}) (Fig. 2). Further addition(s) of IPP forms FPP (one additional IPP) or GGPP (two additional IPPs).

Fig. 2 Condensation reaction of prenyltransferase to join together two hemiterpenes (C_5) to form geranyl diphosphate (GPP). In Step 1, divalent metal cofactors facilitate delocalization of a carbocation, allowing DMAPP to join with IPP through a condensation reaction (Step 2). In Step 3, a proton is extracted from the enzyme-bound intermediate, producing GPP.

TERPENE SYNTHASE ENZYMES

The production of terpenoid compounds from GPP, FPP of GGPP involves an initial ionization to promote cyclization, the primary catalyst being terpene synthase (or terpene cyclase) enzymes. (Acyclic terpenes are known to exist, but most are cyclic.) Many terpene synthases catalyze the synthesis of multiple terpene products; this is permitted because of the multiple fates that are possible for the carbocation intermediate that is formed from the cyclization catalyzed by terpene synthases.^[8] Over thirty different terpene synthases from angiosperms and gymnosperms, with roles in both primary and secondary metabolic pathways, have been identified on the basis of cDNA sequences. Sequence analysis has revealed that the evolutionary diversification of terpene synthases has occurred through gene duplication and divergence of enzymes; the primary direction of diversification appears to be from ancestral genes involved in primary metabolism toward derived genes involved in secondary metabolism.^[9] Given the ubiquitous distribution of terpene synthase genes in plants, it is likely that future phylogenetic studies of divergent plant groups will benefit from studies of sequence homology among terpene synthase genes.

THE ISOPRENOID CONNECTION TO ATMOSPHERIC CHEMISTRY

In 1960, Fritz Went recognized the potential for plants to add large amounts of volatile isoprenoid molecules to the atmosphere; using the concentration of terpene-containing leaf oils in sagebrush, he estimated global terpene emissions to represent 175 Tg C y^{-1} ($1 \text{ Tg} = 10^{12} \text{ g}$).^[10]

More recent estimates suggest that as much as 500–1000 Tg C y⁻¹ may enter the atmosphere as volatile isoprenoid compounds.^[11] Although estimates of the global magnitude of these emissions contain many uncertainties, it is clear that the emissions have a profound effect on photochemical reactions in the lower atmosphere. Isoprene, which is formed in the leaves of many tree species, has a boiling point of 39°C, causing it to volatilize from leaves at high rates immediately after being formed. Once in the atmosphere, isoprene has an average lifetime of only 0.2 hours before its double bonds are oxidized by reaction with hydroxyl radicals. A similar fate exists for monoterpene molecules that escape their storage reservoirs in the leaves and enter the atmosphere. The oxidation of isoprenoid molecules by OH causes an increase in the lifetime of CH₄, a compound with strong potential to cause climate warming, because the primary path for the oxidative breakdown of CH₄ also requires OH molecules. The atmospheric oxidation of isoprenoid molecules forms a series of secondary compounds, which participate in even further chemical oxidation. The net result of these oxidations is the formation of organic peroxy compounds, which can react with NO to form NO₂ and ultimately promote the reaction of NO₂ with O₂ to form tropospheric O₃, an important pollutant and radiatively active greenhouse gas. Globally, the emission of isoprenoid molecules from plants is estimated to promote a 30% increase in tropospheric O₃ and to increase the lifetime of CH₄ by 15%.^[12]

CONCLUSION

The formation of isoprenoid molecules in plants has important ramifications for issues associated with agriculture and human nutrition, plant adaptation to stress, and global ecology. Studies of the metabolic pathways leading to isoprenoid molecules have revealed several fundamental principles of plant biochemistry, and have provided the foundation for highly recognized scientific research. These fundamental discoveries will allow future research on this topic to focus on the genes that control the expression of isoprenoid biochemistry and permit transgenic approaches to be developed for the manipulation of isoprenoids in various plant tissues.

Larvicidal Proteins from *Bacillus thuringiensis* in Soil: Release, Persistence, and Effects

G. Stotzky

New York University, New York, New York, U.S.A.

INTRODUCTION

Bacillus thuringiensis (*Bt*) produces a parasporal, proteinaceous, crystalline inclusion during sporulation. This inclusion is solubilized and hydrolyzed in the midgut of larvae of susceptible insects, releasing polypeptide toxins that cause death.^[1–3] Distinct insecticidal crystal protein (IPC) *cry* genes code for larvicidal Cry proteins: Cry1 and Cry2B proteins are specifically toxic to Lepidoptera, Cry2A proteins to Lepidoptera and Diptera, Cry3 proteins to Coleoptera, and four Cry4 proteins to Diptera. Two genes (*cytA*, *cytB*) that code for cytolytic proteins (CytA, CytB) are present with the Cry4 proteins. Some ICPs exhibit activity against Homoptera, Hymenoptera, Orthoptera, Mallophaga, nematodes, mites, *Collembola*, protozoa, and other organisms.^[1–3]

DISCUSSION

Sprays of *Bt* containing cells, spores, and ICPs have been used as insecticides for more than 30 years with generally no unexpected toxicities, probably because *Bt* does not survive or grow well in soil, and its spores are rapidly inactivated by ultraviolet (UV) light.^[1,2,4,5] Hence, there is little production of the proteins in soil, and persistence of introduced toxins is a function primarily of the 1) amount added, 2) rate of consumption and inactivation by insect larvae, 3) rate of degradation by microorganisms, and 4) rate of abiotic inactivation. However, when genes that code for these proteins are genetically engineered into plants, the proteins continue to be synthesized during growth. If production exceeds consumption, inactivation, and degradation, toxins could accumulate and enhance control of target pests; constitute a hazard to nontarget organisms, such as the soil microbiota, beneficial insects, and other animals; and result in the selection and enrichment of toxin-resistant target insects.^[1,4–6] Persistence is enhanced when the proteins are bound on surface-active particles (e.g., clays and humic substances) in soil and, thereby rendered less accessible for microbial degradation, although toxicity is retained.^[4,5]

Potential hazards and benefits are affected by modifications (e.g., truncation, rearrangement of codons)^[2] of introduced *cry* genes to code only for synthesis of “active” toxins, or a portion of the toxins, rather than code for synthesis of nontoxic ICPs. Consequently, it will not be necessary for an organism to have a high midgut pH (ca. 10.5) for solubilization of ICPs and specific proteolytic enzymes to cleave them into toxic subunits. Nontarget insects and organisms in higher and lower trophic levels could, therefore, be susceptible, leaving only the third barrier apparently responsible for host specificity; i.e., specific receptors on midgut epithelium that are often, but not always, present in larger numbers in susceptible larvae.^[1,2,5]

Binding of toxins from *B. thuringiensis* subsp. *kurstaki* (*Btk*, 66 kDa, active against Lepidoptera), subsp. *tenebrionis* (*Btt*, 68 kDa, active against Coleoptera), and subsp. *israelensis* (*Bti*, 25–130 kDa, active against Diptera) on montmorillonite (M) and kaolinite (K); clay-, silt-, and sand-size fractions of soil; humic acids from different soils; and complexes of clay-humic acid-Al hydroxypolymers have been studied.^[4,5] M and K are predominant clay minerals in many soils and differ in structure, physicochemical characteristics, and effects on biological activity.^[7] The purpose of these in vitro studies, the results of which are summarized in Table 1, was to determine whether toxins in transgenic *Bt* plants or ICPs in sprays are bound on surface-active soil particles and whether binding results in the proteins becoming resistant to biodegradation and to persist while retaining larvicidal activity.^[4,5]

INTERACTIONS IN SOIL OF LARVICIDAL PROTEINS IN TRANSGENIC *Bt* PLANTS

Biodegradation of Biomass of *Bt* Plants

Addition of biomass from transgenic corn (*Zea mays* L.) expressing Cry1Ab protein resulted in a significantly lower gross metabolic activity (as measured by CO₂ evolution) of soil than addition of isogenic nontransgenic biomass (Flores, Saxena, and Stotzky, unpublished).^[4,5]

Table 1 Summary of interactions of purified *Bt* toxins with surface-active particles: Effects on persistence and larvicidal activity

- Larvicidal proteins from *Bacillus thuringiensis* subsp. *kurstaki* (*Btk*; antilepidopteran), *tenebrionis* (*Btt*; anticoleopteran), and *israelensis* (*Bti*; antidipteran) bound rapidly and tightly on clays, humic acids, and complexes of clay-humic acid-Al hydroxypolymers; binding was pH dependent and greatest near the isoelectric point (pI) of the proteins; binding of the toxin from *Btk* was greater than binding of the toxin from *Btt*, even though the M_r of both was similar (66 and 68 kDa, respectively).
- Bound toxins retained their structure, antigenicity, and insecticidal activity.
- Intercalation of clays by the toxins was minimal.
- Biodegradation of the toxins was reduced when bound; microbial utilization of the toxins as a source of carbon was reduced significantly more than utilization as a source of nitrogen.
- Larvicidal activity of bound toxins was retained.
- Larvicidal activity of the toxin from *Btk* was detected 234 days after addition to nonsterile soils (longest time studied).
- Persistence of larvicidal activity was greater in acidic soils, in part probably because microbial activity was lower than in less acidic soils; persistence was reduced when the pH of acidic soils was raised to ca. 7.0 with CaCO_3 .
- Persistence was similar under aerobic and anaerobic conditions and when soil was alternately wetted and dried or frozen and thawed, which indicated tight binding.
- Persistence in soil was demonstrated by dot-blot enzyme-linked immunosorbent assay (ELISA), flow cytometry, Western blots, and larvicidal assays.
- Toxins from *Btk*, *Btt*, and *Bti* had no microbiostatic or microbicidal effect against a spectrum of bacteria (gram positive and negative), fungi (filamentous and yeast), and algae, neither in pure nor in mixed cultures.

Soils amended with biomass of *Bt* corn were lethal to larvae of the tobacco hornworm (*Menduca sexta*), whereas there was essentially no mortality with soils amended with biomass of non-*Bt* corn or unamended. Similar results were obtained with biomass of *Bt* rice, cotton, canola, tobacco, and potato.

The lower biodegradation of *Bt* corn biomass was not the result of differences in the C:N ratio of the biomasses, as altering the ratio did not significantly alter the relative differences in biodegradation. It was apparently not the result of inhibition of the soil microbiota, as numbers of culturable bacteria and fungi and the activity of enzymes representative of those involved in the degradation of plant biomass were not significantly different in soil amended with biomass of *Bt* as opposed to non-*Bt* corn. These results confirmed in vitro observations that the Cry

proteins from *Btk*, *Btt*, and *Bti* were not toxic to pure and mixed cultures of microbes and in situ observations of no consistent and lasting effects of biomass of transgenic *Bt* plants on the soil microbiota.^[4,5]

Lignin Content of *Bt* Plants

The lignin content of 10 hybrids of *Bt* corn was 33–97% higher than that of their respective non-*Bt* near-isolines.^[8] It was significantly higher in plants transformed by event Bt11 than by event MON810; the lignin content of the only available hybrid transformed by event 176 was lowest. There were no significant differences among isogenic non-*Bt* hybrids. However, the lignin content of the biomass of the other plant species, which was considerably lower than that of corn, was not significantly different in *Bt* and non-*Bt* plants. Hence, the higher lignin content of *Bt* corn may not be an important factor in its lower biodegradation. Nevertheless, modifications in lignin content could have ecological implications, e.g., higher lignin content in *Bt* corn may provide greater resistance to attack by second-generation European corn borer; reduce susceptibility to molds; and retard litter degradation and decomposition, which may be beneficial, as organic matter from *Bt* corn may persist and accumulate longer and at higher levels, thereby improving soil structure and reducing erosion.^[8] By contrast, longer persistence may extend the time the toxin is present in soil and enhance the hazard to nontarget organisms and selection of toxin-resistant target insects.

Release of Cry Proteins in Root Exudates

Cry1Ab protein was released in root exudates from 13 hybrids of *Bt* corn (transformation events Bt11, MON810, and 176).^[9] Presence of the toxin in sterile hydroponic culture was indicated by a major band migrating on sodium dodecyl sulfate polyacrylamide gel electrophoresis to a position corresponding to a molecular mass (M_r) of 66 kDa, the same as that of Cry1Ab protein, and confirmed by immunological and larvicidal assays. After 25 days, when the hydroponic culture was no longer sterile, the 66-kDa band was not detected (there were several new protein bands of smaller M_r) and immunological and larvicidal assays were negative, indicating that microbial proteases had hydrolyzed the protein. By contrast, toxin was detected after 180 days—the longest time studied—from *Bt* corn grown in nonsterile soil in a plant-growth room, confirming that toxin was bound on surface-active soil particles, which protected it from hydrolysis.

To estimate the importance of clays and other physicochemical characteristics—which influence activity and

ecology of microbes in soil^[5,7,10]—to persistence of toxin released in root exudates, studies were done in soil amended to 3, 6, 9, or 12% with M or K. Forty days after germination, all samples of rhizosphere soil from *Bt* corn were immunologically positive for the Cry1Ab protein and toxic to larvae of *M. sexta*, whereas there was no significant mortality with soil from non-*Bt* corn or without plants.^[9] The weight of surviving larvae exposed to soils from *Bt* corn was 50–92% lower than the weight of larvae exposed to soils from non-*Bt* corn or without plants.

Larvicidal activity was higher initially in soil amended with M than with K, probably because M—a swelling 2:1, Si:Al, clay with a significantly higher cation-exchange capacity and specific surface area than K, a nonswelling 1:1, Si:Al, clay—bound more toxin in root exudates, as also observed with pure toxin.^[4,5] However, mortality was essentially the same after 40 days, indicating that over a longer time, persistence of larvicidal activity appeared to be independent of clay mineralogy and other physicochemical characteristics of soils, and that toxin was concentrated when adsorbed on surface-active soil components.

Immunological and larvicidal assays of rhizosphere soil from *Bt* corn grown in the field were also positive, even in soil collected after frost from plants that had been dead for several months.^[5,9] There were no consistent differences in exudation of toxin between hybrids derived from different transformation events, neither in the plant-growth room nor in the field.

In addition to toxin introduced to soil in plant biomass after harvest and in pollen during tasseling,^[11] toxin will be released to soil from roots during growth of *Bt* corn, which could improve control of insect pests, enhance selection of toxin-resistant target insects, and/or constitute a hazard to nontarget organisms. Because *Bt* corn contains truncated genes that encode toxin rather than nontoxic ICP, potential hazards are exacerbated. This is because it is not necessary for an organism to have a high gut pH and specific proteases, and receptors for toxin are present in target and nontarget insects.^[11] Consequently, nontarget insects and other organisms in higher and lower trophic levels could be susceptible.^[5]

Cry1Ac protein was not detected in hydroponic culture or nonsterile soil in root exudates of *Bt* cotton, canola, or tobacco, whereas Cry1Ab protein was detected in root exudates of *Bt* rice. Cry3A protein was detected in root exudates of *Bt* potato immunologically and by their toxicity to larvae of the Colorado potato beetle (*Leptinotarsa decemlineata*) (Saxena and Stotzky, unpublished). It is not clear how such large proteins (e.g., the 66-kDa Cry1Ab protein) are released intact from roots, because the release of molecules with high M_r usually requires the presence of a “signal peptide.”^[12] The endoplasmic

reticulum is apparently close to or associated with the plasma membrane in roots of corn and, perhaps, of rice and potato but apparently not of cotton, canola, or tobacco. Although some toxin from corn, rice, and potato was probably derived from sloughed and damaged root cells, the major portion was from root exudates, as there was no discernable root debris in sterile hydroponic cultures. Moreover, no toxin was detected from cotton, canola, or tobacco in soil, again indicating that any damage to roots was a minor source of the toxins.

Effects of Toxins on Worms, Nematodes, and Microbes

There were no significant differences in mortality and weight of earthworms (*Lumbricus terrestris*) after 40 days in soil planted with *Bt* or non-*Bt* corn or not planted and after 45 days in soil amended with biomass of *Bt* or non-*Bt* corn or not amended.^[13] Toxin was present in casts and guts of worms grown in *Bt*-contaminated soil, indicating again that toxin had bound on surface-active particles in soil, which protected it from biodegradation. When worms were transferred from *Bt*-containing soil to fresh soil, toxin was cleared from guts in 1–2 days. There were also no statistically significant differences in numbers of nematodes and culturable protozoa, bacteria (including actinomycetes), and fungi between rhizosphere soil of *Bt* and non-*Bt* corn or between soil amended with *Bt* or non-*Bt* biomass. Soil with biomass of *Bt* corn and from the rhizosphere of *Bt* corn was immunologically positive for toxin and lethal to larvae of *M. sexta* after 45 and 40 days, respectively. Although these results suggested that toxin released in root exudates of *Bt* corn or from degradation of biomass of *Bt* corn is not toxic to a variety of organisms in soil, only one species of earthworms and only culturable microorganisms and nematodes were evaluated. More detailed studies, including techniques of molecular biology, are necessary to confirm the absence of effects of Cry1Ab and other Cry proteins on biodiversity in soil.

Uptake by Plants of Cry Proteins from Soil

When non-*Bt* corn, carrot, radish, and turnip were grown in nonsterile soil amended with Cry1Ab protein or biomass of *Bt* corn or in soil in which *Bt* corn had been grown, the toxin was not detected in any plants, whereas it was present in soil even after 180 days, the longest time evaluated.^[14,15] No Cry1Ab protein was detected in non-*Bt* corn grown aseptically in hydroponic culture in which *Bt* corn had been grown aseptically, whereas it was easily

Table 2 Summary of fate and effects of *Bt* toxins in root exudates and biomass of transgenic plants

- Biodegradation of biomass of transgenic *Bt* corn, measured by CO₂ evolution, was significantly lower than that of near-isogenic non-*Bt* corn.
- No consistent statistically significant differences in the numbers of culturable bacteria, fungi, and the activity of representative enzymes between soil amended with *Bt* or non-*Bt* corn or not amended.
- Reduced metabolic activity of soil amended with *Bt* corn may have been result of significantly higher lignin content in *Bt* than in non-*Bt* corn.
- Biodegradation of biomass of *Bt* rice, cotton, canola, tobacco, and potato was also significantly lower than that of biomass of near-isogenic non-*Bt* plants, but lignin content of these plant species, which was significantly lower than that of corn, was not significantly different in *Bt* and non-*Bt* biomass.
- CryIAb protein was released in root exudates of *Bt* corn (13 hybrids representing three transformation events) and persisted in rhizosphere soil *in vitro* and *in situ*; protein accumulated more in soil amended (3 to 12%) with montmorillonite than with kaolinite.
- CryIAb protein released in root exudates or from biomass of *Bt* corn appeared to have no effect on numbers of earthworms, nematodes, protozoa, bacteria, and fungi in soil.
- CryIAc protein was not released in root exudates of *Bt* canola, tobacco, or cotton. CryIAb protein was released in root exudates of rice, and Cry3A protein was released in root exudates of *Bt* potato.
- CryIAb protein released in root exudates and from biomass of *Bt* corn was not taken up from nonsterile soil or sterile hydroponic culture by non-*Bt* corn, carrot, radish, or turnip, even though the toxin persisted for at least 180 days in soil (the longest time studied).
- CryIAb protein—purified, in root exudates, and from biomass of *Bt* corn—moved through soil during leaching with water; movement was less in soils amended with montmorillonite than with kaolinite and decreased as the concentration of added clays increased.
- Toxins from *Bt* could persist, accumulate, and remain insecticidal in soil as the result of binding on clays and humic substances and, therefore, pose a hazard to nontarget organisms, enhance selection of toxin-resistant target species, or enhance control of insect pests.

detected in the solution. Hence, the apparent lack of uptake of toxin from soil was not the result of binding on surface-active particles, as no such particles were in the solution.

Movement of Cry Proteins in Soil

CryIAb protein added to the top of columns of soil was detected in leachates 1 and 3 hours after addition, with ca.

75% detected from soil not amended with clay and ca. 16% detected from soil amended to 12% with M or K; intermediate amounts were leached from soils amended to 3, 6, or 9% with the clays.^[16] Larvicidal activity was higher with leachates from soil not amended or amended to 3 or 6% than from soil amended to 9 or 12%. After 12 and 24 h, no protein was detected, indicating that it bound on the soils and desorption was reduced. Vertical distribution, in the columns, of protein not recovered in leachates confirmed that it moved less through soil amended with higher amounts of clay. Larvicidal activity of soil generally decreased with depth as clay concentration increased.

CryIAb protein was present in leachates from soil columns in which *Bt* corn hybrids of the three transformation events were grown, indicating some vertical movement from the rhizosphere. The protein was also present in leachates from soil amended three years earlier with *Bt* corn biomass, indicating that as the biomass degraded, toxin was released, and some bound on soil particles and some dissolved in and moved down with soil water.

Movement of CryIAb protein through soil was influenced by its tendency to stick on soil particles.^[4,5,7,10] The protein exhibited stronger binding and higher persistence in soils with higher clay concentrations—especially of M—and it remained near the soil surface, increasing the probability of it being transported to surface waters via erosion and runoff. In contrast, the protein was leached more through soils with lower clay concentrations, and may contaminate groundwater. Contamination of surface or groundwater, which depends greatly on the desorption of the protein and on the amount of water impacting soil as rain, irrigation, snow melts, etc., may pose a hazard to nontarget aquatic Lepidoptera, which are more plentiful in water than in soil.^[17] Without sufficient water, the protein will remain within the biologically-active root zone, where some protein, especially that not bound on particles, will be mineralized.

CONCLUSION

The interaction of larvicidal proteins with surface-active particles that differ greatly in composition and structure demonstrates the importance of such particles to the biology of natural habitats. These studies (summarized in Tables 1 and 2) also confirm and extend previous observations on the influence of surface-active particles on the activity, ecology, and population dynamics of microbes and viruses, as well as on the transfer of genetic information among bacteria in soil and other habitats.^[7,10,18]

Persistence of bound toxins from *Bt* could pose a hazard to nontarget organisms and result in selection of

toxin-resistant target insects and thereby negate benefits of using a biological insecticide. However, persistence of bound toxins could also enhance control of target pests, particularly soil-borne ones. These aspects require more study, especially a case-by-case evaluation of each toxin.

These studies also indicate that caution must be exercised before the release to the environment of transgenic plants and animals that are genetically modified to function as “factories” (“biopharms”) for production of vaccines, hormones, antibodies, blood substitutes, toxins, and other pharmaceuticals. As with *Bt* plants, biomass of these plant factories will be incorporated into soil. Feces, urine, and even carcasses containing bioactive compounds from transgenic animals will also reach soil and other habitats. If these compounds (including prions from contaminated animal carcasses) bind on clays and humic substances, they may persist, and if they retain their bioactivity, they may affect the biology of these habitats. Consequently, before extensive use of such plant and animal factories, their persistence and the potential effects of their products on inhabitants of soil and other habitats must be evaluated.

Late Blight

Francine Govers

Maita Latijnhouwers

Wageningen University, Wageningen, The Netherlands

INTRODUCTION

Late blight is a destructive disease found in nearly all areas of the world where potatoes are grown. Typical symptoms are water-soaked lesions on leaves that rapidly enlarge, resulting in dark, blighted areas and, eventually, in total destruction of the plant. Without chemical control and when cool and wet weather conditions prevail, late blight kills all plants in a field within 10–14 days. Extensive breeding efforts have failed to yield resistant cultivars satisfying the quality demanded by producers and consumers. The causal agent is *Phytophthora infestans*, a spore-producing, filamentous eukaryote classified as an oomycete. Oomycetes resemble fungi but have an independent evolutionary history. A recent worldwide displacement of the pathogen population caused a reemergence of late blight. Costs of losses and crop protection are estimated at US\$3.25 billion per annum worldwide, ranking late blight as the number one disease in potatoes.

THE PATHOGEN *P. INFESTANS*

The first reports of late blight epidemics date from the 1840s when the disease devastated the foliage and tubers of potatoes in nearly all of Europe and the northeastern United States, and set the stage for the disaster recorded in history as the Irish potato famine. Ireland, at that time dependent on potato as the chief staple, lost nearly half of its population; over a million Irish starved to death and many more emigrated. This epidemic occurred prior to the development of the germ theory and, as a result, it was not until 1867 that Anton de Bary first demonstrated conclusively that a water mold, which he named *P. infestans*, was the causal agent of the disease—hence the official name *P. infestans* (Mont.) de Bary.^[1,2]

More than a hundred years later, it became clear that *Phytophthora* is not a true fungus but instead belongs to a unique eukaryotic lineage, called oomycetes, that is evolutionarily unrelated to fungi. Features such as distinct cell wall compositions and metabolic pathways^[1,3] partly explain the differences in sensitivity between fungi and oomycetes to certain classes of fungicides, and justify the

introduction of the term “oomicides” as a generic name for drugs effective against oomycetes.^[4]

Phytophthora (Greek for “plant destroyer”) is undoubtedly the best-studied oomycete genus because it encompasses species causing severe diseases on economically important crops such as soybeans, cocoa, and potatoes, and on valuable tree species such as Californian oaks, Australian jarrah trees, and European alder trees. Over 60 *Phytophthora* species have been identified and, regularly, new species are discovered. The host range of *P. infestans* is limited to the Solanaceae, with potato (*Solanum tuberosum*) and tomato (*Lycopersicon esculentum*) as the most prominent hosts.^[1,5] However, many species have a broad host range and thousands of plant species can be infected by *Phytophthora*.

THE DISEASE CYCLE

At the start of the growing season, spores may be produced from diseased potato sprouts arising from infected tubers. Well-known sources from where inoculum can easily develop and spread are cull piles or dumps, volunteer plants, and seed tubers. In addition, sexual spores, called oospores, can act as an inoculum source, but this is limited to areas where the two mating types that are required for completion of the sexual life cycle are present. Oospores are dormant structures that can survive in soil for many years in the absence of a host. When oospore germination is triggered, the germ tube develops into a sporangium, which can easily enter the infection cycle (Fig. 1C).

The disease spreads optimally under cool, moist conditions. Asexual spores, called sporangia, are dispersed by wind or in water drops. Infection generally occurs in the foliage and, occasionally, on stems (Fig. 2A). When sporangia land on a host, they either germinate directly or undergo cytoplasmic cleavage to form seven to eight swimming zoospores. Zoospores are attracted to the host where they halt, retract their flagella, and secrete materials to form a cell wall. This process is referred to as encystment. A sporangium or cyst germinates and the germ tube tip differentiates into an appressorium—a spherical or elliptical structure from which a penetration

peg emerges to breach the plant cuticle and the cell wall (Fig. 2B). After having passed the epidermis, the hyphae grow mainly intercellularly and form haustorium-like feeding structures that protrude into mesophyll cells (Fig. 2C). This biotrophic phase is an essential step in the disease cycle. In later stages, the pathogen adopts a necrotrophic lifestyle: it kills plant cells and feeds on dead tissues. Once in this phase, sporangia are formed on branched hyphae called sporangiophores, which emerge from the stomata and cover the lesion surface. Leaf symptoms consist of water-soaked, dark lesions that expand rapidly, resulting in total destruction of the plant in a few days (Fig. 1A). Individual lesions can produce 100,000–300,000 sporangia/day. In favorable weather, the period from infection to sporangia formation may be as short as 4 days; therefore, many generations of asexual spores can be formed and dispersed in one growing season, leading to late blight epidemics.

Tubers may be infected whenever sporangia and tubers come into contact. Infections can occur in both developing and mature tubers. Sporangia are washed from lesions on stems and foliage to the soil, and then through the soil to the tubers. They can survive for days or weeks in soil; therefore, tubers can still become infected for a period of time after lesions on the foliage are no longer producing sporangia. At first, infected tubers show dark blotches. The invasion proceeds into the outer layers of the tuber tissue, and the affected areas become firm and dry and somewhat sunken (dry rot) (Fig. 1B). The rot continues to develop after the tubers are harvested. Infected tubers are especially susceptible to secondary infections by fungi and bacteria, resulting in soft rot. During storage, soft rot can spread to previously healthy tubers.

Sexual reproduction only occurs when a leaf or a stem is invaded by two *P. infestans* strains, each with a different mating type. *P. infestans* is an outcrossing heterothallic species with two known mating types, A1 and A2. When the mycelium of an opposite mating type grows in the vicinity, specific hormones are produced, which trigger the formation of oogonia (♀) and antheridia (♂) on the opposite mating type. Subsequently, the nuclei in the gametangia undergo meiosis and, via a fertilization tube, a male haploid nucleus is deposited in the oogonium, which then develops into a thick-walled oospore (Fig. 3A). The nuclei fuse during the maturation of the oospore. When blighted potato plants decompose, numerous oospores are released (Fig. 3B) and are able to overwinter in the soil.

POPULATION DISPLACEMENT AND REEMERGENCE OF LATE BLIGHT

Central Mexico is considered to be the origin of *P. infestans* and the region where *Solanum* and *P. infestans*

Fig. 1 Late blight symptoms on (A) a potato leaf and (B) tuber, and (C; facing page) the late blight disease cycle. (View this art in color at www.dekker.com.)

coevolved. Prior to 1980, the A1 mating type was distributed all over the world, whereas the A2 mating type was confined to Mexico. Mexican populations of the pathogen consist of many different genotypes and with a high variation in race structure. In contrast, one single genotype, designated US-1, populated the rest of the world, and all isolates seemed to belong to this clonal lineage. This situation changed in the 1980s when A2 mating type isolates were discovered in Europe. This was due to new migrations presumably initiated in 1976 by a large shipment of potatoes from Mexico to Europe. In the 1980s, these new and more diverse genotypes gradually migrated eastward to Eurasia and further to the Far East and Japan, resulting in a significant increase in the genetic variation and coexistence of the two mating types within populations. Sexual reproduction—and hence new recombinant types—may account for the observed increase in genetic variation and, indeed, occasionally oospores are detected in the field. Also in the United States and Canada, new genotypes that migrated from

C

Fig. 1 (Continued.) (View this art in color at www.dekker.com.)

Mexico replaced the US-1 genotype. However, only a few clonal lineages settled successfully, and the genetic variation is much less diverse than in Europe. Overall, the new genotypes of *P. infestans* seem more aggressive than old US-1 isolates and, as a result, the epidemics have become more severe.^[6]

LATE BLIGHT CONTROL

Integrated management practices are necessary to control late blight. Sanitary measures such as eliminating primary sources of inoculum, and cultural practices including early planting, can lower the chance of infections early in the growing season. In addition, continuous scouting for disease foci in potato fields is critical. In industrialized countries, regular spaying with agrochemicals is a common practice and keeps losses limited to about 15%.^[7] The basic strategy is to prevent the establishment of any infection within the crop. For this purpose, fungicides with three types of activity can be used: those with protectant (contact) activity on the surface of leaves, those with penetrant (locally systemic) activity, and

systemic fungicides. For the timing of applications, decision support systems (DSS) are used, giving recommendations based on the epidemiology of *P. infestans*, climatic conditions, infection pressure, and the costs and efficacy of crop protection measures.

A substantial contribution to late blight control would be the availability of resistant cultivars that also meet production and processing requirements. A continuing challenge for potato breeders is to combine resistance with commercial values in one potato cultivar. In the first half of the 20th century, late blight resistance derived from *Solanum demissum* and conferring resistance based on the gene-for-gene interaction were bred into *S. tuberosum*. Unfortunately, each of the 11 genes succumbed to attack by *P. infestans* within a few years, demonstrating the capacity of this pathogen to quickly circumvent recognition by its host. Breeding programs subsequently focused on quantitative resistance, often referred to as horizontal resistance, again without much success. In recent years, the idea that horizontal resistance and single gene resistance are truly distinct is being challenged, thus forcing a resetting of breeding strategies.^[8] Currently, a wide variety of wild *Solanum* species are being explored

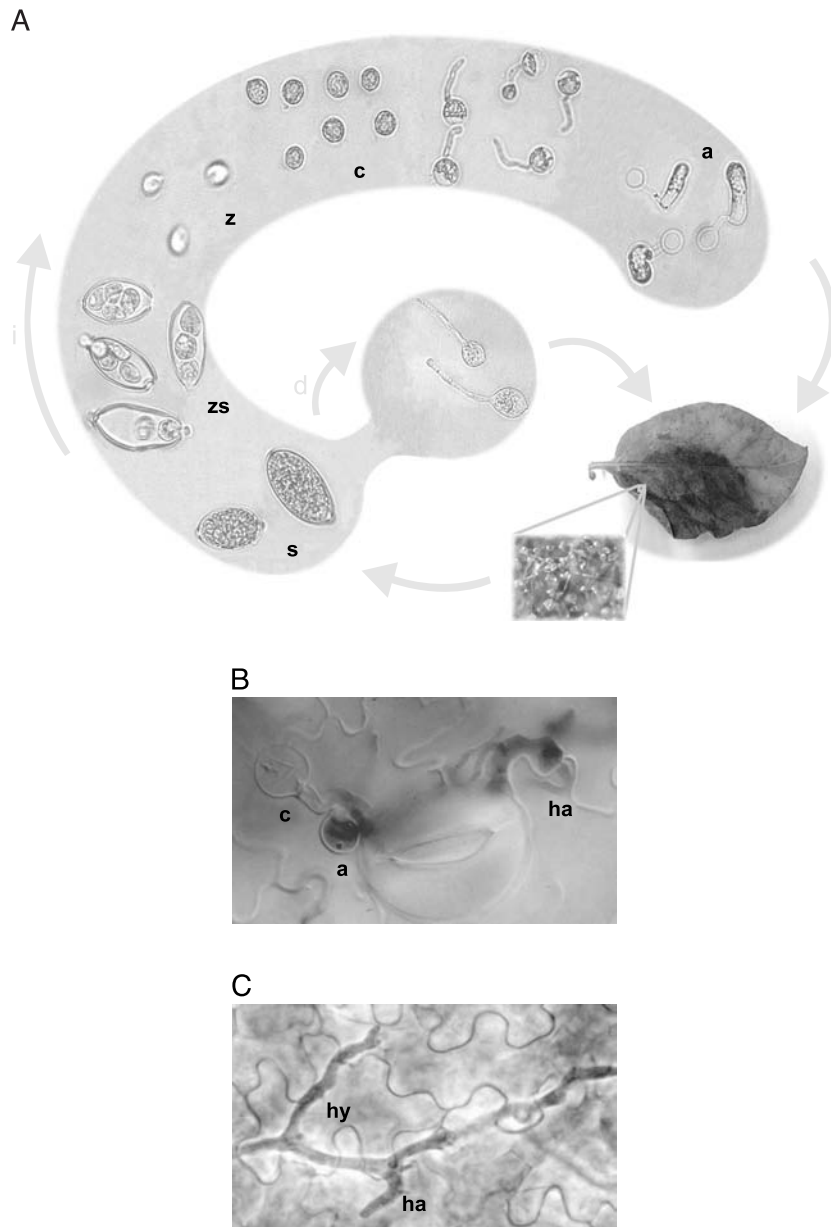

Fig. 2 Asexual reproduction. (A) Sporangioophores, emerging through the stomata from an infected leaf, produce numerous asexual spores named sporangia (s). At temperatures above 15°C, sporangia can germinate directly (d) by producing a germ tube whereas lower temperatures induce indirect (i) germination via zoosporangia (zs) that release zoospores (z). Once zoospores have reached the host, they retract their flagella and form a cell wall (encystment). Cysts (c) germinate and the tip of the cyst germ tube develops into an appressorium (a). (B) From the appressorium, a penetration peg emerges, which invades the epidermal cell (visualized at 22 hr after infection of a susceptible potato cultivar). (C) Hyphae (hy) continue to grow intracellularly, branch, and form haustoria (ha), which penetrate the mesophyll cells (31 hr after infection). (B and C are courtesy of V.G.A.A. Vleeshouwers, Wageningen University.) (View this art in color at www.dekker.com.)

for novel resistance genes, and there is a strong tendency toward *R* gene “pyramiding.” Recently, the first two late blight resistance genes were cloned. *R1* is derived from *S. demissum* and confers resistance to strains carrying the avirulence gene *Avr1*. The other gene *Rpi-*

blb is from *Solanum bulbocastanum* and is thought to confer resistance to a much broader range of strains.^[7] They both belong to the NBS-LRR class of resistance genes—a large super family effective against a wide variety of pathogens.^[9] Deploying resistance genes using

Fig. 3 Sexual reproduction. (A) Oospore with an empty antheridium surrounding the oogonial stalk. (B) Oospores in a late blight lesion on a potato leaf. Up to 6000 oospores/cm² can be formed in leaves from a susceptible potato cultivar. (View this art in color at www.dekker.com.)

a genetically modified organism (GMO) approach may bring us closer to the resistant potato cultivar with the desired characteristics.

CONCLUSION

Every strategy to develop a durable solution for the late blight problem, either by crop protection or via resistant cultivars, should consider the role of both the pathogen and the host. In recent years, large genomics resources

have been developed for potato^[7] and *P. infestans*,^[10] and the challenge for the near future is to explore and exploit these resources to unravel infection strategies of the pathogen and resistance mechanisms that can defeat the pathogen. This knowledge would help establish a more rational design of oomycetes and more strategic breeding programs. However, for the time being, growers will have to cope with this devastating pathogen.

Leaf Cuticle

Gwyn A. Beattie

Iowa State University, Ames, Iowa, U.S.A.

INTRODUCTION

The leaf cuticle is the waxy layer that covers the surface of leaves. Its main function is to protect the plant against water loss, and it is therefore critical to life in an aerial environment. It offers protection against environmental stresses as well as microbial pathogens and herbivorous insects, and contributes to the ability of many plant species to keep their leaves clean. These functions are related to the structure and composition of the cuticle, and particularly its main functional component, the cuticular and epicuticular waxes.

THE STRUCTURE AND FUNCTION OF LEAF CUTICLES

The thin continuous layer known as the cuticle is present on the epidermal cell surfaces of leaves, including on the trichomes and guard cells, as well as on the cells lining the substomatal cavities. This nearly impermeable membrane was likely a key development during the evolution of plants from aquatic to terrestrial habitats.^[1] Plant cuticles consist of a network of insoluble structural polymers, typically cutin, that is infused with a complex mixture of lipids, or cuticular waxes.^[2] These waxes are usually very long-chain fatty acids and their oxygenated derivatives, including alcohols, aldehydes, ketones, and esters. In contrast to cellular lipids, which are usually 15 to 18 carbons in length, cuticular waxes are usually much longer, often 20 to 40 carbons in length. Some of the waxes are extruded onto the surface of the cutin layer (Fig. 1). These epicuticular waxes form a relatively smooth layer on some plant surfaces, and on others they form crystals (Fig. 2). Epicuticular wax crystals vary greatly across plant species in their morphology and distribution.^[1,3]

A major function of the leaf cuticle is to serve as a diffusion barrier; it minimizes the loss of water and solutes while also limiting the inward movement of aqueous pollutants. The leaf cuticle can reflect light, particularly when crystalline epicuticular waxes are present, and this provides protection against both damaging UV radiation and light-driven temperature increases and their consequent reductions in transpiration, thus improving

water conservation.^[3] The presence of crystalline epicuticular waxes can confer water repellency. Water applied to the surface of water-repellent leaves forms droplets that roll off, and these droplets collect nonadhering contaminating particles such as dust and microbes, thus effectively cleaning the leaf surface.^[4] Water repellency is particularly common to the adaxial surfaces of many plant leaves, where it may help prevent the formation of water films over the stomata in humid environments. Low leaf wettability resulting from the hydrophobic waxes—particularly crystalline waxes—contributes to a small contact area between aqueous solutions and the leaf surface. This is likely of great importance to photosynthetic gas exchange and thus plant growth, to the ecology of the leaf-associated microflora (including the potential infectivity of pathogens), and to the retention and uptake of aqueous pollutants and agricultural sprays such as pesticides, herbicides, and plant growth regulators.^[3,5] Last, the leaf cuticle contributes to protection from herbivorous insects and phytopathogenic microbes by a variety of mechanisms.

FACTORS INFLUENCING LEAF CUTICLES

The quantity, composition, and structure of the cuticular waxes are specific to the plant species, the plant age, and even the adaxial versus abaxial leaf surface. For example, as leaves age, crystalline waxes appear to be degraded and this changes the surface characteristics and topography of the leaf. Environmental conditions that affect the waxes include light intensity, UV-B exposure, water stress and temperature.^[3] For example, plants grown under elevated light intensity or drought stress often produce more, or different, cuticular waxes than nonstressed plants. Wind can disrupt or remove the waxes by rubbing, flexing, or particle impaction, and also has been suggested to melt the waxes due to frictional heat. Rain can remove epicuticular waxes from the leaves (as illustrated by the presence of crystalline waxes in rain drops after they impact the leaf surface) and can alter wax composition by selectively removing certain classes of crystals. Air pollutants and acid rain can cause structural degradation of the waxes, stomatal occlusions, and shifts in wax composition, as has been well documented with conifer needles. In fact, wax

Fig. 1 Generalized structure of a leaf cuticle. The epicuticular waxes may be crystalline or amorphous. Additional cuticular waxes are infused in the cutin layer and are often impregnated in the upper epidermal cell wall.

degradation and compositional shifts have been used as bioindicators of air pollution in forests.^[3]

LEAF CUTICLES AS PLAYING FIELDS FOR INSECT HERBIVORES AND THEIR PREDATORS

Leaf–insect interactions are dominated by the cuticle as an obstacle to insect attachment and movement.^[6] Cuticular waxes interfere with attachment and movement of insects primarily by exfoliation of the wax crystals. In fact, carnivorous pitcher plants have capitalized on wax exfoliation. (The pitcher plant captures insects by producing wax plates that are readily released upon contact by an insect.) This exfoliation can deter insect herbivores, thus providing defense against herbivory, but may also deter the predators of these herbivores. Among the many diverse surfaces that support insects, leaves with crystalline waxes are unusual in the effectiveness with which they prevent insect adherence.

The chemical and physical properties of leaf cuticles influence host plant selection by herbivorous insects.^[6]

For example, the crystalline waxes can dictate the appearance of leaves, often giving them a whitish color, which affects their attractiveness to some herbivorous insects. Similarly, specific waxes can influence the acceptance or rejection of a potential plant host for feeding or for the deposition of eggs, which often requires selection of a host that is suitable for larval development. Insect behavior may be affected by the ability of cuticular waxes to serve as solvents for insect pheromones or other volatile compounds from the environment; however, this area has been relatively understudied considering its potential ecological significance.

INTERACTIONS BETWEEN LEAF CUTICLES AND THE LEAF MICROFLORA

The leaf cuticle influences the immigration of waterborne and airborne microbes by affecting water repellency and the formation of a still-air boundary layer surrounding the leaf. The cuticle also affects the attachment of some bacteria, yeasts, and fungi to leaves, as illustrated by the finding that leaf surface hydrophobicity

Fig. 2 Epicuticular crystalline waxes on the surface of maize (*Zea mays*) leaves under (A) low (500X) and (B) high (2000X) magnification.

promotes attachment by many fungal spores. Similarly, although not well characterized, the cuticle can influence the size of the resident bacterial and yeast populations, an influence that may be mediated, to a large degree, by leaf cuticle–water relations.^[5] A few recent studies suggest that bacteria may have mechanisms for penetrating plant cuticles;^[5] however, bacteria are generally regarded as unable to penetrate intact cuticles. This is supported by the finding that bacterial production of known cuticle-degrading enzymes—namely cutinases—is a rare trait, and by knowledge that phytopathogenic bacteria invade leaves via natural openings, wounds, and insect damage, but not via direct penetration. In contrast, phytopathogenic fungi have evolved multiple mechanisms for penetrating plant cuticles, and clearly respond to distinct cuticle-dependent signals.^[7] Spores and germlings of phytopathogenic fungi are often associated with visible erosion of the cuticle, which likely results from enzymatic degradation. Cutin-degrading enzymes have been characterized in many fungal species, although wax-degrading enzymes have not been identified. Some fungal species penetrate leaves without producing highly developed infection structures, whereas others produce appressoria (structures that aid penetration). These structures often employ turgor pressure as a mechanism of force. Simple contact with a surface—particularly a hydrophobic surface—induces appressorium formation as well as adhesion and germination in some fungi. For example, upon contact with the leaf cuticle, *Erysiphe graminis* secretes a liquid that aids adherence and creates a localized hydrophilic region, presumably by degrading cutin, and the resulting hydrophilicity stimulates germination. Similar to their effect on insects, specific cuticular waxes can act as stimulants or deterrents of specific fungal behaviors, including germination and appressorium formation.

CONCLUSION

Current research interests in leaf cuticles—particularly in cuticular waxes—include their diversity and biosynthesis; their role in plant evolution and development; their role in plant responses to insects and microbes, as discussed here, as well as to drought, freezing temperatures, solar radiation, and air pollution; their role in the retention and penetration of agricultural sprays; their use as industrial plant waxes; their use in breeding of ornamental and agronomic plants with improved performance; and their contribution to atmosphere aerosols.^[8] Mutants that are altered in loci involved in the biosynthesis, secretion, and regulation of cuticular wax production have been identified for several plant species. The cloning and characterization of these and other loci involved in cuticle synthesis

and regulation, along with current tools in plant molecular biology, should benefit these research areas by increasing our fundamental understanding of cuticle formation and regulation and by providing information useful for cuticle modification, such as for crop improvement.

Leaf Structure

Vincent P. Gutschick

Lou Ellen Kay

New Mexico State University, Las Cruces, New Mexico, U.S.A.

INTRODUCTION

Leaves are constructed mechanically and biochemically primarily for their function in photosynthesis. They must be constructed at low metabolic cost and protect themselves against mechanical stresses, climatic extremes, excess light, and damage by herbivores and pathogens. Concurrently, they must balance water use efficiently. Some leaves are specialized for additional functions such as support of the whole plant or storage. The leaf surface, parenchyma, and vascular system show unique contributions to each of these functions. The overall size and shape of leaves are also relevant for construction cost, energy transfer, light interception, and mechanical properties. The development of each leaf and its functions, from inception to death, is subject to a number of controls. These respond to the environment (nutrition, water and solute status, etc.) in ways that are often manifestly adaptive. Leaf traits exist in very diverse combinations in response to natural selection on the net benefit of a leaf in all its functions. Artificial selection imposes different weightings of traits; the optimal combinations in agriculture are in some cases quite divergent from wild types, as in leaf area per mass and geometry of leaf display.

PERFORMING PHOTOSYNTHESIS

The primary function of a leaf is photosynthesis. Leaves are typically thin, providing maximum surface area for light interception at the lowest cost in metabolites and nutrients. Nonetheless, leaves are diverse in thickness, size, shape, reflectivity and other optical properties, and presence of trichomes. The diversity reflects demands to 1) use all resources—not just light—efficiently (particularly water and nitrogen and sometimes other nutrients), and not just for photosynthesis but also for defense;^[1] and 2) avoid damage, both biotic (from herbivores, fungi, etc.) and abiotic (from wind, extreme temperatures, ultraviolet radiation, acute shortage of water, etc.).

STRUCTURE OF THE LEAF

The leaf surface is covered by a cuticle (Fig. 1). This hydrophobic layer limits losses of water and ions, offers the first defense against pathogens, and conditions the optical properties of the leaf. When thick and scalelike, it reduces light interception as a protection against photo-inhibition and thermal loading. The outermost layer of cells is the epidermis. This layer provides some structural strength and significant ultraviolet screening via absorptive chemicals. A small percentage of epidermal cells is specialized as guard cells, forming the stomata that regulate the exchange of gases, primarily CO₂ and water vapor but also leaf volatiles such as terpenes and a portion of the O₂. Other specialized cells (trichomes) may be present, presenting long hairs that have many functions—defense, radiative balance, control of surface wetting, etc.

The largest volume of cells is parenchyma cells specialized for photosynthesis. Palisade cells are columnar and strongly photosynthetic. Spongy mesophyll cells are also photosynthetic, while offering air passages for gas exchange. Complete photosynthesis (both the capture of light to produce reductant and carbon fixation) is present in all these cells in most plants. In plants with the C₄ pathway, the parenchyma cells other than the bundle sheath capture CO₂ in a transportable form (such as malate) and generate reductant. Final sugar generation occurs inside the bundle sheath, which is poorly gas-permeable, allowing high partial pressures of CO₂ to build up.

Photosynthetic cells typically have thin cell walls for high conductivity to dissolved gases. Stress-tolerant plants—the sclerophylls—toughen their leaves with secondary cell wall growth, plus dense packing; consequently, they have low photosynthetic rates. Other structural features of the leaf interior include sclereids (as in sclerophylls) and, in grasses, silica bodies (whose evolution may even have caused some herbivore extinction^[2]). Some leaves contain laticifers, fused cells that transport quantities of insect-detering latex.

Veins are a major leaf structure. The xylem imports water, of which usually more than 99% is used over the life of the plant for transpiration as opposed to for new

Fig. 1 Transverse section through the leaf of oleander (*Nerium oleander*), a xerophyte with thick cuticle, multilayered epidermis, and recessed stomata. (From *Biology of Plants*, 6th Ed., P. H. Raven et al.; 1999; W. H. Freeman; New York; used with permission.)

growth. The xylem also imports some nutrients. It may be strongly lignified; this condition, plus the vascular geometry as branched cylinders, is the dominant contribution to biomechanical integrity. Leaves must be strong (resisting high forces of gravitational loads, winds, and herbivore action), stiff (resisting bending, to maintain light capture), tough (requiring much work to break them), and resistant to crack propagation.^[3] Phloem is the other major vascular component. It transports photosynthesized sugars out of mature leaves. It also transports hormones, some photosynthetically reduced nutrients (N and S compounds), and nutrients that recycle as signals to regulate root activity. The phloem possesses some parenchyma cells, some fibers, and sclereids as lesser contributors to structure and defense. The vascular bundles of xylem and phloem occur commonly in nets or, in monocots and ginkgos, as parallel strands. The pattern is in part adaptive (e.g., grasses withstand grazing by regrowth from the base, easiest biomechanically with parallel veins) and is in part an evolutionary constraint. In C_4 plants, mesophyll and bundle-sheath cells cluster tightly around xylem and phloem in the Kranz anatomy, which enables concentration of CO_2 for efficient photosynthesis.

A number of variations occur in internal structure. Thick mesophyll of high water content stores water in succulent species. In those species performing CAM photosynthesis, this also serves as inexpensive, copious storage for malate, reducing the limit on growth rate.

LEAF MORPHOLOGY

The leaf proper commonly has a petiole, supporting it away from the stem and other leaves. The petiole, although minimally photosynthetic has a significant fraction of total leaf mass; minimization of this mass is often important in carbon gain per mass and growth rate.

Overall shapes of leaves and their arrangement on the stem are usually diagnostic of a species or an ecotype; occasionally the shape is plastic, as in safflower (lobing) and aquatic plants (long, thin water leaves contrast with aerial leaves). Leaf types divide fundamentally into simple and compound (Fig. 2). Compound leaves appear to cost less energy to construct but are less durable.^[4] Other geometric features include entirety (no reentrant curves) vs. dissection into discrete lobes. Dissection increases the boundary layer conductance for gases and heat;^[5] dissected leaves remain closer to air temperature than do entire leaves. Another marked division is between flat leaves and the needle-shaped leaves of conifers (most rushes and sedges have tiny leaves but photosynthetic stems). Needle leaves have low photosynthetic area per unit mass but possess strength and damage-resistance.

Leaf size also varies among species, and is more plastic than is geometric shape within a species. Thick leaves have low area per mass (i.e., per specific leaf area). All else being equal, thickness confers high photosynthetic capacity per area but correlates with smaller leaf area. The

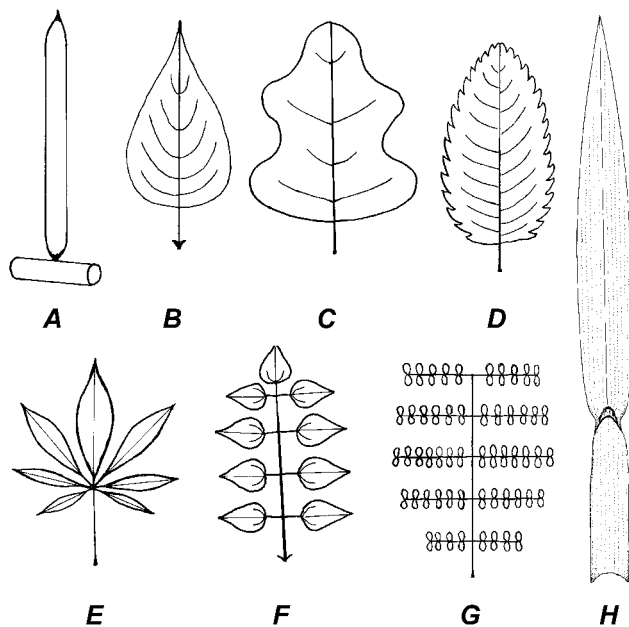

Fig. 2 A selection of leaf shapes and their terminology: (A) needle leaf; (B) entire leaf (ovate shape); (C) lobed leaf; (D) dissected leaf; (E) palmately compound leaf with many leaflets; (F) pinnately compound leaf; (G) doubly (bipinnately) compound leaf; (H) grass leaf (a residual meristem at the base of the blade (at the narrow point in drawing) supports continuing leaf growth). (Artwork by L. E. Kay.)

net effect on photosynthesis per mass—the most important correlate of relative growth rate—is nearly neutral.^[6] Thinness, however, is correlated with higher N content that raises photosynthesis per unit mass, and offers greater shading of competitors. The lower structural content makes such leaves more damage-prone; they are typically short-lived and never evergreen. Leaves of an individual plant can acclimate in thickness. Leaves receiving more sunlight develop higher photosynthetic capacity, commonly from larger cells and more layers. Higher photosynthetic capacity relative to stomatal conductance can also confer higher water-use efficiency by virtue of a lower operating point in leaf-internal CO_2 .

CONTROLS OVER DEVELOPMENT AND DEATH

Leaves vary widely in development rate and lifespan. Initiation has numerous controls, both intrinsic and environmental. Leaf expansion (initiation time and duration) is paced to thermal time in degree-days, which has been shown to have a molecular basis in cyclin proteins.^[7] Cell division and cell enlargement are restricted to rather

fixed intervals; adverse conditions during early expansion (low light, dryness of air or soil) permanently eliminate some growth potential, which shows up later as smaller leaves.^[7] Leaf thickness and attendant photosynthetic capacity responds as well to temperature and irradiance during expansion. Patterns are apparently adaptive, as in making leaves of greater protein content at low temperature, largely compensating for lower activity per unit mass of protein.

Leaves lose function gradually from causes such as UV damage and abruptly from causes such as salt accumulation.^[8] Ultimately, even in the absence of lethal insults such as pathogens or frost, a leaf's death is programmed by internal and environmental signals (e.g., by the photoperiod as a reliable signal of the end of frost-free or drought-free days). Leaves thus can be evergreen or deciduous in response to drought or photoperiod. Leaf death is an orderly process. An abscission zone forms at the base, and typically half of the nutrients are scavenged, to be stored or used in newer leaves. Limits to the fraction scavenged are set by the need to maintain export functions.

ADDITIONAL MODES OF STRESS PROTECTION AND SPECIALIZATION

Leaves withstand wind stresses by drag reduction as well as by simple strength and toughness. The lamina must bend and fold properly, requiring specialized shapes.^[3] Excess light or heat loading induces in selected species (e.g., grasses, legumes) alterations of leaf shape (e.g., rolling) and gross orientation (heliotropism). These changes complement the protection offered by reflective cuticles and pubescence. Tolerance of trampling in grasses is conferred in part by flexible and readily repaired vasculature. Leaves have other structures ancillary to photosynthesis but important nonetheless. These include salt glands for ion balance, trichomes, or hairs for physical and chemical defense.

Pathogens are deterred by many defenses, including cuticular integrity, chemical composition, and stomatal design. Drip tips in the wet tropics reduce wetness duration and thus fungal challenges. Herbivory by insects and vertebrates is deterred chemically and structurally, as noted earlier. Leaves of sclerophylls are tough and thick primarily for such defense during their long lifetimes; inelasticity is no particular advantage for handling turgor pressure changes in water stress.

Some leaves are modified for functions remote from photosynthesis. Some tendrils—which provide support for the whole plant—are modified leaves, as in the garden pea. Bulbs incorporate thick leaves modified for food storage; the petioles of celery function similarly. Leaves

may be modified into spines for protection. Leaves may trap and digest insects, as in pitcher plants, sundews, and flytraps. These modifications are almost always an adaptation to low nutrient availability in soil.

TRAIT SELECTION AND THE NET VALUE OF A LEAF

What do these diverse leaf designs achieve under the diversity of growing conditions? One can estimate costs of constructing and maintaining a leaf in operation,^[6,9] as well as current and lifelong-integrated benefits. A sine qua non for survival—much less for productivity—is that a leaf must pay back its own construction costs in photosynthate. This constrains the design lifetime, the nutrient content, and other features. Leaves must also be efficient in using scarce resources such as N and water. Conifers and sclerophylls appear to be selected for this. A conifer may have a low photosynthetic rate (1/4 that of a forb), but may maintain this rate over longer times (threefold) with less N (half as much). The conifer's N-use efficiency is $(3/4)/(1/2) = 1.5$ -fold greater than the forb's.

A great many traits—structural, biochemical, and phenological—are thus under selection. Crop plants retain many traits and trait combinations selected under pre-domestication natural conditions. Artificial selection goals now conflict with fitness criteria of old; this conflict is important to understand in breeding improved crops.^[6] An example is breeding for plants with erect leaves that share light interception well with other plants of the same stand; this design consciously forgoes competitor shading. In this task, it is well to consider that selection is diluted among many traits,^[10] such that many tradeoffs in structure (as in specific leaf area) currently operate near neutrality; performance is nearly insensitive to variations near the current mean. Extreme events may be most important in selection. These are rarely monitored or quantified in importance in current breeding or crop ecology.

Leaf Surface Sugars

Johan H. J. Leveau

Netherlands Institute of Ecology (NIOO-KNAW), Heteren, The Netherlands

INTRODUCTION

Plant leaves attract a wide variety of organisms. For most of them, the appeal lies in the fact that the leaf is the primary site of photosynthesis, and thus represents an abundant source of carbohydrates such as glucose, fructose, and sucrose, as well as oligosaccharides (e.g., raffinose, stachyose, and verbascose) and sugar alcohols (e.g., mannitol and sorbitol). The waxy cuticle that covers the leaf effectively confines these compounds to the leaf's interior, but it cannot entirely prevent small amounts from finding their way to the outside. Furthermore, it offers only minimal protection against the attacks of herbivorous insects, by which substantial amounts of leaf sap can reach the leaf surface. Some plants actually invite the visitation of insects and other organisms by the release of highly localized puddles of sugar on their leaf surfaces. In this regard, the leaf surface, or phyllosphere, functions as an interface where sugars serve different purposes to the plant and to its visitors.

The first part of this article lists the shapes and abundances in which sugars can be found on the surfaces of plant leaves. In the second part, the fates and relevance of leaf surface sugars are discussed.

SOURCES OF LEAF SURFACE SUGARS

Leachates

Leaching is defined as the process by which organic and inorganic metabolites are lost from above-ground plant parts by leakage from the leaf interior. It is considered a passive and reversible process that is driven by the difference in metabolite concentrations across the leaf cuticle, i.e., between the inside of the leaf and the leaf surface. When there is water present on the leaf, for example, as drops of rain or dew, leaching to the surface is greatly stimulated, probably because the water acts as an effective sink for the leachates.

The most common method for assessing the occurrence and abundance of leachates is by repetitious rinsing of the leaf surface, usually with water. Such leaf washings contain an impressive collection of inorganic and organic substances.^[1] The bulk of leachates consist of sugars, with

fructose, sucrose, and glucose being most predominant. Usually, leachates are not found in very great abundance. For example, only about 2.5 µg of fructose, glucose, and sucrose can be washed off a greenhouse-grown bean plant leaf.^[2] A leaf like this contains between 1 and 5 mg sugars on the inside, so that losses due to leaching account for only 0.05 to 0.25%. While such amounts may appear small on a per-leaf basis, they are quite impressive on a larger scale. One report details the loss of 800 pounds of carbohydrates per year per acre from an apple tree orchard as a result of leaching.^[1]

There are numerous factors that influence the rate by which sugars are leached to the leaf surface; Tukey provides a comprehensive list.^[1] One is the wettability of the leaf, which is often directly related to its waxiness. Leaves of pea, orange, and sugar beet are wetted with more difficulty than those of bean, squash, banana, cacao, and coffee, and hence are less susceptible to leaching. Leaf surface structures such as hairs and veins can hold water by capillary action and may in that way enhance leaching. Other important factors are the time, intensity, and amount of rain, mist, or dew that a plant is exposed to. In rainwater, for example, sugar concentrations have been measured in the range of tens of milligrams per liter, whereas in dew, which is more stagnant, they were 10 times higher. A continuous light drizzle increases leaching more than the same amount of water in a short, heavy rain. This may be explained partly by the increased runoff from leaves during heavy rain.

Extrafloral Nectaries

Extrafloral nectaries are secretory glands on leaves and stems of plants. They produce a liquid with nectarlike qualities, and they have been found on plants from over 1000 species. An extrafloral nectary can appear nonstructural, as a modified stipule, or as modified trichomes on the margins or surfaces of a leaf. Extrafloral nectaries secrete the sugars glucose, fructose, and sucrose, along with smaller amounts of protein and inorganics. The source of the sugars is the phloem, which often—but not always—ends near the nectary. Extrafloral nectar tends to be sweeter than phloem sap, in part because it is exposed to the air, and therefore more prone to evaporation. Extrafloral nectaries of broad bean (*Vicia faba*) secrete a nectar that can contain

several hundreds of micrograms of sugar per μl . Leaves of the castor bean (*Ricinus communis*) produce an average of about 2 microliters of nectar per day, consisting of 75% sugars (sucrose, glucose, and fructose).

Guttation Fluid

Guttation is caused when the transpiration from a leaf is so low that the hydrostatic pressure in the xylem is able to force apoplastic fluid out to the leaf surface. This occurs in the early morning or late evening when humidity is high, temperature is low, and soil moisture is abundant. Guttation fluid follows the path of least resistance, and usually comes out of modified stomata called hydathodes. Depending on the plant species, hydathodes are located at the tips or margins of leaves, or on the leaf surface. Guttation fluids contain relatively low concentrations of sugar, usually anywhere from less than 1 μg per liter up to nearly 40 μg per liter. Guttation fluids from rye, wheat, and barley seedlings contain mostly glucose and galactose. A secondary effect of guttation fluids is leaf injury caused by an accumulation of salts when guttation droplets on the leaf surface evaporate.

Manna

Manna is a sugary substance that is excreted from leaves and stems of certain trees and eucalypts (*Eucalyptus* and *Angophora* species). It exudes after injury from incisions or from feeding by insects such as the gum tree bug (*Amorbus obscuricornus*). The exudate crystallizes and forms white beads that oftentimes fall to the ground. Manna generally consists of 60% sugars, most of which is raffinose, a trisaccharide of fructose, glucose, and galactose, with smaller amounts of other sugars such as melibiose (a disaccharide of glucose and galactose), sucrose, glucose, fructose, and stachyose (a tetrasaccharide of fructose, glucose, and two units of galactose). A major component of the manna from the ash tree (*Fraxinus ornus*) is the sugar alcohol mannitol, also called mannite or manna sugar. Manna may resemble phloem sap in sugar composition, but the proportional abundances of individual sugars can be markedly different, which in part may be due to the presence of sugar-specific enzymes such as sucrases and oxidases in the saliva of the feeding insect. Manna is oftentimes confused with other insect-mediated sources of leaf surface sugar. For instance, one hypothesis for the biblical reference to manna points to honeydew (see below).

Honeydew

Honeydew is the sugary excretion of nymphal stages of aphids, coccids, and insects belonging to the family

Psyllidae (plant lice). These phloem feeders insert their stylets into the plant leaf and take advantage of the positive pressure of the phloem for the collection of leaf sap. Because phloem is high in sugars but low in nitrogen, the insect must ingest large amounts of phloem to meet its nitrogen demands. The excess phloem sugars pass through the gut of the insect and are excreted as waste. This honeydew is ejected with force from the end of the insect's abdomen, which prevents the insects from sticking to one another and to the leaf surface. Honeydew contains about one-third sugars, most of which are small polysaccharides with additional glucose, fructose, and sucrose. Other sugars such as melezitose, erlose, raffinose, and trehalose have been found in the honeydew of some sapfeeders. These sugars are synthesized from plant-derived sugars during passage through the insect gut, and they are thought to help the sapfeeder keep its osmotic balance while feeding.

Lerp

Lerp is a waxy material secreted as a protective scale by psyllids such as the lerp psyllid (*Glycaspis brimblecombei*). A lerp (the Australian Aborigine word for house) is a small conical structure under which the larva feeds and grows to adulthood. It is made by the larva itself from excreted honeydew, and is composed for 90% of glucose polymers.

Pollen and Fungal Spores

Pollen consists of up to 10% carbohydrates (dry weight), including starch and soluble sugars (fructose, glucose, sucrose). It is also a good source of protein and lipids. The diameter of a pollen grain is about 15–50 μm , which makes it highly motile in the wind. High concentrations of up to thousands of grains per square centimeter can easily be found deposited on leaf surfaces. The pollen can also be readily washed from leaves again, for example, by rain. Wind and rain also help disperse fungal spores that can be covered with a gelatinous coat containing considerable amounts of sugar.

FATES AND RELEVANCE OF LEAF SURFACE SUGARS

Food

Many organisms rely on plant leaf sugars for nutrition. For some, it is their main source of carbohydrates; for others, an occasional delicacy. Native Americans reportedly collected honeydew and ate it as candy. In Turkey, Iran, and Iraq honeydew is harvested from branches

infested by aphids by shaking or beating the honeydew off. It is then dissolved in water, strained, mixed with eggs, almonds and spices, and sold as a popular sweet. Aboriginal Australians ate lerp as a staple food, and they prepared manna from the leaves of the eucalyptus tree.

Manna, honeydew, and lerp are also common food sources for a variety of bird species.^[3] Their high carbohydrate content makes them very attractive sources of energy. Many of these birds have to supplement this diet by feeding on insects to meet their protein requirements. Many species of ants are readily attracted to the sugar in extrafloral nectaries, honeydew, and manna as sources of carbohydrates.^[4,5] Forest- or leaf-honey is produced by bees from the honeydew of certain aphids and various other insects.

Microbes that visit or inhabit leaf surfaces have quantity requirements for sugars that are very different from those of humans, birds, or insects. For example, while a human may crave 300 grams of carbohydrates per day just for maintenance, a bacterium is able to replicate itself with 10^{15} times less, or a mere 0.3 picograms of glucose.^[6] Obviously then, the tiny amounts of sugars that are found in leachates and guttation fluids are most relevant to such bacteria because they are sufficient to allow the generation of a substantial population size on plant leaves. For example, 3 micrograms of leached sugar could and often does produce 10 million bacterial cells on a single bean leaf under environmentally favorable conditions.

For many bacteria that have made the plant leaf surface their preferred habitat, sugars appear to be the limiting factor for growth. Not unexpectedly, many of these bacteria have adopted ways to gain access to more of the sweet stuff. One is the ability to lower the surface tension of water, thereby, for example, making rain drops on the leaf surface flatter so that the efficiency of leaching is increased as a result of the larger surface area.^[7] Another bacterial adaptation is the ability to synthesize the plant hormone auxin, which is thought to trick the plant into the release of nutrients, including sugars. Because sugars are often a limiting factor in bacterial growth, they can evoke fierce competition.^[8] Such competition is the basis for many of the strategies for the biological control of microbial plant pests.

Redistribution and Removal of Sugars from the Leaf Surface

Water that moves freely across the leaf surface is able to redistribute sugars and wash them off the leaf surface. These washed-off nutrients can land on lower leaves, where they can be taken up again by the plant, or on the ground below, where they can be used by the root system or other organisms. Such leachates may contain consid-

erable amounts of nutrients; in one experiment, bean plants were grown through one complete generation on the leachates from squash leaves.^[1]

Carriers of Information

Some organisms rely on leaf surface sugars as carriers of information during their interaction with the plant and with other organisms. For example, when choosing a spot to lay her eggs, a female of the european corn borer butterfly (*Ostrinia nubilalis*) relies on the surface sugars fructose, sucrose, and glucose to assess the carbohydrate content of the leaf.^[9] Extrafloral nectaries attract ants, which in turn protect the plant by removing herbivorous insects. Parasitic wasps and flies use these extrafloral nectaries as meeting places for mates. Some plants have ways to control the amount, composition, and viscosity of this nectar and are so able to selectively attract or deter protectors or herbivores. The mutualistic interaction between aphids and ants is based on the attraction of ants to the honeydew.^[4] For the aphid, removal of the sugary compound prevents itself and the leaf surface from becoming too sticky. Aphids also can choose their mutualists and antagonists by making the honeydew selectively attractive through the synthesis of honeydew-specific sugars, such as melezitose or erlose.

CONCLUSION

Because of its exposed character, the leaf is subject to many physical, chemical and biological influences that greatly affect the form and quantities of sugars found on its surface. This makes the leaf a highly dynamic and heterogeneous environment, for which the ecological role of sugars and changes in their abundance is not always easy to interpret or predict. This holds true in particular for microbial visitors to the leaf surface. For the most part this is due to the wholly different scale at which these microbes experience the leaf surface and its sugars. Because their carbohydrate requirements are so small, even small changes in sugar availability can have tremendous consequences. Furthermore, spatial variation in sugar availability is much more pronounced on the micrometer scale at which these microbes live. Only recently a successful attempt was made to follow the sugar consumption of individual bacteria in the phyllosphere.^[6] From this study and more to come, an understanding will emerge that will enhance our appreciation for the role of sugars in microbial colonization of the leaf surface, and which could well help to improve current methods for biological control of plant pests.^[10]

Leaves and Canopies: Physical Environment

George W. Sundin

Michigan State University, East Lansing, Michigan, U.S.A.

Cindy E. Morris

Institut National de la Recherche Agronomique, Montfavet, France

INTRODUCTION

The phyllosphere supports the growth of a diverse flora of bacteria and fungi; however, as a habitat for microbes, the phyllosphere presents a stressful environment that is strongly influenced by physical factors. Phyllosphere microbial residents grow through the utilization of the limited resources available in this habitat; survival is also predicated upon the ability of organisms to cope with the varied environmental stress conditions including fluctuating water availability, heat, osmotic stress, and exposure to solar UV radiation (UVR).

PHYSICAL NATURE OF THE LEAF SURFACE

Leaves are surrounded by a boundary layer of air that can influence temperature, relative humidity, and concentrations of gases and volatile metabolites relative to that of the ambient air. Within the leaf boundary layer, temperature can be as much as 4–7° different (generally greater) from that of the air^[1] and RH as much as 20% above ambient conditions.^[2] Humidity effects, especially the increased RH within thick closed canopies, tend to favor the epidemic development of some plant pathogens. Modification of the canopy environment of a crop, if possible, can affect disease incidence. For example, closed-canopy cultivars of bean are more susceptible to white mold than open-canopy cultivars.^[3] The epidermal cells of leaves are covered by a cuticle. Cuticles are significant barriers to the diffusion of water-soluble compounds from the leaf apoplast toward the surface of the leaf and thereby probably foster oligotrophic conditions on leaf surfaces. Cuticles also influence the hydrophobicity of leaves, the reflectance of light, and leaf cooling. Leaf surfaces have topographical features such as leaf hairs, glandular trichomes, stomata, junctions of epidermal cells, hydathodes, and grooves over leaf veins, some of which are associated with thinner cuticles and boundary layers or may facilitate local accumulation of water. Terrestrial plants experience incessant fluctuations in the quantity of free water present on their leaves. Condensation and

impaction of water droplets on leaf surfaces alternate with evaporation and runoff of water in cycles that are generally diurnal. The ebb and flow of free water in the phyllosphere lead to variations in local pH, as substances such as ammonia, sulfur dioxide, and calcium carbonate that may be present on leaf surfaces are dissolved, and also lead to variation in local concentrations of leaf surface nutrients.^[4]

Rapid fluctuations in the physical environment of the phyllosphere are normal; those parameters of most importance to microbes include ultraviolet radiation (UVR), water and nutrient availability, temperature, and osmotic stress. The geography of leaf surfaces and the physiology of leaves of different ages co-occurring on the same plant also influence microbial growth in the phyllosphere habitat. The ecological view of leaves as islands and of each leaf as an individual habitat is instructive with particular reference to plant pathogen interactions and the potential for biological control.

SOLAR ULTRAVIOLET RADIATION

Leaf size, angle, and the density of plant canopies can markedly reduce UVR penetration to lower leaves; conversely, the relative humidity and free surface moisture within lower areas of dense canopies is typically maintained at higher levels. The abaxial (upper) surface of completely exposed leaves is one of the most light-intense of the terrestrial microbial habitats. Several reports have shown that microbial populations tend to be larger on adaxial surfaces,^[5] although some fungal species can survive equally well on abaxial surfaces.^[6] UVR filtering by leaves higher in the canopy can modulate microbial populations on lower leaves. The UVR-sensitive fungal plant pathogen *Exobasidium vexans* colonizes and incites disease symptoms on lower leaves of its tea host, and the fungus is otherwise highly sensitive to solar UVB radiation.^[7] Solar UVR affects microbial populations on a daily basis,^[8] however, long-term seasonal effects, although evident,^[9] are more difficult to discern because of the confounding effects of temperature and desiccation.

PLANT CANOPY EFFECTS

Plant canopies affect plant disease epidemiology, particularly in the rain-splash dispersal of fungal spores. Understanding the physics of rain splash and impacting droplets has been important to modeling studies of spore dislodging and movement.^[10] Drop size plays a major role in the overall splash process.^[11] Canopy effects include secondary movement of raindrops; “drip” drops, or secondary drops falling from leaves, travel at reduced speeds and play a reduced role in spore dispersal. Thus, thicker canopies tend to reduce spore dispersal possibly due to decrease in spore removal by drip drops or because fewer raindrops reach impaction sites, and by direct interception of spore-carrying droplets by intervening plant surfaces prior to spore “escape.”^[12] However, it should be noted that thicker canopies can have a positive effect on spore germination by lengthening the duration of leaf wetness. The momentum of rain is important in stimulating the growth of the plant-pathogenic bacterium *Pseudomonas syringae* in the bean phyllosphere.^[13] Although the effect of plant canopy or canopy position is not known for this example, it is intriguing that the ecology of both plant pathogenic bacteria and fungi can be strongly influenced by rain, the effect of which is markedly conditioned by the canopy micro- and macroenvironment.

Leaves are also exposed to exogenous compounds that may be deleterious to bacteria. These include pesticides, the major air pollutants originating from the combustion of fossil fuels and from intensive agricultural practices, and heavy metals from smelting factories.^[10] Exposure of leaves to agricultural chemicals utilized for pest or pathogen control is another area influenced by plant canopies. In these cases, uniform pesticide distribution is the desired outcome. However, this goal is typically achieved only in situations of low density of crop canopies.^[14]

CONCLUSION

The physical environment of the phyllosphere and the role of environmental stress in modulating microbial phyllosphere populations remains a field of investigation still relatively early in its development. While environmental parameters have been examined singly, the integration of multiple environmental effects has been experimentally difficult and, for the most part, not undertaken. Because of the direct effect of the environment on phyllosphere

microbes, and the influence of some of these microbes on plant health, an expanded understanding of the phyllosphere physical environment is a goal for a more integrated understanding of plant disease management.

INTRODUCTION

Since the onset of the Industrial Revolution, the use of fossil fuel and the clearing of land have led to a dramatic rise in the concentration of carbon dioxide (CO₂) in the atmosphere. This increase has significant implications for green plants because CO₂ is the prime input to photosynthesis. Leaves are the first point of contact for the majority of carbon transfer from atmosphere to biosphere. This capture of carbon by leaves enables the growth of plants, which play a vital role in maintaining the environment and form the base of agriculture. Humans and other organisms depend on this thin layer of leaves for food. Leaves collect highly dilute CO₂ from the atmosphere and concentrate and transform it into organic compounds. These compounds ultimately combine to form useful products (food and fiber). Leaf litter decomposition (by microbes) is a key process in agroecosystems through its role in carbon and nutrient cycling and storage. Leaves and their functions are pivotal in agroecosystems (and are sensitive to environmental change, especially rising CO₂); this article provides a short overview.

PHYSIOLOGICAL PROCESSES IN LEAVES

Changes in atmospheric CO₂ level have been shown to impact two major functions of leaves—photosynthesis and transpiration.^[1–3] Crops grown under CO₂ enrichment usually exhibit increased mass, which is attributed to more photosynthetic capacity and enhanced water use efficiency (ratio of CO₂ assimilated to water transpired). There are, however, differences among plants. For example, plants with a C₃ photosynthetic pathway often exhibit a greater response to high CO₂. The CO₂-concentrating mechanism in C₄ species limits the response, but C₄ plants can nevertheless exhibit growth stimulation because elevated CO₂ can increase water use efficiency. The C₃ plant generally benefits from both increased photosynthesis and water use efficiency. Increases in water use

efficiency are notable, although the combined effects of CO₂ on decreasing stomatal conductance and increasing leaf area and leaf temperature have resulted in modest reductions in estimated whole plant water use.^[3]

An often reported consequence of enhanced photosynthesis is the accumulation of nonstructural carbohydrates.^[1,2] Photosynthetic acclimation (a decline in photosynthesis over time) can be related to the buildup of nonstructural carbohydrates in leaves. The coupling of carbohydrate accumulation in leaves and acclimation is probably related to source-sink imbalances, with sink strength an important controlling factor. Some evidence shows a correlation between rooting volume and photosynthetic capacity as well as limitations in resource availability (e.g., soil nitrogen) influencing source-sink activity.^[1,2] Increases in soluble carbohydrate concentration may repress photosynthetic gene expression, leading to reductions in photosynthetic pigments (e.g., chlorophyll and carotenoids) and important soluble proteins, including rubisco and antioxidant enzymes.^[4] The photosynthetic apparatus may be more susceptible to photodamage due to decreased carotenoid content. There are some indications that increases in carbohydrates and decreases in protein are associated with a slight suppression of growth respiration and construction costs of leaves.^[5] Rubisco represents a sizable portion of leaf nitrogen and plays a significant role in the reduction of foliar nitrogen concentration commonly found under high CO₂ conditions.^[1,2] Reductions in antioxidant enzyme activities observed under high CO₂ may be reflective of less oxidative stress resulting from growth in CO₂-enriched atmospheres.^[4] Furthermore, antioxidant systems can differ according to plant genotype, suggesting differential resistance to biotic and abiotic stresses.

LEAF STRUCTURE AND DEVELOPMENT

Changes in the internal structure of leaves can occur under elevated CO₂ conditions.^[6] Consideration of leaf

structural changes may help interpret divergent findings with regard to photosynthetic acclimation. Fixation of CO₂ occurs at specific sites within the chloroplast and, under high CO₂, starch accumulation may change chloroplast structure and function (e.g., altered chloroplast integrity may limit carbohydrate transport to other organs). Both photosynthetic and assimilate transport capacity may also be altered by CO₂-induced shifts in mesophyll and vascular tissue. Leaves grown under elevated CO₂ have exhibited an extra layer (a third layer) of palisade cells as well as increased total mesophyll cross-sectional area and vascular tissue area. Stomatal density has been shown to decrease with elevated CO₂ in some, but not all cases. A further alteration is changes in epicuticular wax on high CO₂-grown leaves.^[7,8] Little is known about how CO₂ will affect trichomes. Changes in the leaf surface could affect water relations, susceptibility to pests and diseases, and surface properties that are important in chemical protectant application.

Plants grown under high CO₂ often exhibit increased area per leaf, greater leaf thickness, more leaves per plant, and higher total leaf area per plant,^[6] but effects on leaf area index are variable.^[2,3] Exposure to elevated CO₂ is thought to have little impact on rates of leaf initiation. Reported increases in leaf thickness and decreases in specific leaf area (leaf area/total leaf dry weight) are often the result of altered anatomy or increased starch accumulation. Although highly variable, increases in cell expansion may contribute to larger leaf size more than increased cell division. Increased expansion appears to result from greater cell wall relaxation and/or greater cell turgor. There is little information on how high CO₂ will affect leaf shape or duration.

ENVIRONMENTAL CONSIDERATIONS

CO₂-induced increases in leaf production and changes in leaf composition can significantly affect other trophic level organisms that utilize leaf tissue as a food substrate. The nitrogen concentration of green leaf material is often lower under high CO₂, whereas leaf carbon:nitrogen ratio, nonstructural carbohydrates, and secondary defense compounds can be increased. Effects on senescent leaf quality are more variable, but tend to be lower in magnitude.^[1,3,5] Changes in green leaves are relevant to phyllosphere organisms (fungi and bacteria living on leaf surfaces) and grazers (insects and livestock). The reproductive success of insects may be altered by diets of high CO₂-leaf tissue. However, the sparseness of information prevents generalization concerning the life cycle strategies of these organisms in a high CO₂ world. Information on this topic is critical for effective pest management (rates, timing, and number of pesticide applications may change under

higher CO₂ environments). Trace gas emission (e.g., methane) associated with cattle production is related to low forage quality, thus any CO₂-induced downward shift in leaf nitrogen concentration may be significant.

Senesced leaves are a food source for soil organisms and a major component of carbon inputs for agroecosystems.^[9] Leaf litter input can be increased by high CO₂, but decomposition rates will vary by crop species. Some decomposition work suggests that CO₂-enriched cropping systems may store more carbon, decomposition may be limited by nitrogen, and nitrogen release from litter may be slowed. A more thorough understanding of carbon and nitrogen cycling is needed to predict the potential for soil carbon storage in agroecosystems.^[1,9] Green leaf material can also contribute to litter production in systems using cover crops. Plant growth stage and leaf tissue nitrogen need to be considered for cover crop termination to optimize resource availability (nitrogen and/or water) to the following crop. There are some indications that CO₂ can alter crop phenology,^[3] which may alter kill time for cover crops and subsequent timing of farm operations, including planting. Another complication is that herbicide efficacy can vary by weed species under elevated CO₂.^[10] This has important implications for future weed management (frequency of spraying/rate adjustments), including control of invasive species, and also raises questions about herbicide efficacy on cover crops.

CONCLUSION

Leaf responses to elevated atmospheric CO₂ will need to be further elucidated if we are to accurately understand and predict the development and growth of crops under future environmental conditions. Future research will need to address:

1. How alterations in leaf structure are related to both cellular and higher-level growth processes;
2. Whether increased cell division is driven by greater rates of cell expansion or by molecular cues;
3. The role of ultrastructural, anatomical, and morphological leaf adjustments in photosynthetic acclimation;
4. How CO₂-induced changes in leaf structure and leaf function will alter the degree of impact of multiple crop stresses (abiotic and biotic);
5. How CO₂-induced shifts in leaf quality and/or changes in leaf surface features (e.g., epicuticular waxes, trichomes) will alter herbivore and pathogen attacks;
6. Mechanisms for herbicide tolerance of plants grown under high CO₂;
7. How CO₂ alters leaf nutrient composition of cover crops over time (growth stage and phenology); and

- With regard to leaf residue (green and senesced) supplying carbon and nitrogen to the soil, how elevated CO₂ will affect available crop nitrogen and the residence time of leaf-derived carbon in the soil.

Legumes: Nutraceutical and Pharmaceutical Uses

J. Bradley Morris

USDA—ARS, PGRCU, University of Georgia, Griffin, Georgia, U.S.A.

INTRODUCTION

Legumes are one of the three largest families of flowering plants, with approximately 690 genera and about 18,000 species. Many legumes are currently used for nutraceutical and pharmaceutical purposes, whereas others contain medically important phytochemicals with potential for further use.

The legumes currently recognized by the Pharmacist's letter/Prescriber's letter natural medicines comprehensive database for nutraceutical effectiveness include guar [*Cyamopsis tetragonoloba* (L.) Taub.], soybean [*Glycine max* (L.) Merr.], winged bean [*Psophocarpus tetragonolobus* (L.) DC.], and fenugreek [*Trigonella foenum-graecum* L.]. Several other legumes are currently recognized for pharmaceutical effectiveness.

NUTRACEUTICALS

Many other legumes are or contain phytochemicals that are possibly effective or have been shown to have potential therapeutic effects. One of these is field beans (*Phaseolus* spp.), which provide one of the most important sources of dietary protein for human consumption. These legumes are rich in the amino acids lysine and tryptophane. Dry adzuki beans [*P. angularis* (Willd.) W. Wight] contain about 22% protein. Mung bean (*P. aureus* Roxb.) seed contains about 23.6% protein and 3.3% fiber. Rice bean (*P. calcaratus* Roxb.) pulse contains about 21.7% protein and 5.2% fiber. Lima (also known as butter bean) (*P. lunatus* L.) pulse contains 20.7% protein and 4.3% fiber. The most popular and widely used bean is the common bean known as French bean, kidney bean, runner bean, snap bean, and string bean. These bean pods have been shown to be possibly effective when used orally as a supportive treatment for the inability to urinate.^[1,2] In addition, *P. vulgaris* L., winged bean, jicama [*Pachyrhizus erosus* (L.) Urban], *Lablab purpureus* (L.) Sweet, soybean, and kudzu [*Pueraria montana* var. *lobata* (Willd.) Maesen & S. Almeida] guar [*Cyamopsis tetragonoloba* (L.) Taub.] are excellent sources of fiber

(Fig. 1).^[3] Winged bean leaves, flowers, shoots, immature pods, immature dry seeds, and tubers are edible and highly nutritious. The mature dry seeds are especially nutritious because of their high protein content (30–42%). However, the seeds can be soaked for 10 hours and then boiled for 30 minutes to rid them of any antinutritional components. Winged bean contains oil consisting of tocopherols that are antioxidants. These antioxidants improve the utilization of vitamin A in the human body.

Peanut (*Arachis hypogaea* L.) seed is rich in oil, containing about 53% oleic acid and 25% linoleic acid with about 30% protein. Peanut contains two important antioxidants: protocatechuic acid and lecithin.^[3] Peanut oil is potentially useful for lowering cholesterol and preventing heart disease; however, allergic reactions are fairly common among the human population.^[1] Aesculetin found in the peanut plant has been shown to be anti-inflammatory and a cancer preventive.^[3] Lecithin exists in the peanut seed and has been found to range from 5000 to 7000 ppm. Lecithin has been shown to have antioxidant activity and some activity related to antialzheimeran.^[3] It also appears to be possibly effective for treating gall bladder disease and hypercholesterolemia.^[1]

Kudzu is used in traditional Chinese medicine for managing alcoholism, fever, cold, flu, and neck stiffness.^[1] Kudzu contains other important phytochemicals—namely, isoflavones including daidzin, daidzein, and puerarin. Both daidzein and daidzin decrease alcohol consumption in rats.^[4] A few products containing kudzu extracts are on the market; however, studies are needed to investigate the effects of kudzu in humans. The product known as Estroven, marketed by Amerifit, contains kudzu root isoflavones; a nutraceutical known as kudzu root is marketed by General Nutrition Center (GNC).

Velvetbean [*Mucuna pruriens* (L.) DC.] seed extract contains L-dopa, which is used as an antiparkinsonian.^[3] Sabinsa Corporation markets velvetbean seed extract in powder form for use as a nutraceutical (Fig. 2).

Astragalus [*Astragalus membranaceus* (Fisch.) ex Link] has shown some preliminary evidence that it can reduce the chance of developing the common cold. The

Fig. 1 Functional foods containing guar gum. (View this art in color at www.dekker.com.)

active components appear to be in the root, consisting of saponins, flavonoids, polysaccharides, and coumarins.^[5] It is an antioxidant and improves the immune response by potentiating the effects of interferon.^[1] Several *Vigna* spp. including [*V. aconitifolia* (Jacq.) Marechal], *V. angularis* (Willd.) Ohwi & H. Ohashi, *V. mungo* (L.) Hepper, *V. radiata* (L.) R. Wilczek, and *V. subterranean* (L.) Verdc. contain fiber from seed ranging from 9000 to 79,591 ppm. Plant fiber ranges from 31,700 to 286,000 ppm, whereas fruit fiber ranges from 9000 to 299,000 ppm in *V. aconitifolia*, *V. mungo*, and *V. subterranean*. Sprout seedling fiber ranges from 7200 to 94,500 ppm in *V. radiata*.^[3] See [Table 1](#) for therapeutically effective nutraceuticals.

PHARMACEUTICALS

See [Table 2](#) for currently recognized legumes with pharmaceutical effectiveness. The following discussion will include additional effective qualities for the phyto-pharmaceuticals listed in [Table 2](#).

Beta-sitosterol found in jackbean [*Canavalia ensiformis* (L.) DC.] is a plant sterol similar to cholesterol; however, arterogenesis does not occur with beta-sitosterol because less than 5% is actually absorbed. Beta-sitosterol significantly improves urinary symptoms, increases maximum urinary flow, and decreases postvoid residual urine volume. It also significantly reduces total and low-density lipoprotein (LDL) cholesterol levels, but has little or no effect on high-density lipoprotein (HDL) cholesterol levels.^[1] Pectin is possibly effective for

lowering cholesterol.^[1] Currently most of the therapeutic qualities from pectin have been discovered in citrus and apples. However, a substantial portion has been identified in the sunn hemp [*Crotalaria juncea* (L.) stem].^[3] Guar gum ([Fig. 3](#)) is possibly effective for reducing triglycerides.^[1] Abbott Laboratories markets Ensure Glucerna, in which the key ingredient is guar gum for helping people with diabetes ([Fig. 4](#)). Several legumes have or contain potentially useful phytochemicals with pharmaceutical properties. Luteolin found in [*Chamaecrista mimosoides* (L.) E. Greene] and kaempferol from [*Sesbania sesban* (L.) Merr.] have anti-inflammatory, antioxidant, and cancer-preventive potential. Pinitol from [*Macrotyloma uniflorum* (Lam.) Verdc.] has antidiabetic and expectorant possibilities. Lecithin found in velvet bean ([Fig. 5](#)) and other legumes is likely effective when used for reducing hepatic steatosis in long-term parenteral nutrition patients and when used topically for dermatitis and dry skin.^[1] Some noteworthy discoveries for cancer treatments include plant-derived isoflavones. Genistein has thus far been shown to be more abundant in subclover (*Trifolium subterraneum* L.) than soybean or red clover (*Trifolium pratense* L.).^[6] Clinical trials have revealed that genistein inhibits the growth of both MCF-7 breast cancer cells and human mammary epithelial cells in vitro, whereas biochanin, another isoflavone found in subclover, is just as effective against these tumor cells but is five times less potent in the inhibition of normal cells.^[7] Furthermore, genistein has been shown to inhibit bladder cancer.^[8] Mimosine found in *Leucaena* species (*Leucaena* spp.) blocks cell cycle progression in MDA-MB-453 human breast cancer cells.^[9]

Fig. 5 Productive velvetbean growing in a field (Griffin, GA). (View this art in color at www.dekker.com.)

CONCLUSION

Both nutraceutical and pharmaceutical products have been made from legumes. Many legumes are currently known to be therapeutically effective, whereas others are undergoing research to ascertain whether they are effective in benefiting health-related problems. The use of such natural products has stimulated the interest of the general public because of the health-promoting properties of legumes. These possibilities make legumes very important for the future—and not just a hill of beans.

INTRODUCTION

Lesquerella produces a triglyceride oil that is two-thirds or more lesquerolic acid, a hydroxy fatty acid (HFA). Hydroxy fatty acids are now used in nylon-11 and nylon-6,10, lithium greases, coatings, sulfated and sulfonated oil, sebacic acid, ethoxylated oil, food grade lubricants, polyurethanes, and cosmetics. The current source of HFAs is ricinoleic acid from castor (*Ricinus communis* L.), which was formerly cultivated in the United States. Approximately 41,000 million tons are now imported, primarily from Brazil and India, at a value exceeding \$100 million per year. Lesquerella is native to the United States and could be established as a domestic HFA source and reduce reliance on castor oil importation.

Lesquerella has several novel properties that set it apart from castor and other oilseeds. One property, is its oil functionality, including difunctional hydroxy moieties (in contrast to other seed oils such as castor that are trifunctional). Lesquerella has been reported to contain natural estolides (secondary esters derived from the addition of a fatty acid moiety to the hydroxyl functionality of the hydroxy triglyceride) that improve performance of the oil. Estolides have been encountered in only a few other seed oils, and are not naturally found in castor oil (although they can be synthetically fabricated). Estolides have been shown to improve vegetable oil performance in motor oils by improving pour points (temperature at which the oil no longer pours), and estolides have also been used as viscosity modifiers in lubricating oils. The second of lesquerella's novel properties is its antioxidants, converted from the seed meal fraction that contain unique glucosinolates and have superior oxidative stability properties. The seed meal also has a binder application, unique for seed meals. The third novel property is the seed coat of lesquerella, which contains a unique gum that has rheolog-

ical properties equivalent to guar or xanthan that can be useful in coatings and food thickeners.

MARKET POTENTIAL

Large markets exist for hydroxylated oils as feedstock for lithium greases, polymers in paints and coatings, base-stocks in lubricants, and in applications in the personal care industry.^[1] Lesquerella could be established as a reliable domestic supply of oilseed for all these markets and simultaneously provide an alternative crop for farmers that would indirectly increase local profits. The unique chemical structure of lesquerella oil offers distinct advantages for the development of new applications.^[2]

Increasing attention to environmental issues drives the lubricant industry to increase the ecological friendliness of its products.^[3] The industry has, for the last decade, been trying to formulate biodegradable lubricants with technical characteristics superior to those based on mineral oil (petroleum). Volumes of lubricants, especially engine oils and hydraulic fluid, are relatively large and most are petroleum based. Hydraulic fluids are consumed at 5 million metric tons (MT)/year in the United States, and have the highest need for biodegradable lubricants.^[3]

Until now, petroleum-based lubricants have been superior to biodegradable vegetable oils because of their lower pour points and higher oxidative stability.^[3] Some vegetable oils (such as soybean) require up to 30% synthetic additives to improve their performance. However, the triglyceride estolides that are found in species of the genus *Lesquerella* overcome this vegetable oil deficiency by blocking unsaturation and providing branches that lead to lower pour points.^[4] In fact, vegetable-based lubricants with synthetic additives still do not approach the properties of estolides. The commercialization of lesquerella

oil, with its natural estolides, could lead to the development of a lubricant derived directly from the seed, significantly lowering processing costs. The lower pour point of estolides could also allow soybean oil lubricants to be formulated without synthetic additives. Tests indicate a pour point between -15 and -20°C and a cloud point of -1°C for commercial products made from soybean oil. The potential exists that estolide additives from lesquerella (pour point -33°C , cloud point -37°C) could be used to lower the pour and cloud points of soybean-based lubricants that do not presently match the performance of petroleum-based products (pour points of -21 to -36°C) currently on the market.

Lesquerella glucosinolate, 3-(methylsulfinyl)propyl glucosinolate, is unique in that it breaks down in the meal enzymatically when the seed meal is mixed with water to form 1-isothiocyanato-3-(methylsulfinyl) propane almost exclusively. The isothiocyanate is the precursor to thiourea antioxidants made with natural amines. The isothiocyanate also is a by-product of lesquerella oil deodorization. In both cases the recovered isothiocyanate can be easily converted to an amine and reacted back with the isothiocyanate to form unique thiourea antioxidants.

POTENTIAL FOR YIELD INCREASES

A wealth of genetic variability has been provided for a lesquerella-plant-breeding program that allows for improvements in both plant growth characteristics and oil quantity and quality. Improved germplasm has been developed in the past few years and publically released through the Agricultural Research Service, U.S. Water Conservation Laboratory (USWCL).^[5] Another accomplishment has been the development of hybrids among *L. fendleri* and related species. *L. fendleri* has a limited amount of variation for seed oil lesquerolic acid content (HFA). Other species have much higher HFA content seed oil (89% compared to 54%), but lower seed yields. This trait was found to be maternally inherited in hybrids; a series of backcrosses have allowed the transfer of this trait into *L. fendleri*.

CURRENT PRODUCTION TECHNIQUES

Lesquerella is a low-growing herbaceous shrub with much less biomass for disposal than other oilseed crops. Standard farm equipment with minor modifications can be used for all routine farming practices. Lesquerella should be planted in the fall with planting dates ranging from August 15 to September 1 in Texas and New Mexico, and October 1 to 15 in Arizona. Harvests will occur 8 to 9 months later in the spring.

Lesquerella requires 25 to 26 inches of irrigation water for maximum seed yield, as compared to 30 to 40 inches for cotton.^[6] Nitrogen/acre amounts of 50 to 100 lb. increased lesquerella biomass and seed yields.^[7] Lesquerella can be efficiently harvested by direct combining. Maximum seed yields have been obtained with a planting density of about 400,000 plants/acre (approximately 5.0 to 6.0 lb. of seed/ac).^[8] Crop rotations have been studied and there have been no reports of allelopathy.

Because lesquerella will be grown in irrigated arid and semiarid regions of the southwest United States, a salt-tolerant line has been developed^[9] that is able to grow in these areas where drainage effluents are reused and where the crop could benefit marginal agricultural lands. In addition, lesquerella has been shown to be a potential phytoremediator of selenium (Se)-contaminated soils, because the plant can accumulate this harmful trace element in its leaves and stems. High levels of Se found in areas such as the San Joaquin Valley of California pose health threats to humans, livestock, and wildlife.^[10] Following harvest, the seed oil would be utilized for the proposed industrial purposes described earlier, and the bioaccumulated plant parts that remain could be removed from the area.

In the production areas where lesquerella is likely to be grown, control of weeds is extremely important. In fact, weed control could be a major factor limiting establishment of commercially-viable lesquerella production in the United States. Lesquerella is slow to establish, making the crop less competitive with grass and broadleaf weeds that emerge in crop rows and cannot be removed mechanically. For lesquerella to be produced economically at industrial scale on commercial growers' fields, herbicides must be registered. Several economical and environmentally safe herbicides for this crop have been identified in extensive field research studies.^[11]

CONCLUSION

Agricultural research and extension personnel, USDA/ARS scientists, and agribusiness representatives have identified 21 counties in Arizona, New Mexico, and Texas believed to hold the greatest potential for lesquerella commercialization.^[12] Irrigated acreage in these counties totals almost 1.4 million. Lesquerella will not necessarily replace current commodity crops but will be placed in rotation (e.g., a 2-year, 3-crop rotation of lesquerella, grain sorghum, and cotton). Over the long term, as lesquerella markets strengthen, acreage increases, and net returns remain competitive with other crops, lesquerella could replace commodity crops with negative net returns. Wheat, for example, produced on 320,000 acres in 17 of the 21 aforementioned counties, reported the most crop

budgets with estimated negative net returns. Abandoned cropland in the Trans Pecos region of west Texas alone accounts for another potential growing base of 180,000 acres in addition to irrigated acres. Soil erosion on lesquerella plantings will not be an issue because the crop provides soil cover during the fall and winter, and stubble can be left on the land after harvest.

Because new industrial products unique to lesquerella will be developed, lesquerella would not be expected to replace castor in the event it is reintroduced as a U.S. crop. Therefore, domestic supplies of HFAs would not depend on a single crop. The two crops could be produced in different seasons—lesquerella would be planted in the fall and harvested in late spring, whereas castor would be planted in the spring and harvested in late fall. There would be rotational opportunities for both crops. Castor has a high water requirement, and would not be produced in arid and semiarid environments where lesquerella is best suited. Multiple production regions would provide a more reliable domestic supply of HFA. This in turn could encourage further research and new product development, thus opening additional markets for both crops.

Light-Harvesting Complexes

Laura L. Eggink

Center for the Early Events in Photosynthesis, Arizona State University,
Tempe, Arizona, U.S.A.

INTRODUCTION

Light-harvesting complexes (LHCs) are distinct integral-membrane, pigment-protein assemblies that serve, in association with reaction centers, as antennae. LHCs collect and regulate delivery of the light energy that drives photosynthesis. In green plants (*Chlorophyta*), LHCs are encoded by a nuclear multigene family and post-translationally imported into the chloroplast, where they noncovalently bind chlorophyll (Chl) *a*, Chl *b*, and carotenoids.

LHC GENE FAMILY

A large nuclear gene family, known as *Lhc* genes, encodes LHC proteins (LHCPs) that range from 20 to 30 kDa in mass. Duplication and divergence of the *Lhc* gene family have produced a large number of functionally distinct antennae proteins, of which there are two main groups. The first consists of *Lhca* genes (*Lhca1–Lhca4*), encoding LHCPs associated with photosystem (PS) I (LHCI). The second group includes the *Lhcb* genes (*Lhcb1–Lhcb6*), encoding LHCPs primarily associated with PSII. Each of these individual designations can include several related derivatives, and some plants are known to have up to 20 different *Lhc* genes. The major LHC associated with PSII (LHCII) is the most abundant Chl-binding protein. LHCII exists as a trimer and the apoproteins, encoded by *Lhcb1* and *Lhcb2*, bind over half the Chl in the thylakoid membrane. Four to six trimeric LHCII are associated with each reaction center. *Lhcb3–6*, apoproteins of the minor antennae, exist in roughly a 1:1 ratio with PSII and serve to connect the main antennae, LHCII, with the reaction center.

In vascular plants, transcription of *Lhc* genes is tissue specific and regulated by a network of signals initiated by environmental cues. Signaling molecules such as phytochrome, cryptochrome, the Chl biosynthetic precursors Mg-protoporphyrin IX and Mg-protoporphyrin monomethyl ester, a Chl biosynthetic protein Mg-chelatase subunit H, and plastid redox sensory molecules such as plastoquinol have been implicated in regulation of transcription of *Lhc* genes. These molecules are involved in different signal pathways

that either upregulate or downregulate the expression of these nuclear encoded genes.^[1]

The amino acid similarity between homologous LHC proteins from different plant species is greater than 90%. Differences among the various types of LHCPs, i.e., *Lhca1* vs. *Lhcb1*, are much more substantial. However, two regions, the first membrane-spanning and the third membrane-spanning regions of the proteins, are highly conserved. Within these conserved regions resides a unique motif, EXXH/NXR, repeated in both the first and third membrane-spanning regions, which unequivocally identifies the protein as a non-bacterial LHCP (Fig. 1). Conservation of the first and third helices has led to the hypothesis that LHCPs evolved by duplication of a two-helix membrane-spanning polypeptide to form a four-helix membrane-spanning protein, with loss of the fourth helix.^[2]

STRUCTURE/FUNCTION

The structure of the *Lhcb1* gene product from higher plant, as determined from the structure resolved to 3.4 Å by electron diffraction,^[3] revealed the organization of pigments that are bound to three α -helical membrane-spanning regions and a small, C-terminal amphiphilic helix. Bracing helices 1 and 3 are two molecules of lutein. Twelve Chl molecules were detected, eight of which are ligated through coordination with amino acid sidechains, while ligands to the remaining four Chls were not identified. Biochemical analysis has shown that *Lhcb1* and *Lhcb2* protein complexes coordinate seven Chl *a*, five Chl *b*, two lutein, one neoxanthin, and substoichiometric amounts violaxanthin. Although LHCPs share sequence homology, differences in their pigment-binding preferences have been revealed. Analyses of the minor complexes show *Lhcb 4–6* gene products ligate fewer Chls than *Lhcb1* and *Lhcb2*. *Lhcb4* binds eight Chls (six Chl *a* and two Chl *b*), *Lhcb5* binds nine Chls (six Chl *a* and three Chl *b*), while *Lhcb6* binds 10 Chls (five Chl *a* and five Chl *b*). The minor LHCs also ligate fewer xanthophylls (one lutein, 0.5 neoxanthin, and 0.5–1 violaxanthin).^[4,5]

It is likely, on the basis of the sequence homology, that *Lhca* gene products share a high degree of

Fig. 1 Model of pea (*Pisum sativum*) LHCII showing conserved amino acids, denoted with ●. The numbered membrane spanning helices are boxed, as is the short amphiphilic helix. Chl *a* molecules are numbered a1–7 and Chl *b*, b1–6. Proposed Chl *b* binding positions are colored in green.^[11] (Adapted from Ref.^[2]). (View this art in color at www.dekker.com.)

structural similarity with the LHCII proteins. Similarly to the minor antennae of PSII, apoproteins of LHCI coordinate six to nine Chl *a*, three Chl *b*, one lutein, 0.5 violaxanthin and, instead of neoxanthin, bind substoichiometric amounts of β -carotene.^[6] LHCI can be fractionated into two populations based on their fluorescence emission maximum at 77 K. LHCI-680 is composed of Lhca2 and Lhca3, whereas the second type, LHCI-730, is a heterodimer of Lhca1 and Lhca4.

A correlation seems to exist between the location of an LHC and its preference for binding Chl *a* over that of Chl *b*.^[6] Lhcb4 and Lhcb5 monomers are located adjacent to the PSII core^[7] and preferentially bind Chl *a*, as does Lhca1–4 dimers, which are located directly adjacent to PSI. The most peripheral LHCII trimers contain almost equal numbers of Chl *a* and Chl *b*. This overall structure is closely related with function. LHCs broaden absorption bands by using pigments different from those located in and near the reaction center, which increases the probability that photons not absorbed by the reaction center will be captured. Once the energy is captured, transfer of exciton energy within the LHC is ultrafast, occurring in the range of hundreds of femtoseconds. The primary purpose of LHCs is to transfer captured excitation energy to Chl *a* in a photochemical reaction center for charge

separation. Exciton energy is transferred from LHCs to reaction centers on a picosecond timescale and is essentially 100% efficient.

LHCII is also involved in redistribution of excitation energy between PSII and PSI by state transitions that occur upon overexcitation of PSII. When PSII is saturated with light energy with respect to PSI, the plastoquinone pool becomes reduced and activates a kinase bound to the cytochrome *b₆f* complex. This process results in phosphorylation of the stromal facing N-terminal portion of the major trimeric LHCII, leading to a disassociation from PSII reaction centers and monomerization of LHCII. Lhcb1 and Lhcb2 monomers move laterally out of the grana into the stromal lamellae where they redirect their energy to PSI.^[8] A second, more static strategy that plants have developed to redistribute energy is to quench excitation energy and dissipate that energy through nonradiative mechanisms. The xanthophyll, zeaxanthin, has the most favorable energy level to efficiently quench excited Chl and has been shown to be effective in dissipation of potentially damaging excess energy as heat. The relatively high content of violaxanthin, which is available for conversion to zeaxanthin, is associated with the minor LHCs. Therefore, Lhcb4, 5, and 6 may participate in nonphotochemical quenching as a

means to redirect excitation energy away from the reaction center of PSII.

IMPORT/ASSEMBLY

Nuclear encoded LHCPs are synthesized in the cytoplasm as higher molecular weight precursors and imported into the chloroplast, where the N-terminal transit sequence is removed by a protease in the stroma. Not surprisingly, events occurring at the chloroplast envelope are crucial for in vivo import of LHCP.

For import into the chloroplast, there are several regulatory points that nuclear-encoded proteins must pass. First, LHCP precursors engage a general chloroplast import apparatus. The apparatus is composed of two distinct multi-subunit translocation machines, called Toc and Tic, located in the outer and inner membranes, respectively. Toc is sensitive to nucleotide concentrations and modulates receptor-LHCP precursor binding through GTP/GDP binding cycles. At the inner envelope, redox sensitive components of the Tic complex can regulate import based on the redox state of the chloroplast.^[9]

Once the import apparatus is engaged, a second, and more functional/structural requirement at the inner envelope must be met. Chl must be available to interact with LHCP. If sufficient Chl is not available or mutations are present in the Chl binding sites of the apoprotein, LHCP import is aborted.^[10] Only under certain conditions (growth on an organic carbon source), and with the more hydrophobic LHCs, is interaction with Chl *a* sufficient to retain LHCs in the chloroplast. Otherwise, Chl *b* is required. The stronger coordination bond between Chl *b* and amino acid sidechain ligands in LHCs enhances their import into the chloroplast and assembly of LHCs.^[11]

Assembly of LHCs is wholly dependent upon interaction with Chl *a*, Chl *b*, and carotenoids. Complexes deficient in Chls or xanthophylls are unstable and subject to proteolysis. During early development, i.e., the conversion of proplastid to chloroplast, LHCs assemble on low-density (inner envelope) membranes and within seconds become connected to reaction centers. Other nuclear encoded proteins such as cpSRP54 and cpSRP43 may also facilitate assembly at the membrane.^[10]

In summary, membrane-bound LHCs are transcriptionally controlled, multigene family proteins that require Chl *a*, Chl *b*, and xanthophylls for assembly and to function in the regulation of exciton energy

flow into and away from the photosystems in green plants.

Lipid Metabolism

Jean-Claude Kader

Université Pierre et Marie Curie, Paris, France

INTRODUCTION

Lipids can be defined as a group of fatty-acid-derived compounds soluble in nonaqueous solvents. They constitute a broad family of molecules, which is particularly large in higher plants since more than 300 different fatty acids (FAs) have been characterized. Lipids are important constituents of plant cell membranes and are involved in physiological processes linked to the responses of plants to environmental conditions, to defense reactions, and to intracellular signaling pathways.^[1] Lipids are also an important form of carbon storage in seeds. Oilseeds are among the most ancient crops, cultivated for thousands of years as sources of products used for food and for industrial products such as cosmetics or lubricants. Both uses have led to an increase in the demand for oilseeds, and world oilseed production (mainly soybean, rapeseed, sunflower, palm, cottonseed, and peanut) has expanded in the last 50 years from 160 to 300 million tons per year.^[2]

In order to improve the quality of plant oils (seeds and fruits), it is important to increase our knowledge of the metabolism of plant lipids. It is the aim of this article to summarize the lipid biosynthetic pathways and to present the exciting perspectives offered by the metabolic engineering of oils.

STORAGE AND MEMBRANE LIPIDS HAVE DIFFERENT FATTY ACID COMPOSITION

The major lipids of plant cell membranes are phospholipids (mainly phosphatidylcholine, phosphatidylethanolamine, and phosphatidylinositol) and, in the plastid membranes, galactolipids (mainly monogalactosyldiacylglycerol). It is remarkable that the main FAs present in these membrane lipids are also found in triacylglycerols (TAGs), which are the storage lipids. These FAs are predominantly palmitate (16:0) (the first number refers to the number of carbon atoms, the second to the number of double bonds), stearate (18:0), oleate (18:1), linoleate (18:2), and linolenate (18:3). Seeds contain, in addition to these common acyl chains, a very large diversity of FAs referred to as “unusual.” These FAs vary by their chain length, from 8 to 14 carbons in *Lauraceae* or from 20 to 24 carbons in *Brassicaceae*. Other oils accumulate FAs

with double bonds at positions not usually found in membrane lipids such as petroselinic acid (16:1) or acyl chains containing hydroxy, epoxy, or acetylenic functional groups. The reason for such a large diversity is still unknown, but the fact that these FAs are excluded from membranes and accumulate in TAGs help plants to tolerate high levels of these unusual lipids. These FAs have important industrial applications (lubricants, paints, detergents, cosmetics) due to their unique chemical properties. However, the production of such compounds at a high level is not possible since their sources are plants that are not adapted to classical agricultural practices. This led to the idea to introduce genetic engineering approaches to adapt common crops to industrial needs.^[3,4]

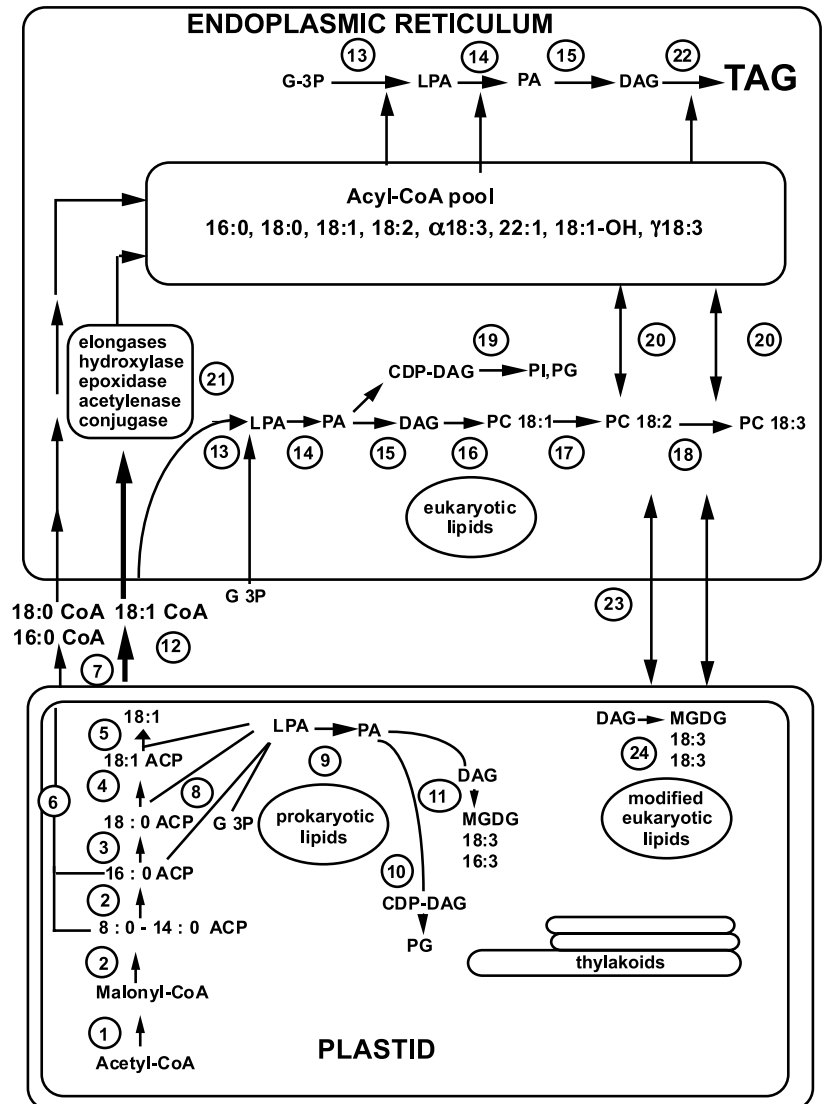

AN INTRACELLULAR COOPERATION IS NEEDED FOR LIPID BIOSYNTHESIS

It is remarkable that the biogenesis of plant glycerolipids needs a complex intracellular cooperation between the plastid and the endoplasmic reticulum. Two distinct pathways are operative: the “prokaryotic” one, localized within the plastid, and the “eukaryotic” pathway, which requires cooperation between the two cell compartments.^[5] The elucidation of these metabolic pathways is the result of early biochemical studies and of approaches of molecular biology and molecular genetics, which, in the case of the model plant *Arabidopsis thaliana*, have allowed the characterization of mutants deficient in enzymes of lipid metabolism. In less than 10 years, these investigations resulted in the cloning and characterization of the key enzymes of the lipid pathways. A survey of genes for plant lipid metabolism has recently been published by searching the public databases for sequences coding for 65 polypeptides involved in lipid biosynthesis and degradation.^[6]

PLASTIDS PLAY A CENTRAL ROLE IN FATTY ACID SYNTHESIS

In the stroma of plastids, the first steps of fatty acid biosynthesis are carried out (Fig. 1). The stepwise condensation of C₂ units to a growing acyl-chain attached

Fig. 1 A simplified scheme of plant lipid biosynthesis. An acetyl-CoA carboxylase (1) catalyzes the formation of malonyl-CoA. The elongation process is catalyzed by a fatty acid synthase complex (2). Acyl chains shorter than 16 carbons are formed in some plants. An additional elongation step catalyzed by a β -ketoacyl synthase (3) and a desaturation mediated by stearoyl-ACP desaturase (4) lead to oleoyl-ACP, which can be partly cleaved by a thioesterase (5) to form free fatty acids (FAs). Another thioesterase (6) is more active with shorter acyl-chains. The free FAs are esterified to CoA (7) and exported. However, some acyl chains of ACPs are used within the plastid for the prokaryotic pathway involving a glycerol-3-phosphate acyltransferase (8) and lyso-phosphatidate acyltransferase (9), thus allowing the formation of phosphatidylglycerol (PG) (10) or monogalactosyl-diacylglycerol (MGDG), which is of prokaryotic type (16 carbons at *sn*-2 position) (11). The eukaryotic pathway involves an export of the various acyl-CoAs to the endoplasmic reticulum by an unknown mechanism (12). Acyl-CoAs are inserted into membrane phospholipids, mainly phosphatidyl-choline (PC), through glycerol-3-phosphate acyltransferase (13), lysophosphatidate acyl-transferase (14), phosphatidate phosphatase (15), and CDP-choline : 1,2 diacylglycerol-choline phosphotransferase (16). The FAs of PC are desaturated (17,18). Some of the FAs are used for the synthesis of other phospholipids (19). PC molecules exchange their FAs with those of the acyl-CoA pool by the action of acyl-CoA lyso-PC-acyltransferase (20). The acyl-CoA pool also comprises other FAs modified by various enzymes, depending on the plant species. The FAs allow the synthesis of triacylglycerols (TAGs) through a series of reactions (13–16) including one step unique to TAG formation, the diacylglycerol acyltransferase (22). The final step of the eukaryotic pathway is the reentry of the FAs into the plastid (23) where they form eukaryotic lipids, mainly MGDG esterified by 18 carbons in both positions (24).

to acyl-carrier protein (ACP) leads to the formation of saturated acyl chains with palmitoyl-ACP (16:0-ACP) as a major product. However, shorter acyl chains could be formed depending on the plant species. The group of enzymes involved in fatty acid synthesis is called fatty acid synthase (FAS), which is, in animals and yeast, a multifunctional enzyme complex characterized by large subunits. By contrast, FAS from plants includes at least 12 separate proteins functioning rather like a metabolic pathway. A further step is the elongation of 16:0-ACP to 18:0-ACP by a β -ketoacyl synthase (the mutant *fab1* of

Arabidopsis is deficient in this enzyme) followed by a desaturation by a stearoyl-ACP-desaturase (corresponding mutant *fab2*), which introduces a double bond at carbon 9 and forms oleoyl-ACP. This desaturase, soluble in the stroma, is unique among all other acyl-desaturases, which are integral membrane proteins. A key step is then termination, which is catalyzed by thioesterases that hydrolyze the acyl-ACPs to produce free FAs. These FAs are exported from the plastid to the endoplasmic reticulum and participate in the eukaryotic pathway. Some of the acyl-ACPs are used within the plastid and enter into the

prokaryotic pathway, allowing the synthesis of plastidial membrane lipids such as phosphatidylglycerol, galactolipids, or sulfolipids.^[1,5] The importance of the prokaryotic pathway depends on the plant species and is minor in oilseeds.

THE ENDOPLASMIC RETICULUM IN DIVERSITY OF PLANT LIPIDS

The exported FAs are involved in the eukaryotic pathway and are esterified to CoA. The acyl-CoAs join the acyl-CoA pool, which is used partly for the production of membrane lipids such as phosphatidylcholine and other phospholipids. In addition, the diacylglycerol moiety of phosphatidylcholine partly returns to the plastid by an unknown mechanism and is used for the synthesis of modified eukaryotic plastidial lipids, mainly galactolipids that have 18:3 in both *sn* positions. These galactolipids differ from the prokaryotic species, which have 16:3 at one of the two positions. The other part of the acyl-CoA pool is used to synthesize TAGs, a process highly active in oilseeds. Several enzymes are involved in these pathways, such as membrane-bound desaturases (oleate desaturase (also named FAD2) and linoleate desaturase (FAD3)) and various types of acyltransferases. One step unique to TAG synthesis is the final one catalyzed by a diacylglycerol transferase specific to the third carbon of the glycerol backbone. Depending on the plant species, other specific enzymes may operate, such as elongases, epoxidases, hydroxylases, and acetylenases. This enzyme diversity explains the broad spectrum of TAGs found in oilseeds. TAGs accumulate in subcellular organelles called oil bodies and are hydrolyzed to provide energy for germination and other processes.^[7] The intensity of the flux of acyl moieties between the two cell membranes and the channeling of FAs toward either membrane or storage lipids depend on the plant species or the tissue considered.

WHAT ARE THE GENETIC ENGINEERING TARGETS?

The improvement of seed oil quality requires either molecular markers to help breeding or cloned genes to manipulate their expression in planta.^[4,7] The two main directions are to modify the level of expression of a gene of interest or to introduce a foreign gene into a common crop to broaden the range of FAs offering industrial

applications. Some of the successful experiments were to improve the quality of edible oils by increasing the proportion of monounsaturated FAs. This was achieved, for example, in soybean by underexpressing the oleate-desaturase. Another successful strategy was to increase the amount of saturated FAs, used for margarines and shortenings, by antisense RNA suppression in rapeseed of a gene coding for stearyl-ACP desaturase. The introduction of a foreign gene was successfully achieved for lauric acid (12:0), which is used for the production of detergents. High laurate oil, commercially sold from 1995, was obtained by expressing a thioesterase isolated from California Bay that terminates the elongation process at a length of 12 carbons. Other FAs interesting for lipochemistry are erucic acid (22:1), a product of an elongase complex in rapeseed; ricinoleic acid (18:1-OH), formed in castor bean by a hydroxylase, and γ -linolenic acid (γ -18:3), synthesized in borage by a specific type of desaturase. These FAs have been produced in model plants by expressing genes corresponding to these enzymes. The latter enzymes belong to the vast family of desaturases (FAD2 type) or are biochemically close to them. A site-directed or random mutagenesis strategy of desaturases offers perspectives for enzyme engineering.^[7]

CONCLUSION

It is easy to conclude that the knowledge of plant lipid metabolism, which has greatly progressed in the last decade, offers exciting perspectives for improving oil quality for food and industrial applications and for producing novel compounds that are renewable and environmentally friendly. Additional examples are the synthesis of polyhydroxybutyrate, a biodegradable plastic, by expressing in plants several bacterial genes or the development of oils suitable for use as lubricants or sources of fuels. Future research will be devoted to understanding the role of membrane lipids in the responses of plants to environmental factors or to pathogens. Other promising investigations will be to study the involvement of phosphoinositides in the signal transduction pathways and the participation of fatty acid derivatives (oxylipins, jasmonate) and enzymes (phospholipases, lipoxygenases) in these important processes.

Long-Term Selection for Biochemical Traits

John W. Dudley

University of Illinois, Urbana, Illinois, U.S.A.

INTRODUCTION

There have been very few continuous, planned, long-term selection studies for biochemical traits in plants even though such studies provide valuable information about limits to selection, genetic control of biochemical traits, and potential for improvement of chemical composition of a crop. In this article, results of the longest, continuous selection program for chemical composition in higher plants will be reviewed and the implications of the results of that program to plant breeding progress will be discussed.

BACKGROUND

There have been very few long-term selection experiments for biochemical traits in plants. The earliest known experiment of this type (begun in 1786 and continued until 1830) was the transformation of the fodder beet into the sugar beet (*Beta vulgaris* L.) by selection for sucrose concentration in the beet root.^[1] This selection was done well before the discovery of genetics. Thus data, which would allow measurement of genetic variability or determination of genetic control of sucrose concentration, are not available. However, it had the very practical result of providing the groundwork of an entirely new industry and changing a fodder crop into a food crop. In addition, the success of this selection likely provided the impetus for the Illinois long-term selection experiment for oil and protein in corn (*Zea mays* L.), the longest continuous selection experiment in higher plants. The Illinois experiment is the major emphasis of this article.

THE ILLINOIS LONG-TERM SELECTION EXPERIMENT

Background

Selection for oil and protein concentration in the corn kernel was started in 1896 at the University of Illinois by Hopkins.^[2] In 2003, the experiment is in its 104th generation. Hopkins was a soil chemist who recognized the importance of improving the quality of corn for animal feeding. The success of selection for sucrose, which

resulted in the sugar beet, likely influenced Hopkins' decision to select for oil and protein in corn. Details of the selection procedures have been described.^[3] Briefly, Hopkins measured oil and protein concentrations of 163 ears from the open-pollinated corn cultivar "Burr's white." He selected the 24 ears highest in protein to initiate the Illinois High-Protein (IHP) strain; the 24 ears highest in oil to initiate the Illinois High-Oil (IHO) strain; the 12 ears lowest in protein to initiate the Illinois Low-Protein (ILP) strain; and the 12 ears lowest in oil to begin the Illinois Low-Oil strain (ILO). Over the years, minor modifications were made to the selection procedure but a form of mass selection was used throughout.^[4] In generation 48, reverse selection [i.e., selection for low oil in IHO, to produce Reverse High Oil (RHO), and for high oil in ILO, to produce Reverse Low Oil (RLO), with similar selection for protein in IHP and ILP to produce Reverse High Protein (RHP) and Reverse Low Protein (RLP)] was initiated to determine whether genetic variability had been exhausted.^[5] In generation 7 of RHO, selection for high oil was used to initiate the Switchback High-Oil (SHO) strain.

Results

Progress from selection is still being made after over 100 years in IHO, SHO, RHO, and RLO (Ref. [4] and Fig. 1).

The rate of gain in SHO has been slightly greater than in IHO, and the mean for SHO is now near that of IHO (Fig. 1). The means for RLO and RHO are now nearly the same, but both are lower than the original mean. ILO reached a lower limit of selection when oil became so low (<1.0% oil) that it was no longer measurable.

Progress from selection in IHP was not as uniform as in IHO (Fig. 2).

Following generation 52 when N fertilizer was added to IHP, the rate of progress increased. ILP reached a lower limit after approximately 65 generations. Although the protein level (4.5% protein) was still measurable, no further progress was made. A selection limit may have been reached for RHP because the protein level has reached the level at which progress ceased in ILP (Ref. [6] and Fig. 2).

As measured by realized heritability, response to selection was symmetrical in IHO and ILO. However,

Fig. 1 Oil response.

Fig. 2 Protein response.

change per generation, after generation 9, was much greater in IHO than in ILO (Fig. 1) because of the much larger selection differential in IHO. The pattern was not as clear in IHP and ILP. For the first nine generations, realized heritabilities were similar in IHP and ILP, but in later segments of the experiment, realized heritabilities in IHP were higher than in ILP. Change per generation after generation 9 was much higher in IHP than in ILP (Fig. 2). Reverse selection was effective in all four strains. In general, change per generation was higher in RHP and RHO than in RLP and RLO.

Correlated Response

In this experiment, selection was for a single trait measured in terms of concentration. Because concentration of one component is relative to the constitution of the entire kernel, when oil or protein concentration changes, the absolute concentration of another component of the kernel must change. Increases in oil in IHO and SHO were accompanied by decreases in percentage of starch and kernel weight, increases in percentage of germ, and small increases in percentage of protein.^[4] Increases in protein in IHP and RLP were accompanied by decreases in percentage of starch, but there were no significant changes in percentage of oil. The fact that increases in percentage of oil or percentage of protein are accompanied by decreases in percentage of starch is not surprising given that starch makes up about 70% of the dry weight of the kernel.

Genetic Control of Oil and Protein

The number of effective factors differentiating IHO and ILO was estimated as 54, whereas the number differentiating IHP and ILP was 123.^[4] The average frequency of the favorable allele for high oil in the original population was estimated as 0.20. For protein, the estimate of the average frequency of the favorable allele was 0.24. Using these data, it is possible to show that all the progress which has been made in the IHO and IHP strains can be accounted for by a low initial gene frequency and a large number of genes segregating in the original Burr's white population.^[4] Alternatively, Walsh^[6] suggests that gain based on mutational variance is expected to eventually exceed that from gain based on residual segregation from the original population.

In addition to providing valuable insights into the process of selection, this experiment has produced strains that provide a unique set of materials for use in molecular marker studies aimed at identifying and locating genes that control oil and protein concentration in the grain. One of the requirements of such studies is parents differing widely for the trait. IHP and ILP, or IHO and ILO are as

different in protein or oil as any strains known. Thus crosses between them should be segregating for many genes. These strains are currently being used in studies aimed at identifying quantitative trait loci (QTL) affecting oil and protein concentrations.^[7] The number of QTL identified is much smaller than expected based on estimates of the number of effective factors. However, limitations of the QTL studies, such as resolving linked loci and difficulties resulting from small sample size, may account for this discrepancy.

These strains also provide unique germplasm for studying the physiology of oil and protein production in corn. Studies of the IHP and ILP strains have shown unique differences in the way in which the two strains utilize nitrogen to produce grain protein.^[8]

IMPLICATIONS TO BREEDING

The progress made in the IHP and IHO strains is such that the current means (20.5% oil in IHO and 30% protein in IHP) are approximately four and three times the means in the original population. Another way of measuring progress, which can be translated to other traits, is the number of additive standard deviations (σ_A) of progress made in a given strain. For IHO, gain was $21\sigma_A$, and for IHP, gain was $28\sigma_A$, for an average of $24\sigma_A$. These gains from selection are well beyond what might have been predicted from the distribution of oil and protein values in the original population. What would grain yields be if as much progress could be made for yield as was made for oil and protein? In two populations where good estimates of means and σ_A for grain yield were available, gains of $24\sigma_A$ were estimated as 33.3 and 27.4 t ha⁻¹ in the two populations. Predicted yield of the hybrid between the strains was 44 t ha⁻¹.^[4] Given that the average yield of corn in Illinois is approximately 9.1 t ha⁻¹, this means that yields could quadruple before reaching a limit. Thus the results from this experiment suggest that much more progress from selection may be made than is usually considered possible.

CONCLUSION

The limit to selection has not been reached for high protein or high oil. Thus continued gains are to be expected from additional generations of selection. By using newer techniques for identifying QTL in crosses of IHP × ILP and IHO × ILO, there is promise for identifying more QTL controlling oil or protein. Such studies should also identify QTL responsible for the negative correlation between protein and starch, or between oil and starch.

Continued use of the strains to study protein and oil metabolism should lead to enhanced understanding of genetic control of grain quality in corn.

Long-Term Selection: Repeatability of Response in Finite Populations

Bruce Walsh

The University of Arizona, Tucson, Arizona, U.S.A.

INTRODUCTION

With finite population size comes genetic drift, random change in allele frequencies because of random sampling of gametes to form the next generation. Even when loci are under selection, genetic drift is still potentially important in that favorable alleles can become lost from a population because of drift. A direct consequence of drift is considerable variation in the response to selection, even among initially identical replicate lines under identical selection. Under long-term selection, mutation introduces additional variation in response by introducing different mutations in different lines.

A SIMPLE EXAMPLE

Consider a cross between two inbred lines—the first fixed for favorable alleles (A, B) at two loci and the second fixed for favorable alleles at two different loci (C, D)—so that the resulting cross is $AABBccdd \times aabbCCDD$. All F_1 individuals are $AaBbCcDd$, carrying favorable alleles at each of the four loci. Genetically identical F_1 individuals form the replicate lines that are then subjected to identical selection.

If selection is weak on a favorable allele (as would occur if the allele has only a small effect on improving the trait of interest), the probability that the allele is fixed is near 1/2. Hence, when considering the A locus, 50% of the lines will eventually become AA ; the other 50% will be aa . In the absence of selection, the probability that a line will eventually be fixed for favorable alleles at all loci by chance ($AABBCCDD$) is $(1/2)^4 = 0.0625$. The probabilities that a line is fixed for favorable alleles at only three, two, or one loci are likewise found to be 0.25, 0.375, and 0.25. Thus one expects considerable genetic variation between lines, hence differences in the mean performance of the replicate lines. This variation is expected to occur even though the initial lines were completely identical and subjected to identical selection. Obviously, slight variations between the genetic composition of the initial lines and/or variation in the nature of selection on the lines will generate additional variation in line performance.

A final point is that lines identical in performance may, in reality, be fixed for different alleles. For example, two lines each fixed for two favorable alleles may (in fact) actually be genetically very different (e.g., $AABBcccc$ and $aabbCCDD$). Crossing these two fixed lines and selecting allow for the possibility of recovering a new line fixed for all four favorable alleles. Thus the amount of genetic variance between fixed replicate lines is of considerable importance in breeding. If the between-line genetic variance is high, crossing lines followed by a second round of selection can result in further improvement in the best performing lines. Similarly, if the variance is low, there is little to be gained by crossing and further selection.

VARIANCE IN LINE MEANS UNDER PURE DRIFT

The expected variation in the means of lines experiencing only drift provides a useful starting point for examining the expected variance in response under selection. In particular, if a trait is determined by a large number of loci each of small effect (so that selection is weak on each), the allelic frequency dynamics is often much closer to those expected under drift than to those for selection. Consider one locus with two alleles, Q and q , and suppose (relative to the mean trait value) that the genotypes $QQ:Qq:qq$ contribute values of $2a:a(1+h):0$ to the trait of interest. In a finite population, in the absence of mutation, eventually either allele Q or q is fixed. Under strict drift, the probability U that allele Q is fixed is just equal to its initial frequency p . Likewise, $1-U=1-p$ is the probability that allele q is fixed instead. Because ultimately the genotypes become either QQ or qq , the expected contribution from this locus becomes:

$$E[R] = 2ap + 0^*(1 - p) = 2ap \quad (1a)$$

For example, if QQ individuals are, on average, 4 cm taller than qq individuals, then $2a=4$, and if (say) the initial frequency of allele Q is $p=0.75$, the average response from this locus is $2ap=3$ cm. Recalling that we can write the variance of a random variable as $E(x^2) - \mu^2$, where μ is the mean value and $E(x^2)$ is the

average value of the square of the variable, the variance about the expected contribution becomes:

$$\begin{aligned}\text{Var}(R) &= (2a)^2p + 0^2(1-p) - R^2 \\ &= 4a^2p(1-p)\end{aligned}\quad (1b)$$

If the alleles show no dominance ($h=0$ so that the value of Qq is exactly intermediate to QQ and qq), the additive genetic variance V_A contributed by the locus equals $2a^2p(1-p)$; hence the variance in response is just twice the additive variance. Because the phenotypic covariance between a parent and its offspring is $V_A/2$,^[1,2] in theory, one could estimate the expected variance in response under strict drift from twice the parent-offspring covariance. When dominance or epistasis is present, this simple relationship between additive variance and variance in response no longer holds.

VARIANCE IN RESPONSE UNDER DRIFT AND SELECTION

When selection occurs, the above expressions for the expected mean and variance in response still hold, provided we replace p by U , the probability of fixation under drift and selection. Substituting U for p in the above expressions gives:

$$E[R] = 2aU + 0(1-U) = 2aU \quad (2a)$$

and

$$\begin{aligned}\text{Var}(R) &= (2a)^2U + 0^2(1-U) - R^2 \\ &= 4a^2U(1-U)\end{aligned}\quad (2b)$$

Figure 1 plots the variance in response as a function of U . Note that the variance achieves its maximum value (a^2) at $U=1/2$. Note from the figure that a mild amount of selection may actually *increase* the variance in response relative to that under strict drift. If Q is favored by selection, its probability of fixation is greater than under drift alone, so that $U > p$. If U is closer to $1/2$ than is p , this results in an increased variance in response (Fig. 1). For example, if $p=0.1$, then under drift $\text{Var}(R) = 4a^2p(1-p) = 0.36a^2$. However, if selection increases the probability of Q being fixed to $U=0.4$, then $\text{Var}(R) = 0.96a^2$. As selection on Q becomes stronger, the variance in response becomes significantly less than that under drift alone. Conceptually, this makes sense in that, if selection makes it likely that most favorable alleles are fixed, then there will be little variation between replicate lines in the alleles that are fixed. Consequently, when there is strong

Fig. 1 The variance in response (in units of a^2) as a function of the probability U that an allele is fixed.

selection on the underlying loci, there is little to be gained by crossing and reselecting replicate lines.

COMPUTING U , THE PROBABILITY OF FIXATION UNDER DRIFT AND SELECTION

To obtain the probability U of fixation of allele Q , we need an expression that relates U to fitness on genotypes and an expression relating how selection on a character translates into fitness at the underlying loci. Suppose the fitness and character values are:

Genotype	QQ	Qq	qq
Fitness	$1 + 2s$	$1 + s$	1
Character value	$1 + 2a$	$1 + a$	1

For these fitness, Kimura^[3] showed that if Q starts at frequency p , its probability of fixation is:

$$U = [1 - \exp(-4Nsp)]/[1 - \exp(-4Ns)] \quad (3)$$

where N is the population size and $\exp(x)$ is the exponential function, e^x . If $4N|s| \ll 1$, $U=p$, and the allele behaves as if it is neutral.

It remains to obtain s as a function of the selection on the trait and the effect of the individual alleles. For a locus underlying a trait under selection, the associated selection coefficient s is approximately:

$$s = (a/\sigma_z)i \quad (4)$$

σ_z is the square root of phenotypic variance of the trait and i is the selection intensity on the character (e.g., if the

upper 20%, 10%, or 5% of the population is saved, $i=1.4$, 1.7, and 2.0). Details are given in Walsh and Lynch.^[4] Thus $U(p)$ only deviates significantly from p when $2N(1-p)(a/\sigma_z)i$ is significantly large. If the product of population (N), individual allelic effect (a/σ_z), and selection (i) on the trait is small, the allele is largely controlled by drift. Using Eqs. 3 and 4, the fixation probability of a favorable allele will exceed 0.7 when:

$$N|i|p(|a|/\sigma_z) > 0.5 \quad (5)$$

Thus if the product of initial allele frequency and standardized allelic effect (a/σ_z) is small, many favorable alleles will be lost. Conversely, if Eq. 5 holds, most favorable alleles are fixed, and the resulting variance in response is small. In such cases, crosses between replicate lines are unlikely to generate significant additional variation for subsequent selection.

THE EFFECTS OF MUTATION

In addition to the variance introduced by drift, additional variation is continually generated by mutation. Let V_M denote the amount of variation introduced in each generation by mutation. Under a pure drift model, the increase in between-line variance from drift for lines separated for t generations approaches $2tNV_M$, which can be substantial. Thus crosses between replicate lines that have been separated for long periods can show considerable potential for additional response. Hill^[5] examines the expected divergence when selection on the underlying loci is strong relative to drift.

CONCLUSION

Considerable variation between the performance of selected replicate lines is expected from both drift and mutation. If selection on any underlying locus is small, considerable variation in response is expected. Crosses between such replicate lines generate significant genetic variation for further selection. If selection is strong on each underlying locus, there is little between-line variation, and selection on crosses between the lines is not expected to result in significant improvement.

Male Gametogenesis

David Honys

Academy of Sciences of the Czech Republic, Praha, Czech Republic

David Twell

University of Leicester, Leicester, U.K.

INTRODUCTION

The haploid male gametophytes of higher plants play a vital role in plant fertility and crop production through the generation and transport of the male gametes to ensure fertilization and seed set. There has been an evolutionary tendency toward reduction of the male gametophyte and its increasing functional dependence on the sporophyte. This trend is most acute within flowering plants, such that the male gametophyte consists of just two or three cells when shed as pollen grains. Despite its diminutive form, the functional specialization of the male gametophyte is thought to be a key factor in the evolutionary success of flowering plants through mechanisms that promote rigorous selection of superior haploid genotypes and outbreeding.

This article describes the sequential phases of angiosperm pollen development—microsporogenesis and microgametogenesis—emphasizing the vital role of the cell wall interface and sporophytic-gametophytic interactions. This article further describes recent progress in genomewide studies of haploid gene expression, genetic approaches that are being used to identify genes required for key cellular processes, and aspects of pollen biotechnology in crop improvement.

POLLEN DEVELOPMENT: FROM MICROSPOROCTE TO MATURE POLLEN

Microsporogenesis and microgametogenesis take place inside the anther loculi that are lined by the tapetal cell layer (tapetum). Microsporogenesis is initiated upon meiotic division of the diploid pollen mother cell (microsporocyte) that produces four haploid microspores composing a tetrad^[1,2] (Fig. 1). During microgametogenesis, microspores released from the tetrads undergo cell expansion, cell wall synthesis, asymmetric division, and differentiation of the vegetative and generative cells before partial desiccation and release from the anther. The tapetal cells play a major role in pollen development through their contribution to microspore release, nutrition, pollen wall

synthesis, and pollen coat deposition. Disturbance of tapetal cell functions usually results in reduced pollen fertility or male sterility through a variety of mechanisms, including arrest of microgametogenesis at the microspore stage or altered pollen hydration through modified pollen coat composition.

Microsporogenesis

A unique feature of the walls surrounding the microsporocytes and newly formed microspores within the tetrad is that they consist largely of callose, a β -1-3-glucan. The callose wall is secreted by microsporocytes before meiosis I and separates the microspores within the tetrad following meiosis II (Fig. 1). Microspores begin to synthesize the first elements of the sculptured outer pollen wall layer (exine), starting with primexine that functions as a template for subsequent exine elaboration. When young microspores are still developing the exine within the tetrad, an enzyme complex (callase) is secreted by the tapetal cells, allowing individual microspores to be released from the tetrads. Correct timing of callase secretion is critical because premature or delayed dissolution of the callose wall results in male sterility.^[3]

Microgametogenesis

Once released, free microspores increase in size and their multiple small vacuoles enlarge and fuse into a single large vacuole, occupying most of the volume of the cell. In concert, the microspore nucleus migrates to a peripheral position that is required for the subsequent asymmetric division at pollen mitosis I (PMI)^[4,5] (Fig. 1). PMI results in two morphologically and functionally distinct cells—a large vegetative cell and a small generative cell. The generative cell subsequently becomes engulfed within a membrane-bound compartment in the cytoplasm of its vegetative sister. This involves dissolution of the hemispherical callose wall separating the vegetative and generative cells, inward migration, and membrane fusion events. The asymmetric division at PMI is a key determinative event in generative cell fate.^[6]

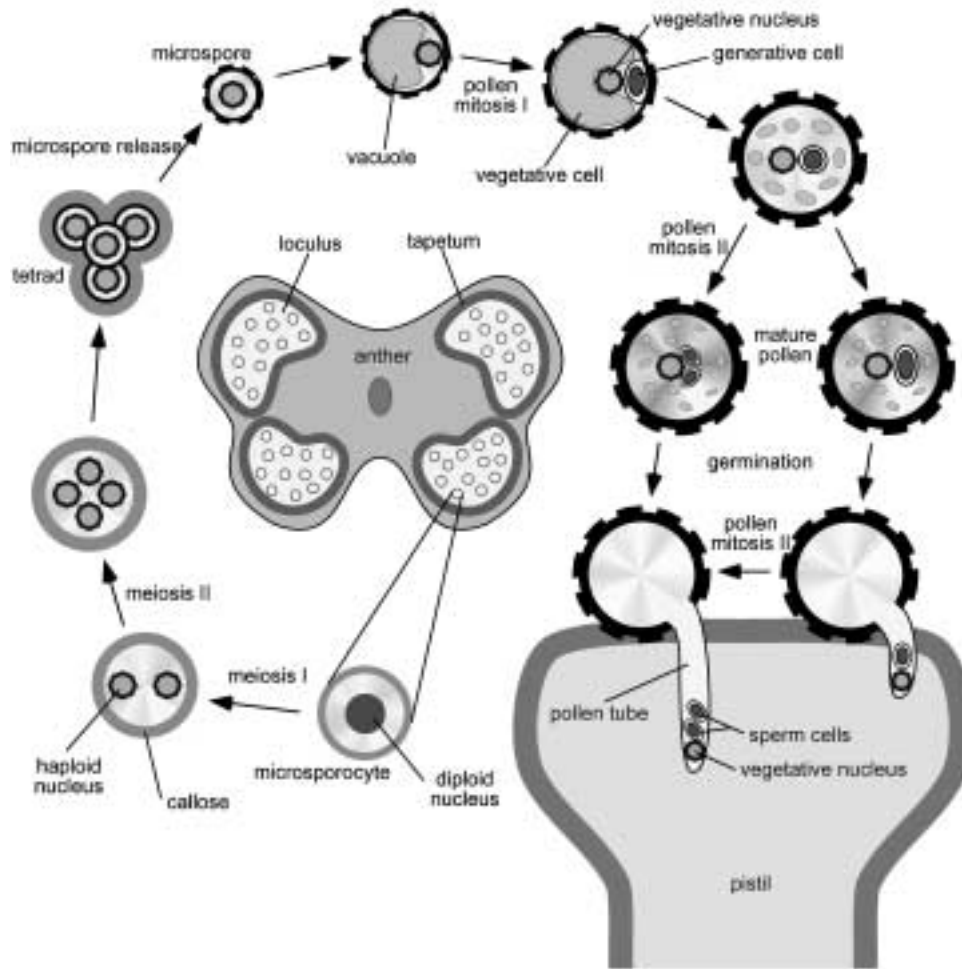

Fig. 1 Schematic diagram illustrating pollen development. (View this art in color at www.dekker.com.)

Fig. 2 Bicellular and tricellular pollen. (A) Bicellular tomato and (B) tricellular oilseed rape pollen-stained with the DNA stain DAPI. Nuclear DNA within the vegetative (V) and generative (G) or vegetative (V) and sperm cells (S) are highlighted. (View this art in color at www.dekker.com.)

In microspores and immature pollen cultivated in vitro, gametophytic development can be switched to a sporophytic pathway by heat stress and/or starvation treatment, leading to microspore embryogenesis and haploid plant formation.^[2] Such techniques are routinely applied to accelerate breeding programs through the rapid generation of double haploid plants and selection among large numbers of homozygous lines.

The generative cell undergoes further mitotic division at pollen mitosis II (PMII) to produce the two sperm cells. In tricellular pollen this division occurs within the anther, whereas in bicellular pollen it occurs within the growing pollen tube. Although the majority of flowering plants produce bicellular pollen, many important food crop plants such as rice, wheat, and maize produce advanced but often short-lived tricellular pollen grains (Fig. 2).^[2]

During pollen maturation the vegetative cell accumulates considerable carbohydrate and/or lipid reserves that are transient or are stored in the mature pollen grain. Transient reserves are thought to provide metabolites for energy-demanding developmental events such as asymmetric division and pollen cell wall (intine) synthesis. Osmoprotectants including proline also accumulate in mature pollen grains to protect vital membrane and proteins from damage. In mature pollen grains the extensive stores of lipids and polysaccharides are required to supply the extensive demands for plasma membrane and pollen tube wall synthesis.

During dehydration, the final phase of pollen maturation, pollen grains are finally prepared for release from the anthers. This represents an adaptation to survive exposure to the hostile terrestrial environment. The extent of dehydration varies widely in different species; for example, in poplar the water content is reduced to only 6%, maize loses 50%, whereas cucumber pollen remains fully hydrated. The degree of dehydration and the levels of cytoplasmic reserves positively correlate with pollen fitness and viability. Hydrated pollen is very susceptible to dehydration stress and generally survives only a few hours, whereas fully dehydrated pollen may survive for months or even years under certain conditions.

THE POLLEN WALL—A VITAL INTERFACE

The unique activities and biological role of the pollen grain are reflected in the unique composition of the pollen wall. The pollen wall and its coatings isolate and protect the male gametophyte and its associated gametes and mediate the complex communication with the stigma surface. The pollen wall consists of an inner intine and outer exine layer. Its synthesis begins at the microspore stage, when the pectocellulosic intine and the primexine are formed. The primexine serves as a matrix for sub-

sequent deposition of sporopollenin. Sporopollenin is a highly resistant biopolymer containing fatty acids and phenylpropanoids; its synthesis involves tight cooperation between microspore cytoplasm and tapetal cells. The exine is not evenly distributed over the pollen grain surface, and regions lacking sporopollenin form apertures that are used as sites for pollen tube emergence. The number and size of apertures and exine patterning are under strict sporophytic control.

The formation of pollen coatings is completed at later stages of microgametogenesis. Remnants of degenerating tapetal cells are deposited onto the pollen grain surface creating the pollen coat. The pollen coat is involved in pollen–pistil signalling, self-incompatibility, pollen hydration, adhesivity, color, and odor. The yellow or purple colors of mature pollen grain results from the presence of both carotenoid and phenylpropanoid compounds. These features, as well as the elaborate patterning of sporopollenin, are highly variable among different plant species. In animal-pollinated species, pollen is often decorated with elaborate structures that facilitate vector adhesion, whereas in wind-pollinated species, pollen lacks such sculpturing or may be decorated with air sacs to increase buoyancy (Fig. 3).

HAPLOID GENE EXPRESSION

Development of the male gametophyte is associated with an extensive haploid gene expression program. To date, approximately 150 pollen-specific genes falling into 50 functional classes have been cloned from various species.^[4,7] Recent genomewide studies using microarray hybridization technology have comprehensively demonstrated the scale and diversity of haploid gene expression in *Arabidopsis thaliana*.^[8] Mature *Arabidopsis* pollen grains express approximately 5000 different mRNA species out of more than 27,000 predicted from the *Arabidopsis* genome. Approximately 40% of these transcripts are predicted to be preferentially or specifically expressed in pollen. Moreover, there is significant overlap between sporophytic and male gametophytic gene expression that reflects the large proportion of genes that are required for basic cellular functions. The most abundant classes of pollen-specific genes are predicted to have functions associated with transcriptional regulation, signal transduction, cytoskeleton organization, and cell wall synthesis. This highlights the importance of these functions for the unique cellular specialization required for pollen differentiation and function.

Interestingly, some of these pollen-specific genes encode proteins representing major allergens, the cause of hayfever and allergic asthma. Recent work has shown that the expression of one class of allergens from ryegrass

Fig. 3 Pollen morphology and wall patterning. Scanning electron micrographs of (A) pine, (B) papaya, (C) passion flower, and (D) sunflower pollen. Bar length = 10 μm .

pollen can be reduced without significant impact on plant fertility,^[9] indicating that the genetic engineering of hypo-allergenic cultivars is possible.

Pollen-expressed genes have also been classified according to their temporal regulation. In addition to constitutively expressed genes, groups of early genes active in microspores and late genes acting after PMI have been identified. The late-pollen genes and their regulation have been most intensively studied, resulting in the functional dissection of several pollen-specific transcriptional and translational regulatory elements.^[7]

GENETIC APPROACHES: MUTANTS AND DEVELOPMENT

Renewed interest in genetic analysis and the use of the model species *A. thaliana* have had a significant impact on the identification of gametophytic genes controlling pollen development. Successful mutant selection approaches have been devised that involve screening for aberrant pollen morphogenesis or marker-segregation ratio distortion in populations of plants treated with chemical or physical mutagens or by T-DNA or transposon-mediated mutagenesis.^[4]

Morphogenesis screens have led to the identification of a number of mutants with novel phenotypes that affect

processes throughout microgametogenesis (Table 1). These include mutants that disturb asymmetric cell division at pollen mitosis I,^[6,10,11] division of the generative cell division,^[4,6] the positioning and structure of the male germ unit,^[12] and the repression of pollen germination within the anther.^[13] Among these, the *gemini pollen1* (*gem1*) mutation has been tracked to a microtubule-associated protein with strong similarity to the human chTOG and *Xenopus* XMAP215 family of microtubule-associated proteins that stimulate plus-end microtubule growth.^[11] The GEM1 protein plays a vital role in microspore polarity and cytokinesis through its involvement in microtubule assembly, and is associated with interphase, spindle, and phragmoplast microtubule arrays.^[11] Further exciting discoveries are expected to arise from the identification of the mutant genes responsible for other gametophytic phenotypes described in Table 1.

Screening for gametophytic mutants using marker-segregation ratio distortion has also been used to identify genes involved in microgametogenesis and/or postpollination events including pollen germination, tube growth, and guidance to the ovule. These screens have mostly employed T-DNA or transposon insertion populations that harbor dominant antibiotic or herbicide resistance markers. For example, if a DNA insertion inactivates an essential male gametophytic gene, then the ratio of resistant to sensitive progeny will deviate significantly

Table 1 Gametophytic mutations and genes that affect pollen development in *Arabidopsis thaliana*

Gene	Mutant	Mutant phenotype	Function	Protein identity	Ref.
<i>BOD</i>	<i>both male and female gametophytic defective</i> (1,2,3)	Pollen arrested during bicellular development with pleiotropic effects	Pollen maturation after pollen mitosis I	ND	[17]
<i>DUO</i>	<i>duo pollen</i> (1,2,3,4,5,6)	Pollen fails to enter or complete generative cell division	Generative cell morphogenesis and cell cycle progression	ND	[4]
<i>EFP</i>	<i>emotionally fragile pollen</i>	Pollen shows diffuse callosic staining	Repression of callose synthesis during pollen maturation	ND	[13]
<i>GEM</i>	<i>gemini pollen</i> (1,2)	Twin-celled and binucleate pollen formed as a result of abnormal division at pollen mitosis I	Regulation of microspore polarity and cytokinesis through microtubule organization	GEM1: Homologous to chTOGp/XMAP215 family of microtubule-associated proteins	[4,11,12]
<i>GUM</i>	<i>male germ unit malformed</i>	Sperm cells separated from the vegetative nucleus	Association of vegetative nucleus and sperm cells	ND	[12]
<i>GWP</i>	<i>gift wrapped pollen</i>	Pollen contains internal callosic tube-like structures	Regulation of callose synthesis	ND	[13]
<i>HAM</i>	<i>halfman</i>	Pollen degenerates during bicellular stage	Pollen maturation after pollen mitosis I	~150 kb deletion including 38 predicted genes	[18]
<i>LIP</i>	<i>limpet pollen</i>	Generative cell remains attached to pollen wall	Required for GC internalization	ND	[15]
<i>MAD</i>	<i>male gametophytic defective</i> (1,2,3)	Pollen arrested during bicellular development	Pollen maturation after pollen mitosis I	ND	[17]
<i>MUD</i>	<i>male germ unit displaced</i>	Male germ unit displaced to the cortical cytoplasm in mature pollen	Regulation of nuclear-cytoplasmic organization	ND	[12]
<i>PDP</i>	<i>polka dot pollen</i>	Pollen shows localized callose staining	Regulation of callose synthesis	ND	[13]
<i>RTG</i>	<i>raring-to-go</i>	Precocious germination of pollen within the anther locule	Regulation of pollen hydration status	ND	[13]
<i>SCP</i>	<i>sidecar pollen</i>	Pollen with an extra vegetative cell resulting from early symmetric microspore division	Control of microspore division timing or polarity establishment	ND	[10]
<i>TDT</i>	<i>T-DNA transmission defective</i> (6,17,38,40)	Aborted mature pollen	Pollen maturation	ND	[14,16]
<i>TIO</i>	<i>two-in-one</i>	Microspores fail to initiate or complete cytokinesis following pollen mitosis I	Regulation of phragmoplast structure and/or function	ND	[4]

Only gametophytic mutants that show phenotypes that are detectable before pollen germination are included. Mutations affecting male meiosis and postpollination events are excluded.

In the column labeled 'mutant,' the numbers in parenthesis refer to individual mutants with the same mutant symbol prefix.

ND = not determined.

below the expected 3:1 ratio toward 1:1. A number of tagged mutants have now been identified that affect microgametogenesis, pollen germination or pollen tube growth.^[14–16] Continued effort in screening and the isolation of tagged genes is expected to lead to a sophisticated genetic map of gametophytic proteins that function during microgametogenesis and postpollination events.

CONCLUSION

The quest to achieve a comprehensive description of the cellular, molecular, and genetic events that control pollen development is not only of fundamental interest, but may find application in the production and genetic improvement of crops. Current knowledge is applied in several areas of crop production, including crop yield optimization and hybrid seed production, and in the production of economic products such as honey and pharmaceuticals. The recent progress in mutational and genome-wide analysis now provides enormous potential to develop new strategies for the molecular dissection and modification of pollen development and functions.

Mammalian Cytokines Produced in Plants

Chihiro Sugimoto

Obihiro University of Agriculture and Veterinary Medicine, Obihiro, Japan

INTRODUCTION

In the classical definition, cytokines are humoral factors secreted from the lymphocytes or monocytes of animals, known as lymphokines and monokines or interleukins as a generic term, and they regulate host immune systems. But now, chemokines, growth factors, and antiviral proteins produced by cells from nonlymphoid origins are included in the cytokine family, and more than 40 proteins are listed.

As more molecules are included in this category, their roles have further expanded to cell growth regulation, antiviral activity, cell differentiation of nonlymphoid cells including those in the nervous system, and the epithelial cells.

The clinical use of cytokines is in the treatment field of neoplastic and viral diseases, and interferon α and β , IL-2, and GCSF have been used for the treatment of neoplastic and viral diseases. Other cytokines may have potential clinical use in tissue regeneration, healing, and for autoimmune diseases. Cytokine receptors and antibodies against cytokines may also be used for therapy of diseases caused by disorder of cytokine network systems including autoimmune diseases.

Updated information including protein and structures, biological activity, receptors, and clinical significance are listed in the references.^[1,2]

EXAMPLES OF PLANT-EXPRESSED CYTOKINES

In the initial phase of research, the expression of antiviral cytokines such as interferon β in plants aimed to produce virus-resistant plants, rather than to produce pharmaceuticals. Although the expression of cytokines themselves did not make plants virus-resistant, the introduction of a mammalian 2-5A oligoadenylate system, one of the interferon-induced antiviral pathways, confers virus resistance.^[3]

Examples of cytokines produced in plants using transgenic or plant viral vector systems are listed in

Table 1. The activity of plant-expressed cytokines is determined in *in vitro* bioassays by using corresponding indicator cells or inhibiting virus replication. Expression levels vary from picograms to micrograms per gram of tissue, but higher expression levels have been achieved by plant viral vector systems. Most cytokines contain intramolecular disulfide linkages that are essential for biological activity. Some cytokines form covalently or noncovalently linked homo or hetero di-, tri-, or tetramers. For example, IL-12 is the heterodimer of p35 and p45 and this heterodimerization is essential for its bioactivity, and TNF α forms a homodimer or trimer. For this reason, their higher structures must remain intact when produced as recombinant polypeptides. In our study, successful expression of biologically active TNF α in the potato plant cells revealed that recombinant products,^[4] which should be multimeric to exert its functions, can be expressed in plant expression system.

The cleavage of signal peptides and the processing of larger precursors may also be essential for bioactivity. For example, because IL-18 should be cleaved by an intracellular proteinase, the coexpression of the enzyme is essential for producing biologically active IL-18.

We could not detect the expression of bovine IL-2 in transgenic tobacco, when we introduced the cDNA with the deleted signal peptide nucleotide sequence. On the other hand, when we introduced the cDNA fragment of bovine IL-2 containing the authentic signal peptide sequence, the transgenic tobacco plants expressed bioactive IL-2 (Sugimoto, C. and Matsumura, T., unpublished observation). In addition, the Western blot analyses of TNF α -transgenic tobacco indicated that proper cleavage of signal peptide occurred in plants because the TNF α band in transgenic plants was found at the same position as that of mature TNF α molecules produced by human cells.^[4] These results suggested that the signal peptides of cytokine molecules may function in plant and are essential for their expressions.

Although production of bioactive cytokines in plants has been reported, there is no information about whether these plant products are used in clinical studies at present.

ADVANTAGES OF PLANT EXPRESSION SYSTEMS

Natural forms of human cytokines are usually produced using human cells stimulated by induction reagents, such as RNA virus, bacterial lipopolysaccharide, etc., but this

production system requires costly cell culture facilities. In addition, safety regulations for animal-derived materials used for animal cell culture such as bovine serum have become a big issue in pharmaceutical industries. Usually, cytokines exhibit their biological activity at the concentrations of nanograms to picograms per milliliter order.^[5]

Therefore their production cost per dose will be much lower than that of the antibodies which is required at the dose of micrograms per milliliter order. However, safer and cheaper production systems are still required.

As animal cells can also produce various cytokines and other bioactive molecules responding to stimuli, these byproducts must be removed during the purification process.

Transgenic animal systems are a possible approach to producing human proteins. However, a problem with cytokines is that several human cytokines are also active in nonhuman species, and their consistent production in any tissue at high doses may have deleterious effects on the homeostasis of the host animal.

Production in bacterial and yeast expression systems are also possible. However, bacterial or yeast products are unglycosylated, or differently glycosylated from authentic molecules, which may produce different results *in vivo* if they are injected into the human body. In addition, several cytokines are produced in inactive or insoluble form in bacterial and yeast cultures, and protein refolding or solubilization processes are required to recover bioactive products.

Recently, we investigated whether orally administered human IFN α (HuIFN α) can augment protection against systemic bacterial infection.^[6,7] Daily oral administrations for 6 days of purified natural HuIFN α reduced bacterial burden in spleen and liver from *Listeria monocytogenes*-infected mice. This effect was observed in the middle phase of *L. monocytogenes* infection, but not in the early phase of the infection. Effects of oral administration of HuIFN α expressed in potato plant^[7] were also examined in this infection model. Daily oral administrations of extracts of the transgenic potato tuber for 6 days decreased bacterial burden in the spleen. Lower doses of HuIFN α in the extracts (20 IU/mouse/day) exerted a protective effect at almost the same level as the results achieved by the administration of 1000 IU of HuIFN α . This oral delivery method may open a new area in the clinical use of plant-based cytokines.

DISADVANTAGES OF PLANT EXPRESSION SYSTEMS

Most cytokines have one or more *N*- or *O*-glycosylation sites, and natural molecules are glycosylated. Generally, glycosylation of cytokines does not affect their *in vitro* activity, but it significantly affects *in vivo* stability and activity. Plants and mammals differ in the construction of *N*-glycans. Moreover, plant glycans lack *N*-acetylneuraminic acid residue, which affects the biological activity

of some plant-expressed cytokines. A typical example is erythropoietin (EPO). Unglycosylated EPO produced in bacterial cells does not show any *in vivo* activity, and tobacco-derived EPO is not effective *in vivo* probably due to difference in sugar modification in plants.^[8]

As the *in vivo* activity of several other cytokines are reported to be affected by glycosylation,^[9] animal-type carbohydrate modification is required for cytokines used therapeutically. In addition, plant-specific sugar modification such as α 1–3 fucosylation and β 1–2 xylosylation could alter the *in vivo* activity of glycosylated cytokines and produce unexpected side effects including an immune reaction to these structures.

CONCLUSION

Plant production may be useful for cytokine production with regard to production cost, infrastructure investment, biological safety, and production of fully bioactive forms. Cytokine-producing plants raise concerns about safety. As cytokines are highly bioactive products, environmental contamination or contamination of the food chain may cause serious problems in human and animal health. Therefore guidelines with special consideration for culturing in fields, harvesting, and processing pharmaceutical-producing plants should be established as a matter of priority.^[10]

Management of Bacterial Diseases of Plants: Biological Control

Mark Wilson

The Colorado College, Colorado Springs, Colorado, U.S.A.

INTRODUCTION

While several biological control agents are commercially available for fungal plant pathogens,^[1–4] relatively few are available for bacterial plant pathogens. This chapter will discuss the characteristics and applications of two of the more successful commercially available biological control agents, NOGALL™ and BlightBan™ A506, as well as some novel approaches being examined for the control of bacterial speck and bacterial spot of tomato. Finally, the chapter will speculate on the future of biological control of bacterial diseases in commercial agriculture.

COMMERCIALY AVAILABLE BIOLOGICAL CONTROL AGENTS

Biological Control of Crown Gall

The most successful biological control agent for a bacterium is *Agrobacterium radiobacter* strain K84, developed for the control of crown gall. Kerr discovered that application of *A. radiobacter* strain K84 to bare roots or cuttings prior to planting effectively prevented crown gall development. The mode of action is thought, in part, to be production of the bacteriocin agrocin 84. Until recently, in the United States *A. radiobacter* strain K84 had been available as Galltrol™, supplied as a culture on an agar plate, and Norbac 84C™, supplied as a liquid suspension. Currently, only Galltrol™ is available^[2] (Table 1). Concerns about the lateral transfer of the plasmid that encodes bacteriocin resistance to *Agrobacterium tumefaciens*, leading to loss of efficacy of the biological control agent, prompted the development of the genetically modified *A. radiobacter* strain K1026 with a nontransferable plasmid. NOGALL™, the product based on strain K1026 (Table 1), was the first U.S. Environmental Protection Agency (EPA)-approved, commercially available biological control agent based on a genetically modified organism.^[2] The success of this biological control agent is evidenced by its longevity in the market and worldwide usage. This success might also be

attributed to the absence of alternative control products, the widespread occurrence of the disease, and the production and distribution by small companies. While much of the biological success may be attributable to the application of the organism to the plant, rather than soil, other factors remain unclear. An analysis of such factors might be informative for the development of future biological control agents of phytopathogenic bacteria.

Biological Control of Fire Blight of Pear and Apple

Fire blight of apple and pear, caused by *Erwinia amylovora*, occurs throughout the pome-fruit production areas of the United States, Europe, New Zealand, and Israel. BlightBan™ A506, based on *Pseudomonas fluorescens* strain A506^[2,5,6] (Table 1), is used widely for fire blight management in California, Oregon, and Washington. This biological control agent is applied to apple and pear blossoms at the start of bloom and colonizes the blossom, preemptively excluding the pathogen.^[6] The success of this biological control agent is due to its activity against more than one target pathogen and its compatibility with standard chemical-based practices. In addition to *E. amylovora*, BlightBan™ A506 also protects blossoms against frost injury, caused by ice nucleation-active *Pseudomonas syringae* strains, and protects developing fruit against russet, caused by indole-3-acetic acid-producing bacteria. BlightBan™ A506's compatibility with streptomycin, routinely used in pear orchards for fire blight control, not only provides additive protection,^[5] but has also facilitated the adoption of this product by growers. The search for strains superior in efficacy or complementary to *P. fluorescens* A506 continues. *Pantoea agglomerans* (*Erwinia herbicola*) C9-1, registered with the U.S. EPA as BlightBan™ C9-1 (Table 1), is superior to BlightBan™ A506 under certain environmental conditions, and when used with A506 it extends the environmental conditions under which the product is effective. However, *P. agglomerans* C9-1 is unlikely to be developed commercially due to concerns about taxonomic relatedness to human pathogens. Despite these concerns, two other *P. agglomerans* strains have been developed

Table 1 Commercially available biological control agents

Biological control product	Producer	Biological control agent	Target disease
Agriphage™	Agriphi	H-mutant bacteriophages	Bacterial spot of tomato
BlightBan™ A506	Plant Health Technologies	<i>Pseudomonas fluorescens</i> A506	Fire blight, frost injury, and russet of pear
BlightBan™ C9-1	Plant Health Technologies	<i>Pantoea agglomerans</i>	Fire blight
Bloomtime Biological™	Northwest Agricultural Products	<i>P. agglomerans</i> C9-1	Fire blight
Blossom Bless™	HortResearch, New Zealand	<i>P. agglomerans</i> P10c	Fire blight
Galltrol™	AgBioChem, Inc.	<i>Agrobacterium radiobacter</i> K84	Crown gall
NOGALL™	New BioProducts, Inc.	<i>Agrobacterium radiobacter</i> K1026	Crown gall

commercially, as Bloomtime Biological™ and Blossom Bless™ (Table 1), and assuming there are no health issues associated with these products, we may see increasing use of *P. agglomerans* in the biological control of fire blight.

BIOLOGICAL CONTROL AGENTS IN DEVELOPMENT

Biological Control of Bacterial Spot and Bacterial Speck of Tomato: A Model System

The biological control of bacterial spot, caused by the pathogens *Xanthomonas campestris* pv. *vesicatoria* and *Xanthomonas vesicatoria*, and bacterial speck, caused by *Pseudomonas syringae* pv. *tomato*, has served as a model system for the investigation of different approaches to biological control of foliar bacterial diseases.^[7-10] Interestingly, *P. fluorescens* A506 provided significant control of bacterial speck under field conditions.^[7] However, while BlightBan™ A506 is registered for use on tomatoes for frost protection, the level of bacterial speck control was not adequate to justify commercial development for this purpose.^[7] Surprisingly, the most effective biological control agent of bacterial speck^[7] and bacterial spot^[8] was *P. syringae* strain Cit7, an ice nucleation-active strain recovered from citrus. Unfortunately, even the most effective strain provided an average of only ~30% reduction in disease severity. Furthermore, the biological control agents rarely improved marketable fruit yields.^[7,8]

The use of nonpathogenic *hrp* (hypersensitive response and pathogenicity) mutants of pathogens as potential biological control agents has been reported for *Ralstonia solanacearum* and *E. amylovora*. Nonpathogenic *hrp* mutants of *X. campestris* pv. *vesicatoria* and *P. syringae* pv. *tomato* were examined as potential biological control agents of bacterial spot and speck of tomato, respectively.^[7,9] While *hrpA*, *hrpH*, and *hrpS* mutants of *P. syringae* pv. *tomato* provided significant protection against bacterial speck under greenhouse conditions, only

the *hrpS* mutant reduced disease in the field and it was not superior to *P. syringae* Cit7.^[7] In contrast, the *hrpX* and *hrpG* mutants of *X. campestris* pv. *vesicatoria* provided significant reductions in bacterial spot severity under field conditions, and the *hrpG* mutant was almost as effective as Actigard™, an activator of plant defenses. The mode of action with the *hrpG* mutant appears to be a dramatic induction of local resistance in the host tissues. Whether the *hrp* mutants of *P. syringae* pv. *tomato* do not induce such host resistance or *P. syringae* pv. *tomato* is not as sensitive to induced host resistance mechanisms is not known. However, it is clear that the host response to *hrp* mutants is not universal, as *hrpE* and *hrpB* mutants of *X. campestris* pv. *vesicatoria* were relatively ineffective as biological control agents. Further development of *hrp* mutants therefore will clearly require a greater understanding of host response.

In an attempt to achieve higher levels of control of bacterial spot and speck, different approaches have been integrated. *Pseudomonas fluorescens-putida* 89-B61 applied to tomato seed and roots provided significant protection against bacterial speck and bacterial spot in the field. Presumably, this is through induction of systemic resistance in the host, although the possibility of foliar colonization and direct interaction with the pathogens cannot be excluded.^[10] Unfortunately, the combination of foliar-applied *P. syringae* Cit7 and *P. fluorescens-putida* 89-B61 applied to the seed and roots provided greater control than either biological control agent in only a few instances.^[10] This failure to achieve additive levels of protection illustrates that it is important to integrate complementary disease control mechanisms and not just complementary control approaches. For example, we speculate that Cit7 may provide protection through induction of host responses; hence if the signal transduction pathways and host responses induced by Cit7 are similar to those induced by the *P. fluorescens-putida* 89-B61, then one would not expect additive effects in disease control.^[10] It is also possible that the biological control agents may be

antagonistic in their activities. Despite spatial separation, if the systemic resistance induced by the rhizobacterium inhibits colonization by the foliar biological control agent, there will be reduced biological control activity. Clearly, integration is neither simple nor guaranteed to provide superior levels of disease control.

Another approach to biological control of bacterial spot of tomato has been developed based on bacteriophages.^[11] Agriphage™ (Table 1), a mixture of bacteriophages, against which the pathogen is unlikely to evolve resistance, has been successfully applied for the control of bacterial spot under field conditions in Florida,^[11] and this novel product is being adopted by the local growers. It may be possible to incorporate phage into an integrated control strategy against both bacterial spot and bacterial speck, along with rhizobacteria, that induce systemic resistance, or with chemical plant activators.

THE FUTURE OF BIOLOGICAL CONTROL OF BACTERIAL PLANT DISEASES

While there are relatively few chemicals available for disease control, and antibiotic and copper resistance continues to be a problem, losses due to bacterial diseases in the United States and Europe are too small to attract investment by the agbiotech industry. While losses due to phytopathogenic bacteria are significantly greater in developing tropical and subtropical countries, these countries often lack the expertise or funding to develop biological control agents. If developed for diseases such as bacterial spot of tomato, biological control agents will probably be marketed by small companies, such as those that market NOGALL™ and BlightBan™ A506,^[2] or produce the bacteriophage mixtures (Table 1).

One of the most promising approaches is the induction of systemic or local host resistance either by living biological control agents, maybe *hrp* mutants or rhizobacteria; bacterial cell components, such as extracellular polysaccharides, lipopolysaccharides, or flagellin; or bacterial products, such as harpin. These approaches will require significant investment in developing an understanding of antibacterial plant responses and the factors triggering them. Such data are now becoming available.

Management of Bacterial Diseases: Chemical Methods

Donald L. Hopkins

University of Florida, Apopka, Florida, U.S.A.

INTRODUCTION

Bacterial diseases of plants are difficult to control when environmental conditions favor the pathogen's proliferation. Bacterial disease control often requires a combination of management measures including host resistance, sanitation, cultural practices, and chemicals. Copper-based bactericides and antibiotics, primarily streptomycin and oxytetracycline, are commonly (if imperfectly) used in the management of bacterial plant diseases. In addition to disease management with copper bactericides and antibiotics, the future role of plant defense activators in the control of bacterial diseases will be discussed.

ANTIBIOTICS AND MANAGEMENT OF BACTERIAL DISEASES OF PLANTS

With the introduction of antibiotics in human medicine in the 1950s, their potential in plant disease control was investigated. Although many antibiotics have medical and veterinary uses in the United States, only streptomycin and oxytetracycline currently are used on crop plants, but gentamycin is used in Mexico and several Latin American countries, and quinolones, such as oxolinic acid, are used in Israel for fire blight management.^[1] However, the widespread occurrence of resistance to copper-based bactericides such as streptomycin often result in less than desirable levels of control (Table 1).

Antibiotics are used on a small proportion of the crops grown in the United States. Antibiotics are expensive; therefore they are used on high-value crops where the cost is not prohibitive. The primary uses are on fruit trees, such as apple, pear, peach, and nectarine, but other minor uses include ornamental trees, floriculture crops, celery, pepper, potato, tomato, and tobacco. Because of high efficacy and low phytotoxicity, streptomycin is the antibiotic of choice in the United States. Where bacterial pathogens are resistant to streptomycin, oxytetracycline is often used. Externally applied antibiotics or copper is not systemic, but oxytetracycline has been injected into the trunks of trees to control diseases caused by internal bacteria or phytoplasmas.^[3]

Applications of streptomycin and oxytetracycline to plants account for less than 0.5% of total antibiotic use in

the United States.^[1] Whereas streptomycin is bactericidal, oxytetracycline is bacteriostatic. In general, these two antibiotics provide effective control of bacterial diseases of plants, but both have major shortfalls. Streptomycin only remains active on plant surfaces for about 3 days and oxytetracycline is active only for about a day. Thus it is essential to make frequent applications of antibiotics throughout the growing season, which often results in the development of resistance to the antibiotic. The use of streptomycin or oxytetracycline reduces the population of antibiotic-sensitive bacteria, thus favoring the increase of antibiotic-resistant bacteria. Resistance can arise by two distinct mechanisms. The most common is by mutation of a chromosomal gene that reduces binding of the antibiotic to the ribosome, resulting in bacterial strains that are highly resistant and stable. The second mechanism involves the acquisition of a plasmid encoding streptomycin-inactivating enzymes, resulting in moderately resistant strains.^[1] One strategy to avoid or delay the onset of antibiotic resistance is to not use a single antibiotic continuously. Where registration allows, streptomycin and oxytetracycline could be tank mixed or alternated. In some crops, it may be possible to alternate antibiotics and copper.

The control of fire blight of apple (caused by *Erwinia amylovora*) accounts for most of the antibiotic use on plant bacterial diseases. As with most bacterial diseases of plants, fire blight management has many components, with antibiotics being only one of them.^[2] Sanitation is most important and prebloom copper sprays can also contribute to disease management. In areas where resistance to streptomycin occurs, growers usually switch to oxytetracycline.

The efficacy of these antibiotics for the control of plant bacterial diseases has diminished in many areas because of the development of resistant bacterial strains.^[1] Efforts to maintain the effectiveness of antibiotics against human pathogens have led some medical researchers to recommend reduced use of antibiotics. Because of the possibility of the transfer of resistance from plant bacteria to human pathogens, some special interest groups have lobbied for the discontinuation of antibiotic use in agriculture. Whereas streptomycin has limited use and oxytetracycline is not used in clinical settings, other forms of tetracycline are needed in human medicine. Streptomycin and

Table 1 Selected characteristics of chemical controls for bacterial diseases of plants

Strengths	Weaknesses
<i>Antibiotics</i>	
Lethal to many bacteria	Antibiotic-resistant bacterial strains develop
Effective against fire blight (primary use)	Active on plant surface for only 1–3 days
Low phytotoxicity	Labeled for use on only a few crop plants
	Public opposition to use in agriculture
	Expensive
<i>Copper-based bactericides</i>	
Effective against many different bacteria	Require multiple applications
Labeled for many crop plants	Are phytotoxic to many plants
Economical to use	Development of resistant bacterial strains
<i>Plant defense activators</i>	
No direct antimicrobial activity, thus less chance of resistance developing	Generally not as effective as antibiotics or copper when used alone
Induce disease resistance	May be phytotoxic in some cases
Less toxic than most pesticides	May need to be used in conjunction with bactericides
Effective in many plants against many different pathogens	

oxytetracycline remain available for agricultural use, but it appears unlikely that new antibiotics will be developed for bacterial plant disease management.

MANAGEMENT OF BACTERIAL DISEASES WITH COPPER COMPOUNDS

Copper-based bactericides, including Bordeaux mixture, cupric hydroxide, copper salts of fatty acids, tribasic copper sulfate, and mixtures of cupric hydroxide and ethylene *bis*-dithiocarbamates, are widely used to control bacterial diseases of plants with varying levels of success.^[3] A study conducted in the mid-1960s indicated that the combination of copper and mancozeb was more effective than copper alone for control of bacterial spot of tomato (causal agent *Xanthomonas campestris* pv. *vesicatoria*) and also has resulted in increased control of other plant bacterial diseases.^[4,5] Premixing the copper and mancozeb a few hours prior to application is believed by some growers to increase the effectiveness of the combination for the control of bacterial diseases.

Copper compounds are protectants and generally require multiple applications to control bacterial diseases. Copper-based bactericides typically are applied every 5–10 days.

High concentrations of soluble copper must be present on the leaf surface to penetrate and kill bacterial pathogens, and this is also phytotoxic to many crop plants. Most tree-fruit crops, such as apple and peach, are sensitive to copper, and sensitivity may be cumulative. Thus, in some plants, there are limitations on stages of plant growth at which copper can be applied and on application rates, and this may result in less than

desirable disease control. As with streptomycin, the development of bacterial strains resistant to copper bactericides is quite common, primarily because of the horizontal transfer of plasmid-borne resistance genes between bacteria. This often renders copper compounds ineffective. Resistance results from the bacteria producing specific proteins that sequester copper and prevent it from entering the bacterial cell.

FUTURE PROSPECTS FOR MANAGEMENT OF BACTERIAL DISEASES

There is a definite need for new, effective controls for bacterial diseases of plants. However, efforts directed toward the research and development of new chemicals for the management of bacterial plant diseases are very limited. With a shortage of effective antibiotics for human diseases, it seems unlikely that new antibiotics will be developed for plants. Also, agrochemical companies are not putting much effort into developing new controls for plant bacterial diseases because the potential market value of plant bactericides is relatively low.^[6] This lack of interest on the part of major chemical companies is further exacerbated by the sporadic nature of disease epidemics caused by phytopathogenic bacteria.

The development of disease control chemicals that induce plant disease resistance offers a new approach to field management of bacterial diseases (Table 1). These chemicals include synthetic inducers of systemic acquired resistance, such as acibenzolar-*S*-methyl, and natural products such as the harpin protein produced by the bacterium *E. amylovora*. These plant defense activators have no direct antimicrobial activity and work

by inducing plant resistance to bacterial, fungal, and viral diseases.

The plant defense activators are attractive because they offer a different mode of action from other chemicals. They do not act directly on the pathogen, are generally less toxic than most pesticides, and are environmentally benign, thus the required testing for registration by the EPA is less rigorous than for conventional chemical compounds. There is little chance of the eventual development of pathogen resistance to these materials. These nontraditional chemicals have provided some control of bacterial diseases of tomato and pepper.^[7,8] The plant defense activators are not necessarily a replacement for traditional bacterial disease control chemicals, but may be useful in conjunction with conventional pesticides to improve disease control, reduce the effective dosage or frequency of application, or prevent the development of resistance to bactericides.

CONCLUSION

Antibiotics have been, and continue to be, effective for the control of bacterial diseases on the crop plants on which they are used. However, their effectiveness is declining in some cases because of the development of bacterial resistance. New antibiotics are not being developed for plant use. Copper-based bactericides provide effective control of many bacterial diseases of plants; however, the development of bacterial strains resistant to copper is also becoming common. The agricultural chemical industry is putting little effort into the development of new controls for plant bacterial diseases; however, the relatively new group of plant defense activators could offer alternative approaches to the management of bacterial diseases of plants.

Management of Bacterial Diseases of Plants: Regulatory Aspects

Jaap D. Janse

Plant Protection Service, Wageningen, The Netherlands

INTRODUCTION

Because most plant diseases caused by bacteria cannot be controlled by chemicals, they pose a serious threat to important agricultural and horticultural crops through yield loss and trade barriers. Use of uninfested planting material, sanitation at production sites, and other preventive measures have often proved to be inadequate to control bacterial diseases and therefore many governments have implemented regulations to prevent the introduction and spread of new or existing pathogens. The role of quarantine regulations in the management of bacterial plant diseases, the organization thereof in different parts of the world, and their success is the subject of this article.

LONG DISTANCE MOVEMENT OF PHYTOPATHOGENIC BACTERIA

For bacteria, the most important mechanisms of global movement are internationally traded plants, seeds, and plant parts. With new free trade agreements between countries in different parts of the world, the risk of introducing exotic pests is increasing. Furthermore, new, difficult to trace pathways are developing. For example, commercial companies produce basic planting material outside their regions under varying disease management conditions, and then introduce the products into their regions for further propagation and sale. This has led to the introduction of *Ralstonia solanacearum* race 3, biovar 2 with *Pelargonium* cuttings from Kenya into Europe and from Guatemala into the United States.

Other possible pathways for the introduction of exotic phytopathogenic bacteria are the use of nonindigenous pollinating insects and biological control agents. For example, it is suspected that *Liberobacter asiaticum* was introduced into the U.S. state of Florida with parasitoids used for control of the Asian citrus psyllid *Diaphorini citri*. Indeed, certain biological control agents, including *R. solanacearum*, used for control of the forest weed *Hedygium gardnerianum* in Hawaii, may attack cultivated hosts. Additionally, genetically modified *Agrobacterium tumefaciens* strains, used for the genetic manipulation of

plants, should also be regulated because they may survive in the transformed host.^[1]

APPROACHES TO PREVENT INTRODUCTION OF PHYTOPATHOGENIC BACTERIA

Quarantine regulations are mainly aimed at excluding phytopathogenic bacteria from a territory. These may be laws, orders, or decrees that limit the import of plants or plant products and specify the pathogens of interest.^[2] More specifically, quarantines facilitate the isolation and inspection of plants and plant products for prohibited organisms. This is only used for small-scale importations or germplasm sent to postentry quarantine stations for breeding or research purposes. The traditional method of controlling the entry of exotic pests, i.e., inspection at the point of import, is not adequate due to latent symptom development and undetectable levels of bacteria on planting materials. If the host plants are not prohibited, then phytosanitary regulations are based on ensuring that the imported plants are symptomless at the point of origin, as certified by the National Plant Protection Organization (NPPO) of the exporting country. An important principle for ensuring that commodities are pathogen-free is the concept of the pest-free area, assigned when a disease has not been observed in a certain country or part of that country. A pest-free area can be created and officially recognized according to international standards, and commodities can be freely exported from it. Similar in concept is the protected zone, that also must be free of a particular bacterium, but must be especially protected from introduction of the bacterium by stricter phytosanitary measures than adjoining areas. Examples of protected zones can be found in Canada and Europe for *Clavibacter michiganensis* subsp. *sepedonicus* and *Erwinia amylovora*, respectively.^[3]

If a pest-free area cannot be established or maintained, phytosanitary regulations may allow plants or plant products to originate from a production site that has been free from the particular bacterium for a defined period of time. Quarantine regulations should also include the eradication

or containment of introduced bacterial pathogens. Additionally, they should be used to ensure the production of healthy planting materials by certification schemes and standard production protocols.^[4]

Other phytosanitary measures applied to host plants include requirements that the previous generation of the plants or seeds of a commodity be free of the pathogen, and that planting materials be tested or subjected to physical or chemical eradication treatment.^[4] Furthermore, the exchange of bacterial strains from culture collections is subject to greater regulation, mostly at the national level but also through the World Federation for Culture Collections (WFCC). Note that the WFCC also addresses the possibilities that regulations be employed in preventing the use of pathogens in bioterrorism.^[5] It seems unlikely, however, that plant pathogenic bacteria will ever be used as bioterror tools due to their slow and unpredictable mode of action.

REGULATIONS AS TRADE BARRIERS

In the Uruguay round of negotiations (1986–1994) of the World Trade Organization, an agreement on Sanitary and Phytosanitary Measures (SPS Agreement) was developed to discourage the use of phytosanitary measures as non-tariff trade barriers. A pest risk analysis (PRA), including statistically sound surveys of pathogens in the areas or countries involved, was established as the basis for developing regulatory measures. The PRA ensures that an organism is not considered a pest to be quarantined without scientific evidence. For example, *P. syringae* pv. *pisii*, causing pea blight, is seedborne, but severe pea blight outbreaks are more dependent on environmental conditions. Therefore, this bacterium has been withdrawn from the quarantine lists of many European countries. However, effort is still needed to remove unimportant pathogens from quarantine lists.

Regulations should be based on thorough knowledge of the incidence of a disease. In many countries, there is insufficient knowledge of endemic pathogens because systematic surveys are rarely done. Radical changes in standard agricultural practices can promote epidemics that are often claimed to be new pathogen introductions. One example of this is bacterial stripe caused by *Xanthomonas translucens* pv. *translucens*. At low disease incidence, bacterial stripe symptoms are inconspicuous and easily overlooked. The disease is not important in rain-fed cereals in Syria, but outbreaks occurred when irrigation was intensified, and it was thought that seedborne inoculum was responsible for the outbreaks. The introduction of bacteria on planting material should only be concluded when the bacterium is isolated from the suspected tissues. In the case of bacterial diseases this is difficult, because infested planting material may not display obvious symp-

tom, and biochemical and molecular tests may yield false positive results. Pathogen isolation, adequate confirmatory tests, and maintenance of the original samples and isolates should be required in all cases.

CREATION OF REGULATIONS

Sovereign states, under the International Plant Protection Convention and the SPS Agreement, have the right and responsibility for preparing phytosanitary regulations to protect themselves against exotic plant pests. In the past, countries prepared their regulations independently, with the consequence that great discrepancies existed between the principles on which the measures were based, and their degree of technical justification. About fifty years ago, the Food and Agricultural Organization (FAO) of the United Nations, the Regional Plant Protection Organizations (RPPOs), and regional economic integration organizations started supporting countries in this task. The Interim Commission on Phytosanitary Measures, established by the IPPC, develops International Standards on Phytosanitary Measures. These standards establish the principles and procedures of phytosanitary measures, ensuring that countries develop their measures consistently and fairly. In addition, most countries belong to RPPOs that coordinate and harmonize the phytosanitary actions of their member countries on a regional basis. With regard to bacterial pathogens, the European Plant Protection Organization (EPPO) advises its members which bacteria should be quarantine pests, dividing them into A1 quarantine pests (those absent from the region and against which all countries are recommended to take phytosanitary action) and A2 quarantine pests (those present in some parts of the region and of concern to only some countries). The EPPO convenes a panel of experts on bacterial diseases that is responsible for developing technical documentation relevant to each of the quarantined bacteria (e.g., geographic distribution, biology, economic impact), pest-specific phytosanitary requirements (measures that should be adopted by countries that wish to export to an EPPO country), phytosanitary procedures (used by the NPPO of the exporting country to ensure absence of the quarantine bacterium), and pathogen-specific diagnostic protocols. The North American Plant Protection Organization (NAPPO) is developing international standards for phytosanitary measures, a list of regulated plant pests including phytopathogenic bacteria (see Tables 1–3), harmonizing pest management programs through the coordination of pest surveys and developing criteria for seed potato certification.

Regional economic integration organizations such as the European Union (EU) are formed to allow countries to collaborate for the economic benefit of all, and the organizations take over activities that were once conducted

by the individual states. The EU has based its lists of quarantine organisms and their specific phytosanitary measures on the phytosanitary requirements of the EPPO.^[6] Tables 1–3 show the bacteria that are quarantine pests for the EPPO and the EU, and indicate those that are considered to be quarantine pests for other regional organizations. As internal control measures, the EU has developed special control directives for bacterial brown rot and bacterial ring rot that allow the safe movement of potatoes from parts of the community that have the disease.^[7–9] These directives are based on scientific data, and detailed methods for detecting latent infections are provided. Measures are also described for determining pathogen distribution, preventing spread, and suppressing and/or eradicating the disease.

IF QUARANTINE REGULATIONS FAIL

If phytosanitary regulations fail to stop the entry of a pathogen, the success of efforts to prevent long-term establishment depends on early pathogen detection, accurate diagnosis, and rapid implementation of management strategies.^[10] Eradication of pathogens is most likely to be successful on small isolated areas, because it is easier to delimit an outbreak and to prevent re-introductions during the eradication campaign. An example is successful eradication of *Xanthomonas axonopodis* pv. *citri* from Thursday Island, Australia.^[4] Regulatory eradication actions often fail because of 1) incomplete pathogen eradication; 2) natural reinvasion; and 3) reintroduction through short- or long-distance movement of infected material. In that case, the realistic options are functional eradication or areawide suppression. The problems encountered in eradication campaigns in larger landmasses are illustrated by the history of citrus canker (*Xanthomonas axonopodis* pv. *citri*) in the United States. Despite an intensive eradication program in the 1930s, the disease got a foothold in subsequent years and researchers now question whether the pathogen can ever be eradicated under Florida's climatic conditions.^[11]

Management of Diseases in Seed Crops

Lindsey J. du Toit

Washington State University, Mount Vernon, Washington, U.S.A.

INTRODUCTION

The success of modern agriculture is dependent on a vital seed industry that enables the timely production and distribution of high-quality, pathogen-free seed of high-yielding cultivars adapted to specific geographic regions and methods of production. The value of the world seed market is estimated at \$40–60 billion, and the demand for seed is expected to keep pace with the world's growing population.^[1] The increasingly global nature of the seed industry brings an associated risk of widespread dissemination of seedborne pathogens. As a result, effective disease management in seed crops remains central to the seed industry.

SEED CROP DISEASES

Although management of plant diseases is important for most crops, it is particularly critical for production of high-quality seed. Plant pathogens can reduce the quantity and quality of seed harvested, and many can be seedborne (Fig. 1). A significant proportion of the seed market is associated with worldwide movement of seeds, and seeds are distributed internationally for breeding programs and research purposes. Seeds provide an efficient means of inadvertently disseminating plant pathogens. Numerous examples can be found of plant disease epidemics resulting from the introduction of seedborne pathogens, often culminating in significant economic losses.^[2]

Strategies for Managing Seed Crop Diseases

General strategies for disease management in agriculture are pertinent to seed crops, i.e., exclusion of pathogens from regions of seed production, eradication of pathogens from seed crops, protection of seed crops, alleviation of disease pressure using cultural practices, and incorporation of disease resistance into cultivars. However, seed production is a complex process involving meticulous criteria followed rigorously by seed producers.^[3] Consequently, disease management programs for seed crops can be more complex than for commercial crops, and require integration of the many tools available. The specific strategies selected are influenced primarily by eco-

nomical factors, ultimately governing the value and amount of seed produced.

The extremely low tolerance for pathogens in seed crops has resulted in specialized areas of seed production in regions where pathogens are unable to establish or usually remain below threshold levels during seed development.^[4,5] In the United States, seed production occurs primarily in the western states where pressure from fungal and bacterial pathogens is reduced by low rainfall and relative humidity. For example, bean seed production occurs in the semiarid regions of Washington and Idaho. Similarly, the mild winters and dry summers of western Washington make this maritime region ideal for production of biennial Brassica seed crops free of black rot (*Xanthomonas campestris* pv. *campestris*) and black leg (*Phoma lingam*). Crucifer seed crops in Denmark are located in coastal areas where winds ventilate the crops, reducing development of black spot (*Alternaria brassicicola*).^[2] Furthermore, whenever possible seed crops are isolated from commercial crops for disease control. Lettuce seed produced in the San Joaquin valley of California is isolated from commercial crops in the Salinas valley to prevent infestations of aphids carrying lettuce mosaic virus.^[5]

Production of seeds is an energy-intensive process.^[3] Consequently, some plant species become increasingly susceptible to certain pathogens at flowering. Development of leaf spot of spinach caused by *Stemphylium botryosum* is greatly exacerbated in the presence of pollen, necessitating initiation of protective fungicide applications prior to pollen shed in spinach seed crops.^[6] Although *Fusarium oxysporum* f. sp. *spinaciae* causes damping-off of spinach seedlings, symptoms of *Fusarium* wilt in the seed crop are not apparent until flowering. Yield losses in the seed crop can be extensive without ≥ 10 -year crop rotations.^[7]

The duration of the seed crop season may result in a long window of susceptibility to infection or provide opportunities for infection during periods of stress or injury (e.g., winter injury in biennial carrot seed crops). Overwintered biennial and perennial seed crops may harbor pathogens that can spread to neighboring first-year crops. This green bridge effect led to epidemics of the aphid-vectored beet western yellows luteovirus in the beet seed industry in western Oregon.^[8]

Fig. 1 Scape and umbel blight in an onion seed crop, caused by the fungus *Botrytis aclada*, reduces the quantity and quality of seed harvested. (View this art in color at www.dekker.com.)

Cultural practices can create less favorable conditions for disease development. Crop inspections and roguing of symptomatic plants or alternative hosts of plant pathogens can reduce disease in a seed crop. Crop rotation is essential for managing many plant diseases. The minimum duration of rotation depends on the longevity of specific pathogens, and may range from a few years to >10 years. Planting seed crops in suppressive soils can assist in production of pathogen-free seed, as demonstrated for pea seed crops free of *F. oxysporum* f. sp. *pisi* in California.^[5] Furrow irrigation restricts splash-dispersal of many pathogens compared to overhead irrigation. Increased spacing of plants reduces disease pressure for fungal and bacterial pathogens as a result of increased air circulation. Incorporation of infested crop debris into the soil reduces survival of some pathogens. Fire is

used to reduce inoculum levels of certain plant pathogens (e.g., burning of stubble/straw in grass and cereal seed crops).

Foliar applications of fungicides, bactericides, and resistance-inducing chemicals can provide effective management of many plant pathogens in seed crops. The extended season of seed crops, combined with the low tolerance for seedborne pathogens, often necessitates a greater number of pesticide applications than in commercial crops and requires precise timing of applications with periods of increased susceptibility and disease pressure. However, the minor acreage of individual seed crop species impedes attainment of pesticide registrations for seed crops because of the limited returns to pesticide manufacturers. As a result, some states have implemented programs that qualify certain seed crops for non-food, non-feed status to facilitate pesticide registrations.

Fumigation, and biofumigation using cover crops, can eradicate persistent inoculum of some pathogens, but the former may be cost-prohibitive.^[2,4,5] Seed treatments provide effective means of eradicating or reducing some pathogens, and can be applied to both the stock and harvested seed. Fungicide seed treatments eradicate seedborne inoculum, inhibit seed-to-seedling transmission of pathogens, or protect emerging seedlings from soilborne or airborne pathogens. Systemic fungicides are valuable for eradication of internal seed infection and protection of subsequent new growth of seedlings. Physical seed treatments (e.g., hot water, steam, or chlorine) can eradicate or reduce inoculum on seeds. The efficacy of seed treatments depends on the degree of internal infection of the seed, the amount of inoculum in a seed lot, specificity of the treatment, and potential phytotoxicity of the treatments.^[1,3,4]

Plant breeding has successfully introduced disease resistance into many commercial seed crop cultivars. However, resistance may not be available for some pathogens. In hybrid seed crops, resistance may only be present in one of the parent lines, necessitating disease management practices for the susceptible parent. Furthermore, some pathogens have the ability to overcome single-gene resistance, complicating efforts to manage diseases in seed crops using resistance.

Quality control is fundamental to the seed industry.^[2] Seed certification programs encompass field inspections and lab assays so that the history of seed lots can be traced.^[4] Emphasis is placed on assays for seedborne pathogens, as many can go undetected during field inspections. To be of value, seed health assays must be specific, sensitive, reliable, cost-effective, and rapid.^[5] In 1958, the International Seed Testing Association initiated development of standardized seed health assays.^[1] Despite this, most seed testing protocols published in the literature have not been standardized, resulting in a range

of methods utilized by different laboratories. This can lead to different results, sometimes with significant ramifications regarding international seed shipments. Techniques for detecting seedborne pathogens include visual inspection, incubation on agar or blotters, staining, pathogenicity tests, serological assays (e.g., enzyme-linked-immunosorbent assays), and nucleic acid assays (e.g., polymerase chain reaction assays).^[5,9] Approval of seed lots for shipment may be based on results of seed assays, so rapid turnaround is critical in seed testing facilities. Advances in rapid nucleic acid assays have overcome problems with inhibitory seed-derived compounds, resulting in increasing application of this technology for seed health assays.^[9]

CONCLUSION

The new U.S. National Organics Program for certified organic produce states that the “producer must use organically grown seeds,” “may use untreated nonorganic seeds . . . when equivalent organic varieties are not commercially available,” and seeds “treated with prohibited substances may be used to produce an organic crop when the application of the substance is a requirement of Federal or State phytosanitary regulations.”^[10] These standards have increased the demand for organically-produced seed, but have also raised concerns about associated increases in losses from seedborne pathogens because of the limited number of organic options for seed treatment and disease management. Research is needed to investigate alternatives for successful production of pathogen-free organic seed.

The rapid acceleration in worldwide movement of seed can be justification for plant quarantines. However, there is a significant lack of epidemiological research on the economic impacts of specific seedborne pathogens, on which the regulations and quarantines regarding seedborne pathogens need to be based.^[11] Consequently, many of a large number of new phytosanitary regulations cannot be justified scientifically and have been interpreted as

phytosanitary barriers used only to protect domestic agricultural industries.^[11] Epidemiological research is needed to provide a scientific basis on which to implement regulations affecting the global seed industry.

Management of Fungal and Oomycete Diseases: Fruit Crops

Patricia S. McManus

University of Wisconsin, Madison, Wisconsin, U.S.A.

INTRODUCTION

Fruit crops are produced on nearly 50 million hectares worldwide. Fruit plants are susceptible to diseases at every step in their production and distribution, with economic losses occurring at the nursery, in producers' fields, during storage after harvest, and in the marketplace. As with other crops, the majority of diseases of fruit crops are caused by fungi. Fungi primarily cause fruit rots, leaf spots and blights, and stem cankers. However, several fungal genera affect roots of fruit crops, either individually (e.g., *Armillaria*) or as members of a disease complex (e.g., *Fusarium* and *Rhizoctonia*). Oomycetes (water molds) primarily cause root and crown rots, but can also cause fruit rots (e.g., strawberry leather rot caused by *Phytophthora cactorum*) and shoot blights (e.g., grape downy mildew caused by *Plasmopora viticola*).

Consumers have high standards when selecting produce and usually pass over fruit with blemishes or other imperfections. Thus, there is nearly zero tolerance for diseases that directly affect fruit. Aesthetics are less important for fruit that will be processed rather than grown for the fresh market, but growers almost always receive a lower price for fruit destined for processing rather than the fresh market. Since the middle 1990s, the demand for high-quality fruit grown in accordance with organic standards has increased, and organically grown fruit typically is sold at a premium. While growing organic fruit might appear lucrative, managing diseases without synthetic fungicides can be a major challenge depending on the crop and climate where it is produced.

As with other crops, managing diseases of fruit depends on manipulating the host, pathogen(s), and environment to favor plant health and inhibit pathogen growth and spread. Since most fruit plants are long-lived perennials, disease management presents unique challenges. The roles of host resistance, pathogen exclusion, cultural practices, and chemical and biological control in fruit disease management are presented separately. In practice, however, fruit growers integrate multiple methods to manage diseases.

GENETIC RESISTANCE OF THE HOST PLANT

Genetic resistance of the host is often the most effective, least expensive, and safest way to manage diseases of fruit crops. For most fruit crops there are numerous cultivars that vary in susceptibility to important diseases. However, cultivar choice is driven more by processor standards and/or consumer preference than disease resistance. For example, McIntosh is one of the leading apple cultivars for fresh-market sales in the eastern United States, but it is also one of the most susceptible to apple scab. Desirable horticultural traits, such as size-controlling rootstocks on fruit trees, are often higher priorities than disease resistance for growers. The extent to which growers depend on host resistance depends on the crop, the disease, and how the fruit will be marketed (e.g., fresh versus processed; conventional versus organic). Although some fruit crop species have been genetically transformed to improve disease resistance, transgenic fruit crops currently are not produced commercially.

PATHOGEN EXCLUSION

Pathogen exclusion (i.e., preventing a pathogen from reaching its host) is not a practical means of disease management for most fruit crops. Fruit plantings are usually established from nursery stock rather than seed. Indexing stock for viruses is standard practice, but indexing is not practical for most fungal and oomycete pathogens. Thus, pathogens are often carried on nursery stock and remain with the plant its entire life.

CULTURAL PRACTICES

Cultural practices are especially effective in fruit disease management because they can simultaneously improve plant health, reduce pathogen populations, make the environment unfavorable for pathogens, and in the case of pruning, permit more thorough coverage with chemical or biological pesticides.

Site Selection and Water Management

Annual crop rotation is not an option with perennial fruit plants. Therefore, establishing plantings on suitable sites is essential. Most fruit crops prefer lighter soils with good water drainage. Since oomycete pathogens proliferate in water, good drainage is key in managing diseases caused by oomycetes. Installing drainage tiles is sometimes necessary in heavier soils. At the other extreme, too little water can stress woody plants and exacerbate certain canker and shoot blight diseases. For example, various species of the fungus *Phomopsis* cause shoot dieback or cankers on many different woody fruit crops. Symptoms are usually made worse by drought stress on the host. Trickle irrigation generally is preferred to overhead irrigation, because the latter can contribute to leaf and fruit diseases. However, for crops where frost protection is needed (e.g., cranberry and strawberry in cooler climates), overhead irrigation is used.

Sanitation

Removal and destruction of diseased branches, fruit, and other plant debris reduces pathogen inoculum and thereby decreases disease pressure. For tree and vine crops, sanitation is usually accomplished by manually pruning branches and picking mummified fruit. In the case of apple scab, removing leaves from the orchard floor or shredding them to accelerate their decomposition significantly reduces apple scab inoculum. In perennial strawberry production, leaves are mowed from plants and then either removed from the planting or incorporated into the soil to reduce inoculum of fungal leaf spot pathogens. Cranberry beds are flooded either after harvest or in early spring to remove leaf debris and mummified fruit that harbor fungal fruit rot pathogens.

Air Movement

Fungal pathogens of leaves and fruit depend on free water and/or high relative humidity for germination and growth. Any practice that reduces the length of time that foliage and fruit are wet is likely to hinder disease development. Pruning of woody fruit plants, done primarily for horticultural benefits and sanitation, also improves air circulation and drying of foliage. Planting strawberry and raspberry rows parallel to the direction of prevailing winds enhances drying of foliage and fruit. Controlling weeds also reduces the duration of wetness in the lower parts of fruit plants. This is particularly important for cane and bush crops (e.g., raspberry and blueberry), because lower stems are prone to infection by canker-causing fungi.

CHEMICAL CONTROL

Under some conditions, diseases of fruit crops can be managed by integrating host resistance and cultural practices. However, most fruit have at least one disease caused by a fungal or oomycete pathogen that requires application of a chemical fungicide. Because fungi and oomycetes are very different biologically, different chemicals are used to control them.

Chemical Control of Fungi

Synthetic fungicides commonly used on fruit crops include captan, mancozeb, and chlorothalonil. These are broad-spectrum fungicides that prevent spore germination on the surface of the plant. Nonsynthetic fungicides, such as sulfur and copper compounds, also protect plants from infection and are permitted for use in organic production. Synthetic fungicides are often easier to use and more effective against a range of diseases than sulfur or copper. Nevertheless, sulfur and copper are relatively inexpensive and are highly effective in some situations. For example, under dry conditions powdery mildew may be the only disease that develops, and sulfur is very effective against powdery mildew pathogens of fruit crops.

The sterol demethylation inhibitor (DMI) fungicides (e.g., myclobutanil, fenbuconazole, and tebuconazole) prevent infection but are also taken up by leaves and can kill fungi after infection has occurred. Infection prediction systems are available for some important diseases of apple, grape, and cherry; applying DMI fungicides on a post-infection basis has greatly reduced the amount of fungicide applied to these crops.^[1,2] However, infection prediction systems have been developed and validated for relatively few diseases of fruit crops. Also, after many years of use, some fungal pathogens have become less sensitive to the DMI fungicides, and their ability to eradicate fungi after infection may be compromised.

The relatively new strobilurin fungicides (e.g., azoxystrobin, kresoxim methyl, and trifloxystrobin) have a broad spectrum of activity and are relatively nontoxic to applicators, consumers, and the environment. Use of strobilurins on fruit is increasing but with caution, since fungicide resistance is a concern with this class of fungicides.

Chemical Control of Oomycetes

Chemical control of oomycete diseases, especially root and crown rots, is not as effective as good soil drainage. Delivering the chemical to underground plant parts is difficult, and resting spores of oomycetes can withstand chemicals. Moreover, once symptoms of crown rot are detected, the damage is often too great to be mitigated by chemical treatment. However, chemical treatment at the

time of planting can assist root establishment. In established plantings, chemicals are applied in the spring and fall when oomycete pathogens are most active. Mefenoxam is applied directly to soil in enough water to reach roots. Depending on the crop and disease, fosetyl-aluminum is applied to roots as a preplant dip, tree trunks as a wound paint, or leaves, where it is taken up and transported to roots.

BIOLOGICAL CONTROL

Biological control of fruit diseases has been researched extensively, but few products are commercially available. The bacterium *Pseudomonas syringae* and the yeast *Candida oleophila* are used as postharvest treatments on citrus and pome fruits to prevent rots caused by *Botrytis cinerea*, *Penicillium* spp., and other fungi. Strains of the fungus *Trichoderma* are used in greenhouses and nurseries to protect roots from both oomycete and fungal pathogens. The fungus *Ampelomyces quisqualis* is a parasite of powdery mildew fungi and is registered on several fruit crops. The bacterium *Bacillus subtilis* suppresses fungal diseases of many fruit crops. Biological control products have not gained widespread acceptance by fruit growers, because they are often less effective against a range of diseases and more expensive than conventional fungicides.

CONCLUSION

Fruit crop disease management is accomplished primarily by integrating host resistance, cultural practices, and chemical control. Concerns regarding the negative ef-

fects of fungicides on farm workers, consumers, and the environment have spurred the development of safer fungicides and biological control products. Likewise, non-chemical disease management practices are becoming more important because of the high cost of chemicals, restrictions on their use, and the emergence of fungicide-resistant pathogens. Compendia summarizing diseases of the major fruit crops are published by the American Phytopathological Society.^[3]

Management of Fungal and Oomycete Diseases: Turfgrass

Michael J. Boehm
Joseph W. Rimelspach
Samantha L. Thomas

The Ohio State University, Columbus, Ohio, U.S.A.

INTRODUCTION

The aesthetic, ecological, and recreational value of turfgrass is immeasurable. Unfortunately, vast expanses of turfgrass are also susceptible to weed invasion, insect infestations, and disease. Integrated pest management (IPM) or integrated disease management (IDM) strategies based on the use of genetic host resistance, cultural practices, chemical applications, and biological control provide environmentally attractive alternatives to the sole and routine use of pesticides. The goals of this entry are to: 1) highlight some of the unique characteristics and complexities of turfgrass cropping systems; 2) identify the major turfgrass diseases and pathogens; and 3) provide an overview of an integrated approach for the management of turfgrass diseases.

WHY TURFGRASS TURNS BROWN

The main reasons for brown turfgrass are adverse environmental factors such as “poor” soils, unfavorable climatic conditions, excessive wear, and improper maintenance.^[1] Turfgrass pathogens and pests, alone or in tandem with abiotic factors, also significantly impact turfgrass quality. Although turfgrass managers can do little to influence regional weather patterns or regulate the amount of play or use on a given sward of turfgrass, they are entirely responsible for the management practices they employ. Maintenance practices that favor turfgrass growth over pathogen activity often lead to significant reductions in disease pressure and are considered the foundation of effective turfgrass disease management programs (Fig. 1).

Most turfgrass diseases are caused by fungi and fungal-like organisms (Oomycetes). One convenient, albeit not absolute, way to classify turfgrass diseases is to do so based on the part of the plant being attacked (i.e., foliar diseases, foliar and crown diseases, crown and root diseases). Table 1 lists the major turfgrass diseases caused by fungi and Oomycetes. There is only one economically important turfgrass disease caused by a bacterium [bacterial blight of annual bluegrass (*Poa annua*) and of some creeping bentgrass (*Agrostis stolonifera*) cultivars caused

by *Xanthomonas campestris*] and one disease caused by a virus (St. Augustinegrass Decline caused by Panicum mosaic virus). Nematodes may also cause significant losses in turfgrass, especially in tropical and subtropical climates; however, their impact on cool-season turfgrasses in temperate regions is less well understood.

COMPLEXITY OF TURFGRASS CROPPING SYSTEMS

Although the management of turfgrass diseases is similar to managing diseases of other crops, there are several unique characteristics of turfgrass cropping systems that must be considered before an effective disease management program can be developed. First, turfgrass is a perennial crop whose “yield” is measured in terms of how well it withstands use (i.e., playability of athletic fields or golf-course putting greens) and/or aesthetics (color, density, and overall visual quality) rather than in bushels per acre. Second, most turfgrass areas or swards represent mixed stands of multiple species, cultivars, or both. The situation is even more complex because most turfgrass species are composed of synthetic cultivars made up of co-populations of genetically diverse individuals that often segregate over time based on the influence of abiotic and biotic factors. Older creeping bentgrass putting greens typically show this type of segregation. Third, turfgrass is used in many different ways (i.e., athletic fields, golf courses, home lawns, roadside ground cover, grassy waterways, etc.) and typically require individualized management approaches. Golf courses are inherently complex turfgrass cropping systems because different turfgrass species/cultivars and maintenance practices are used for different functional areas (i.e., putting greens, fairways, roughs, tees, and clubhouse surroundings). Finally, high-value turfgrass systems such as golf-course putting greens and professional athletic fields are intensively managed (i.e., daily mowing, irrigation, core aeration, topdressing applications, painting, etc.), and although frequent manipulation allows for timely intervention, it can also lead to increased wear and the predisposition of turfgrass to environmental and

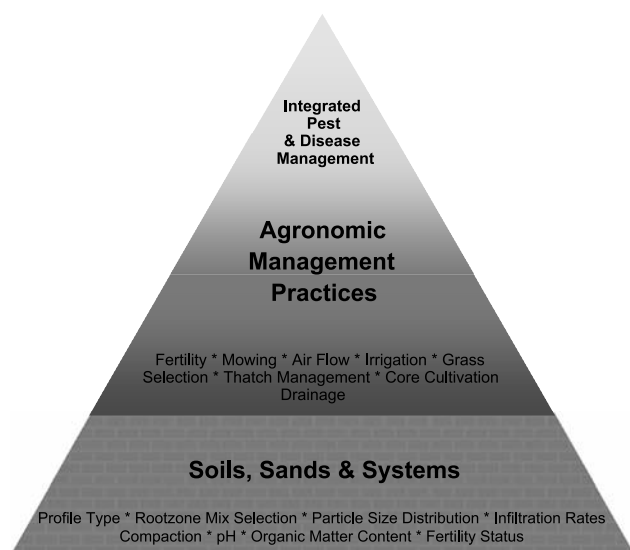

Fig. 1 Integrated management of turfgrass diseases is based on the use of sound soil science and agronomic principles. Properly managed turfgrass typically reduces pest and disease pressures. (View this art in color at www.dekker.com.)

biotic stresses. In summary, the term “turfgrass” is somewhat ambiguous and requires one to have a firm grasp on the specific attributes and complexities of the turfgrass cropping system being managed to develop effective management strategies and properly diagnose turfgrass maladies. Table 2 provides an example of some complexities faced by golf-course superintendents.

INTEGRATED TURFGRASS DISEASE MANAGEMENT

As pressures mount to reduce inorganic fertilizer and pesticide inputs on turfgrass, interest has increased regarding the development and use of IPM programs that either forego or limit the use of fungicides. Although voluntary in some situations, fungicide use is prohibited or strictly regulated in other situations such as in the case of home lawn or residential turfgrass disease management. Thus a significant push is underway to develop, adopt, and use IPM strategies for managing turfgrass diseases.

The first line of defense to preventing or minimizing disease is through the selection and/or use of disease-resistant turfgrass species/cultivars and the use of pathogen-free certified seed. Information regarding disease-resistant turfgrass may be obtained by contacting local turfgrass seed distributors, extension specialists, and via the National Turfgrass Evaluation Program.^[2] The use of genetically resistant turfgrass is limited to newly established or renovated turfgrass areas or in situations

where overseeding is used. The second line of defense against turfgrass diseases is the use of cultural management practices designed to optimize turfgrass growth. Cultural practices related to site and seedbed preparation prior to establishment are of paramount importance especially for seedling and root diseases such as damping off and necrotic ring spot. Sand-based root zone mix considerations for putting greens and athletic fields are equally critical. Under certain situations, it may be possible to modify substandard soil conditions under existing swards through the use of core aerification and organic matter topdressing programs.^[3,4]

Disease management in established turfgrass swards is often achieved by modifying cultural management practices such as mowing, watering, fertilization, tree pruning, topdressing applications, and core aeration. As mentioned previously, intensively managed turfgrass is often more predisposed to environmental and biotic stresses, and so it is crucial that agronomic practices be timed to optimize turfgrass growth and, if possible, minimize pathogen activity. To accomplish disease reductions through modification of cultural practices, intimate knowledge of

the major turfgrass pathogens (listed in Table 1) and the diseases they cause is required. Specifically, those practices which influence the temperature, moisture, and fertility status of turfgrass have been shown to have the greatest impact on turfgrass disease development.^[5–8]

Fungicide applications are generally not justified when the primary cause of turfgrass decline is environmental stress. Fungicide applications are often essential where there is a demand for high-quality turfgrass during environmental periods that favor pathogen growth. Fungicides are typically more effective when applied prior to the onset of disease symptoms (referred to as preventive or preventative applications)—this is especially true for crown and root pathogens. Some fungicides are effective when applied after the onset of symptoms and are said to have curative activity. In either case, fungicides must be delivered to the area of the plant where the pathogen is active to be effective. Numerous on-line extension-outreach resources exist that provide specific fungicide recommendations.^[9] Always read and follow label recommendations when applying pesticides.

Several recent advances in the use of biological control strategies to manage turfgrass diseases have been reported (i.e., the application of composts and antagonistic microbes); however, relatively few products are commercially available that provide consistent and predictable reductions in disease.^[3,4]

CONCLUSION

In summary, disease management strategies must be considered in concert with key agronomic practices such as fertilization, mowing, and irrigation as well as other weed and insect pest management efforts. The keys to the effective management of turfgrass diseases are to: 1) be

knowledgeable about the turfgrass species/cultivars being managed and the diseases for which they are susceptible; 2) identify well-defined acceptability and risk thresholds for each pathogen; 3) identify all budgetary, use, and other limitations that may influence one's ability to implement an integrated management plan; 4) develop an integrated turfgrass health management plan taking into consideration possible or anticipated interactions/conflicts with existing agronomic and pest management practices; and 5) implement the plan, modifying as required to attain desired outcomes.

Management of Fungal and Oomycete Diseases: Vegetable Crops

Debra Ann Inglis

Washington State University, Mount Vernon, Washington, U.S.A.

INTRODUCTION

The vegetable crop industry is unique and complex. A diversity of plants and production techniques, as well as growing and marketing operations, make the management of vegetable diseases caused by fungi and oomycetes particularly interesting and challenging. The occurrence, spread, and severity of vegetable diseases, and consequently their management, often hinges on the cropping situation in question.

VEGETABLE PRODUCTION

There are hundreds of different types of traditional and speciality vegetables for which edible plant parts (e.g., roots, tubers, bulbs, stems, leaves, flowers, fruits, or seed) are consumed.^[1] Vegetables may be grown in home and market gardens, on small truck farms or large farms, or in greenhouses. Production schemes under various climates range from multiple plantings grown sequentially during the same year to annual cropping under rain-fed conditions or irrigation in arid regions. In some cases, crops are hand-planted or direct-seeded; in others, they are hand- or machine-harvested. Marketing schemes for both domestic and export markets affect handling, storage, and packaging practices, and may involve fresh market sales to consumers, retailers or wholesalers, or advanced contracts with processors. All of these factors influence the types of diseases prevalent in specific vegetable crops, as well as the management tools available to specific vegetable producers.

PRINCIPAL PATHOGENS

The number of plant pathogenic fungi and oomycetes affecting various vegetable crops make for hundreds of vegetable diseases. Key diseases are listed in [Table 1](#), although many more comprehensive indices are available.^[3–5] Vegetable pathogens can be either seed-, soil- or airborne, initiating diseases that are monocyclic (one disease cycle per growing season) or polycyclic (many

disease cycles per growing season). Examples of monocyclic diseases are root rots and wilts, where thick-walled resting structures or spores in the soil or decomposing diseased plant debris provide primary sources of inoculum. New spores usually form only toward the end of a growing season, and disease increase is slow but steady over time. In contrast, many foliar diseases such as mildews, leaf spots, and blights are polycyclic diseases. The primary inoculum is often a sexual spore or fruiting body that can withstand adverse environmental conditions. Numerous asexual spores produced on infected plants provide secondary inoculum. These spores are mostly short-lived, but are typically airborne and spread rapidly by wind and rain to cause multiple infections during the growing season.

APPROACHES IN MANAGEMENT

Generally, plant disease control is directed at excluding a pathogen from a particular host or location, eradicating or destroying a pathogen, or offering protection against a pathogen by manipulating the environment or providing some type of effective barrier.^[6] Disease controls directed toward improving the resistance of a host or utilizing microorganisms to reduce a pathogen population are also used.^[7] Regulatory, cultural, biological, physical, and chemical measures^[3] provide the means for accomplishing plant disease control.

Some examples of the exclusion of vegetable pathogens include: 1) bean seed grown in the arid western states of the United States to avoid anthracnose; 2) cabbage transplants inspected before shipment to production fields to manage black leg; and 3) potato seed tubers certified to limit spread of *Fusarium* and *Verticillium*. The eradication of pathogens is often accomplished through sanitation practices. Hot water treatments eliminate *Septoria* from celery, *Phoma* from cabbage, and *Alternaria* from carrot seed. Crop hygiene (i.e., the use of disease-free planting material and removal of infected plants) mitigates other inoculum sources. Planting healthy seed tubers and destroying volunteer potato plants that harbor late blight are examples of crop hygiene. Sodium hypochlorite, quaternary ammonium compounds, and other disinfectants

	<i>Albugo</i>	White rusts	

^aFrom Ref. 2.

tants can be used to eradicate pathogens from seed trays, pots and stakes, greenhouse benches, and storage facilities. Deep plowing and crop rotation allow decomposition of specialized pathogen survival structures. Phytophthora blight and root rot on cucurbits, Fusarium wilt on asparagus, and root rot on pea are all managed in part by rotation with nonhost plants. Steam sterilization in greenhouses, and solarization and fumigation techniques reduce or eradicate fungal and oomycete propagules from soil.

Plant protection can be accomplished by environmental manipulation, cultural practices, and fungicide treatments. Some common ways include selecting healthy seed and transplants; treating, sowing, and transplanting only when soil conditions (temperature, moisture, nutrients, tillth) ensure vigorous plant growth; arranging plant spacing and row orientation to permit ventilation in the canopy (because fungal and oomycete diseases are often favored by high humidity and wet plant surfaces); avoiding overhead irrigation when the crop is vulnerable to infection; avoiding field work when foliage is wet; picking fruit before it overripens; avoiding mechanical damage; removing field

heat as quickly as possible at harvest; controlling weeds that harbor plant pathogens or contribute to humid microclimates; and controlling insects that cause wounds.^[5] Protecting against fungi and oomycetes by using fungicides is also common in vegetable crops. For some vegetable crops like potatoes and tomatoes, the magnitude of fungicide use is quite high; for others it is quite low.^[8] Proper selection, timing, and methods of application are critical to appropriate fungicide use. Seed treatment with fungicides such as captan and thiram minimize the likelihood of damping off caused by *Pythium*, *Rhizoctonia*, and *Fusarium*. Fungicides applied to the foliage such as azoxystrobin, chlorothalonil, copper, fludioxonil, iprodione, mancozeb, sulfur, and thiophanate-methyl are most likely to succeed if used preventively (before infection) rather than curatively (after infection). Presently, there are few systemic fungicides available in vegetable production that have curative properties. Although mefenoxam is one, diseases caused by oomycetes (such as downy mildew on lettuce and late blight on potato) have developed resistance to mefenoxam.

Use of vegetable cultivars with genetic resistance results in fewer fungicide applications, and is widely employed. Rust-resistant asparagus, *Fusarium*- and *Verticillium*-resistant tomato, angular leaf spot-resistant cucumber, powdery mildew-resistant squash, and downy mildew-resistant lettuce cultivars are among those that are widely available commercially. However, new races of pathogens often pose the threat of overcoming such resistances, and must be monitored carefully.

Biological control agents are becoming more commonly available in vegetable disease management.^[7] They provide useful management alternatives, especially for organic production systems. *Trichoderma*, *Gliocladium*, *Streptomyces*, and *Bacillus* spp. are now packaged in commercial products directed mainly at seed- and soil-borne pathogens.

Integrated pest management (IPM) programs embrace the principle of integrating multiple crop protection practices to assure minimal pesticide use. By employing genetic, cultural, and biological strategies, and by monitoring pathogen population levels in relation to crop damage, established environmental or pathogen thresholds can serve as guides for appropriately timed chemical applications. IPM programs such as BOTCAST for onion botrytis leaf blight, TOM-CAST for tomato early blight, and BLITE-CAST for potato blight have been used in vegetable disease control.^[5]

CONCLUSION

Producing healthy vegetables for a growing population with changing food habits^[1] will invite new approaches for managing vegetable diseases in the future. The demand for farm-fresh produce, new alternative specialty vegetables, organic production methods, food that is safe from microbial contaminants and pesticide residues, and food grown under production practices that protect the environment may change the ways in which many vegetable diseases are currently managed. Lack of sufficient farmland to ensure adequate crop rotation schemes, compounded by new strains of pathogens with resistance to commercially desirable cultivars or widely used fungicides, may result in the reemergence of vegetable diseases previously kept adequately in check.

To meet such challenges, the availability of more information-based prediction systems may reduce unnecessary fungicide applications and promote more widespread use of biological controls.^[8] Novel integration of management strategies (e.g., combining soil solarization and biological agents, utilizing organic amendments in culture media to improve soil quality and control root diseases in transplant operations, and exploiting plant growth-promoting

rhizobacteria to induce systemic disease resistance) may be further exploited.^[9] Adapting new fungicides with novel modes of action and compounds that trigger defense mechanisms in plants are on the horizon.^[10] Expansion into the areas of biologically intensive IPM, computer and video technology, and biotechnology will likely bring about new vegetable disease control measures that are unavailable today.

Management of Nematode Diseases: Options

Gregory L. Tylka

Iowa State University, Ames, Iowa, U.S.A.

INTRODUCTION

Plant-parasitic nematodes reduce both the quantity and quality of yield produced by grain, fruit, and vegetable crops and cause discoloration and deformation of plant parts sold for fresh market purposes (Fig. 1). Additionally, many modern, large-scale crop production systems rely on uniform growth and maturation of the crop for efficient mechanical harvesting, and parasitism by nematodes can result in uneven development of plants throughout a field or seed bed, reducing harvest efficiency. Plant-parasitic nematodes in the class Adenophorea also serve as vectors for damaging plant viruses. Consequently, there are direct and indirect yield losses that result from plant-parasitic nematode infestations.

The objective of most nematode management programs is reduction in population densities of the targeted nematode(s), resulting in a direct, concomitant increase in crop yield. Such successful management programs not only increase the short-term economic value of crops being grown, but also maintain the future economic value of the land by maintaining productivity through reduction in pathogen population densities. Successful nematode management also may serve to reduce or eliminate indirect yield losses caused by resistance-breaking pathogen interactions and other disease complexes. For example, tomato cultivars possessing genetic resistance to Fusarium wilt, caused by the fungus *Fusarium oxysporum lycopersici*, will develop the disease if also infected with the root-knot nematode, *Meloidogyne incognita*.^[1] However, use of tomato varieties with genetic resistance to both Fusarium wilt and root-knot nematode results in control of both diseases.

There are numerous strategies or tactics that may be used to manage infestations of plant-parasitic nematodes. However, not all strategies are available for every combination of nematode and host crop. Also, most nematode management strategies are not therapeutic; they must be implemented before the crop is planted. Consequently, growers must have advance knowledge of the presence of damaging population densities of nematodes in the fields where crops will be grown. To develop an effective management program for plant-parasitic nematodes, growers must consider what management tactics are available, the economic costs of

those tactics in relation to the value of the crop being grown, and whether the management tactics can be implemented without disruption of the production system. There are several categories of nematode management strategies.

EFFECTIVE SCOUTING AND IDENTIFICATION

The first step in a successful nematode management program is accurate and early identification or diagnosis of a problem. However, obvious symptoms of damage may not appear for many months or years after a nematode infestation becomes established due to the obligately parasitic nature of plant-parasitic nematodes (Fig. 2). Extension educators and agribusiness personnel (agronomists, crop scouts, crop advisors, etc.), who routinely communicate and interact with growers, are essential in the development of a nematode management program. These individuals often are the first to notice unusual growth patterns in the crops and usually are knowledgeable about appropriate techniques for scouting for plant-parasitic nematodes, as well as other types of pests. Also, these people often assist growers in determining what specific management tactics are deployed.

Effective scouting for plant-parasitic nematode infestations involves careful observation of plant parts for disease symptoms, but confirmation of a nematode infestation usually requires collection and analysis of plant and/or soil samples. Identification of the genera of plant-parasitic nematodes and enumeration of the number of individuals present is often sufficient for diagnosis and subsequent development of a management program. However, identification of plant-parasitic nematodes to species or subspecific level (race or biotype or pathotype) is necessary in some cases. Accurate knowledge of the nematode or nematodes causing damage is essential in defining what tactics will be effective in a management program. For example, the geographic range of numerous species of the lesion nematode *Pratylenchus* overlap, but the host ranges of the species can vary considerably.^[2] Consequently, if a grower wanted to grow a crop that was not a host for the lesion nematode

Fig. 1 Deformed carrot root infected with the northern root-knot nematode, *Meloidogyne hapla*. (Photo by G.L. Tylka.) (View this art in color at www.dekker.com.)

present in a field as part of a management program, it would be necessary to determine the species of *Pratylenchus* present in order to know what crop species will not serve as a host for the nematode. In addition to host range, other aspects of the biology of the nematode that influence the effectiveness of various management options include the length of the nematode life cycle, the reproductive capability of the nematode females, and the ability of the nematode to survive periods of adverse environmental conditions (i.e., temperature extremes, lack of water, lack of food).

HOST RESISTANCE

For many crops and species of plant-parasitic nematodes, host resistance is an effective and economic management strategy. Nematode resistance is defined as a plant allowing only inefficient reproduction of a nematode species.^[3] Because reproduction of the nematode is reduced on resistant plant cultivars, the quantity (and possibly quality) of yield is usually increased, and a reduction in nematode population densities during the

course of a growing season usually occurs. Host resistance to plant-parasitic nematodes has been identified and incorporated into many grain, fruit, and fiber crops, and resistance is mostly to sedentary, endoparasitic nematodes, which have a complex feeding relationship with their hosts.^[4] Although host plant resistance to nematodes reduces nematode reproduction, the resistance is usually not 100% effective, and a small proportion of the nematode population can successfully reproduce on the resistant plants. Consequently, repeated use of the resistance can result in directional selection of a nematode population that is capable of reproducing on the resistant plant. Nevertheless, host plant resistance is an effective and economical nematode management strategy that warrants serious consideration when available as a management option.

HOST TOLERANCE

In addition to host plant resistance, nematode-tolerant plant cultivars can be a useful management tool. Nematode-tolerant plants are those that are relatively insensitive to parasitism by plant-parasitic nematodes.^[3] Tolerant cultivars suffer relatively little yield loss despite being parasitized by nematodes. In addition to providing economically acceptable yields in nematode-infested fields, tolerant plant cultivars can effectively prolong the utility of resistant plant cultivars by not selecting for nematode populations that can reproduce on resistant

Fig. 2 Susceptible soybean cultivars without symptoms despite being grown in field infested with a high population density of the soybean cyst nematode *Heterodera glycines*. (Photo by G.L. Tylka.) (View this art in color at www.dekker.com.)

cultivars. Unfortunately, nematode-tolerant plant cultivars are not available for most crops.

NONHOST CROPS

Because plant-parasitic nematodes are obligate parasites, they are unable to complete their life cycles and reproduce in the absence of a host crop. Thus, growing nonhost crops can be an effective management strategy. But the usefulness of this management strategy depends on several factors. Most obviously, the host range of the damaging plant-parasitic nematodes targeted for control will dictate what nonhost crops can be utilized for management purposes. There will be only a few nonhost crop possibilities for nematodes that have a broad host range, such as many species of lesion nematode (*Pratylenchus*), whereas there are several nonhost crop options for nematodes that can reproduce on only a few crop plants, such as the soybean cyst nematode (*Heterodera glycines*). Also, use of nonhost crops will not be an option if the nonhost crops are not of sufficient economic worth in the production systems in which the nematodes need to be controlled. For example, the soybean cyst nematode is a widespread and very damaging parasite of soybeans throughout the entire midwestern United States, and this nematode is unable to reproduce on many crop species, but corn is the only nonhost crop that is grown in alternating years with soybeans throughout most of this region because of agricultural economic constraints. Finally, use of nonhost crops as a nematode management strategy is more effective for plant-parasitic nematodes that cannot survive long periods of time in the absence of a host crop than for those nematodes that have effective long-term survival mechanisms, such as the cyst nematodes (*Globodera* and *Heterodera*).

CHEMICAL CONTROL

Beginning in the middle of the 20th century, pesticides became an effective and cost-efficient means to manage many plant-parasitic nematodes. Many such products, with various modes of action, were developed and marketed beginning in the 1940s. These pesticides generally can be categorized based on their physical properties as either fumigants or contact nematicides.^[5] Fumigant nematicides vaporize when applied and permeate quickly through the soil. The effectiveness of fumigants is affected by soil factors such as moisture, temperature, texture, and type. Contact nematicides do not vaporize and, con-

sequently, they diffuse more slowly and are not affected by soil factors as much as fumigants. Some of the more common nematicides include those with the common names aldicarb, carbofuran, 1,3 dichloropropene, dibromochloropropane, ethoprop, ethylene dibromide, fenamiphos, oxamyl, and terbufos.^[5,6] Also, broad-spectrum, fumigant biocides used to manage plant-parasitic nematodes include chloropicrin, metam sodium, and methyl bromide.

In the latter part of the 20th century, many nematicides were banned from use in the United States because of environmental concerns. Currently, there are still several nematicidal products registered for use for nematode management, but the legal availability of these products varies greatly depending on the host crop. Nematicides and biocides are an integral part of nematode management programs for high-value fruit and vegetable crops, but very few of these pesticides are still registered for use in the United States for nematode management on low-value row crops and specialty crops grown in relatively small areas. Methyl bromide is widely used for control of insects, weeds, nematodes, and other pathogens in many different crops in the United States, but this biocide is being gradually phased out due to its harmful effects on the Earth's ozone layer. The use of methyl bromide will be completely discontinued in the United States and other developed countries by the year 2005. Research is underway to identify alternatives to methyl bromide for control of these pests and pathogens.

There are several difficulties associated with chemical control of soil-borne, plant-parasitic nematodes.^[6] Crop species vary in their sensitivity to the pesticides used for nematode management, and phytotoxicity is more of a concern with the broad-spectrum biocides than with the nematicides. Additionally, nematodes can be distributed a meter or more down into the soil, so incorporation of the pesticides deep into the soil profile is essential to maximize effectiveness, particularly for those products that are not fumigants. No nematicide or biocide will be able to kill all of the individuals in the targeted nematode population and surviving nematodes usually multiply throughout the growing season, so repeated application of these pesticides every time a susceptible crop is grown is usually necessary. Also, individual nematodes that survive nematicide applications may possess some resistance to the chemicals, so selection for nematicide-resistant nematode populations can be a concern. But despite these practical difficulties, limitations, and concerns, nematicides and broad-spectrum biocides can be effective and economical management tactics for plant-parasitic nematodes for some crop production systems, depending on the value of the crop, the crop production practices that are routinely used, the plant-parasitic nematode species that

are targeted, and the legal availability of the nematicidal or biocide products.

BIOLOGICAL CONTROL

There are many organisms that live in soil and utilize nematodes as a food source, including bacteria, fungi, mites, and other nematodes. Several natural antagonists, primarily bacteria and fungi, have been investigated for use as biological control agents for plant-parasitic nematodes. Although results of some experiments indicate that there is great potential for use of such natural antagonists for management of plant-parasitic nematodes, few products have been commercialized and are available currently for use in managing nematodes.

OTHER TACTICS

There are many other crop production practices that can be employed in attempts to reduce nematode reproduction and/or increase crop yields. As with most every other management strategy, these tactics will not have a beneficial effect for every combination of nematode and host crop. Among the more common practices that have been employed in attempts to achieve management of plant-parasitic nematodes are: 1) planting earlier or later than normal to avoid peak periods of infection of the young crop by the nematode population, 2) growing

Fig. 3 Soybean seed contaminated with soil particles (peds) containing cysts of the soybean cyst nematode *Heterodera glycines*. Planting of such uncleaned seed could introduce the nematode to a previously uninfested field. (Photo by G.L. Tylka.) (View this art in color at www.dekker.com.)

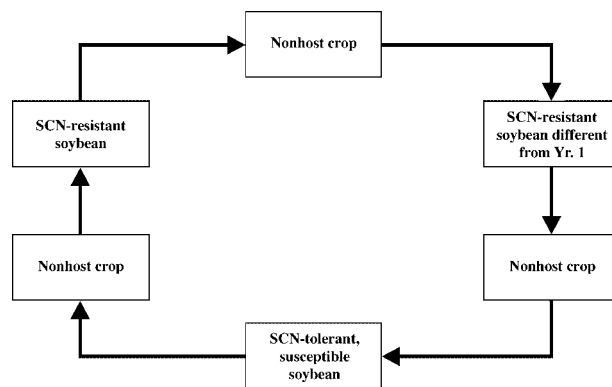

Fig. 4 Crop rotation scheme recommended by the Iowa State University Plant Disease Clinic in conjunction with scouting for early detection of new infestations for integrated management of the soybean cyst nematode (SCN) *Heterodera glycines*.

nematicidal cover crops and trap crops, and 3) leaving infested areas unplanted to reduce nematode population densities directly. Reducing the movement of soil and infected plant tissue, and thus the movement of plant-parasitic nematodes, from field to field by washing off tillage equipment and using only thoroughly cleaned seed (Fig. 3) and propagation materials that are free of nematode infection can also be of great benefit in a nematode management program. But these various tactics vary greatly in their utility based on the biology of the targeted nematode species and crop plant as well as other aspects of the crop production system. Nonetheless, many such tactics can add to the effectiveness of an integrated nematode management program.

CONCLUSION

As is the case with most pests, the most effective management program for plant-parasitic nematodes is one that incorporates several management strategies rather than one that relies on any single tactic. The limitation to integrated pest management (IPM) for plant-parasitic nematodes is the availability of different management tactics, such as host resistance, nonhost crops, and nematicides. Fig. 4 illustrates the recommended program for integrated management of the soybean cyst nematode in Iowa. Coordinated use of all available management strategies serves to reduce the selection pressure on nematode populations to overcome any individual tactic and decreases the risk of failure of any single management tactic.

Marigold Flower: Industrial Applications

James N. BeMiller

Purdue University, West Lafayette, Indiana, U.S.A.

INTRODUCTION

Marigold (*Tagetes erecta*) is grown commercially as a source of lutein, which is used as a poultry feed additive, a yellow food coloring, and a human nutritional supplement. Lutein is absorbed more efficiently from the gastrointestinal tract when the naturally occurring esterified form is saponified. The spent flower meal after lutein ester extraction yields a protein-polysaccharide with citrus oil emulsifying and emulsion-stabilizing properties. This water-soluble gum, called marigold flower polysaccharide (MFP), has been partially characterized.

MARIGOLD FLOWER PRODUCTION AND USE

Marigold (*Tagetes erecta* L., family Asteraceae) is grown not only as an ornamental, cut flower, and landscape plant, but also as a source of lutein for use as an additive to poultry feed, as a yellow food coloring, and as a human nutritional supplement. Marigolds are grown for this purpose in various locations in the Western Hemisphere (primarily in Mexico and Peru) and in Asia, by and for various companies who process flowers into various products. The agronomics of *Tagetes erecta* have been studied rather extensively.

Marigold flower oil, an essential oil obtained by steam distillation, is used for compounding perfumes. The essential oil contains biocidal components (terpenoids) and has been investigated for its bactericidal, fungicidal, larvicidal, insecticidal, and wound healing properties.

PREPARATION OF LUTEIN

Blossoms are collected both by hand and mechanically. Fresh blossoms are either heated or ensiled, then pressed to remove as much water as possible. The resulting cake is dried, pelletized, and subjected to extraction, usually with hexane. The extracted pigment, called marigold oleoresin, is primarily composed of mono- and diesters of lutein (88%).

By far the largest volume use of lutein is as an additive to poultry feed. It is added to intensify the yellow color of egg yolks and broiler skin, especially where white corn is used as feed. However, lutein esters, the primary component of the oleoresin, are not absorbed well, so the pigment is usually saponified. Various degrees of purification are used. For poultry feed, crude saponified extract in the form of an emulsion is usually absorbed on a material such as an earth or the meal remaining after extraction, which has been finely ground to convert it into a dry powder. This product has also been added to fish feed. That used as a food coloring or added to vitamin mixtures must be purified. Lutein is an antioxidant that scavenges singlet oxygen and free radicals. It is claimed to prevent age-related macular degeneration^[1] and is accepted as a "generally recognized as safe" substance by the U.S. Food and Drug Administration. Marigold oleoresin has been investigated as a dye for silk.

MARIGOLD FLOWER POLYSACCHARIDE

Water extraction of the meal remaining after commercial removal of the oleoresin from marigold flowers yields a water-soluble gum called marigold flower polysaccharide (MFP).^[2] Low-concentration, aqueous solutions of MFP have low viscosity and exhibit emulsifying and emulsion-stabilizing properties similar to those of gum arabic (gum acacia).^[2,3] This is important because there is a desire among food processors and other users of gum arabic (gum acacia) to have an alternative to it, because the supply and quality of gum arabic are variable and uncertain. Gum arabic has unique and important properties and applications.^[4] Crucial unique properties of gum arabic are its ability to form high-solids, low-viscosity solutions; its emulsifying and protective colloid properties; its ability to withstand relatively high temperatures during spray-drying; and its adhesive and film-forming properties. It is used in food, beverage, confectionary, and related products. Among its unique and important applications are the preparation of spray-dried, free-flowing citrus oil powders (fixed flavors) and bakers' citrus oil emulsions, and as a glaze on confectionary products.

MFP can be extracted from spent meal with warm (50–55°C) water.^[2,3,5–7] MFP is a heterogenous material. The major component is a protein-polysaccharide,^[2,3] as is the active component of gum arabic.^[8,9] The polysaccharide component is a highly branched, acidic arabinogalactan containing D-galactose, D-glucose, L-arabinose, and D-galacturonic acid in approximate mole ratios of 16:6:3:1.^[2,6,7] The protein part is composed of at least two hydrophobic polypeptide constituents.^[3] The structures of gum arabic and MFP (as protein-polysaccharides) are both unique in the world of industrial and food gums (hydrocolloids) and are key to their properties. In commercial gum arabic, the active component—a protein-polysaccharide—comprises only 1–2% of the total material.

As previously stated, aqueous solutions of MFP, at low concentrations, have low viscosity and have emulsifying and emulsion-stabilizing properties similar to those of gum arabic.^[2,6,7] However, while gum arabic forms low-viscosity solutions at concentrations up to 25%, the concentration at which MFP solutions began to exhibit marked increases in viscosity for small increases in concentration is about 4%. Therefore, it cannot produce high-solids, low-viscosity solutions as gum arabic does.

The crude MFP extract is dark. To obtain minimal color, an oxidative pretreatment of the meal prior to gum extraction was developed.^[2,3] Bleached MFP also has emulsifying and emulsion-stabilizing powers for limonene equivalent to those of gum arabic at equal concentrations.^[2,3] However, the pretreatment increases the viscosity of MFP solutions. Therefore, it is currently not possible to prepare the desired high-solids, low-viscosity solutions of MFP and, hence, the concentrated emulsions. Clearly, this substance warrants further investigation, even though

specially modified starch products are acceptable substitutes for gum arabic in many applications.

Mass Spectrometry for Identifying Proteins, Protein Modifications, and Protein Interactions in Plants

Michael E. Fromm

University of Nebraska, Lincoln, Nebraska, U.S.A.

INTRODUCTION

Proteomics is the large-scale identification and quantitation of the complete set of expressed proteins, defined as the proteome, of the cell. The large number of posttranslational modifications, protein–protein interactions, and subcellular locations make the proteome considerably more complex than the protein-coding capacity of the genome. This article discusses the progress in mass spectrometry in identifying proteins, in protein modifications, and in discovering protein interactions. Not covered here is the progress in other methods.

MASS SPECTROMETRY OF PEPTIDES AND PROTEINS

Mass spectrometry (MS) precisely measures the mass/charge ratio of molecules. Whole protein masses can be measured, but much higher-quality data are obtained by first digesting the proteins to peptides with a site-specific protease such as trypsin. The recent availability of the sequence of most or all of the genome of an organism has revolutionized the interpretation of MS peptide data by allowing the identification of the gene encoding the identified peptide(s).^[3,4]

Single-stage MS instruments only measure the peptide's mass/charge ratio. The resulting precise peptide mass measurements are used to calculate possible amino acid compositions, but not the sequence, of the peptide. If the masses of several peptides from the same protein are obtained, the protein can often be identified from informatics analysis of the masses of the predicted protein's digested peptides from the sequenced, annotated genome. Tandem MS-MS instruments separate the peptides in an initial MS stage and then fragment them by collision with a heavy gas, and the mass/charge ratio of the fragments are then determined in a second tandem MS stage. This fragmentation pattern can be used to determine the actual sequence of the peptide. The sequence of a single peptide is often enough to identify the gene from analysis of the genome sequence (Fig. 1).

The ability of MS instruments to detect smaller amounts of peptides and proteins has improved substantially,^[5] with sensitivity reported in the attomol to femtomol levels. However, the sensitivity is still less than that of DNA techniques because protein technologies still lack two key aspects of nucleic acid technologies: the ability to be amplified directly, as is done with DNA by PCR, and a simple, sequence-dependent detection method analogous to the hybridization of nucleic acids. The lack of a direct protein amplification technology makes the sensitivity of detection by MS critical. The lack of a protein sequence-dependent detection method makes the relative abundance of the protein of interest critical. The net result is that only 10 to 20% of the cell's proteins can be readily detected in the standard 2-D gel electrophoresis methods. Examination of protein modifications and protein–protein interactions generally requires some additional level of prior purification, either to obtain sufficient amounts of protein for a more detailed MS analysis or to obtain copurification of interacting proteins.

MASS SPECTROMETRY IDENTIFICATION OF PROTEINS

Currently, the standard method of using MS to identify new proteins is to fractionate the proteins by 2-D gel electrophoresis (2DE) to provide sufficient resolution to separate many but not all of the proteins. The protein spots are then visualized by staining with either colloidal Coomassie blue or a MS-friendly silver stain protocol or with some of the newer fluorescent dyes that work well for MS, such as Sypro Ruby.^[6] The detection limits of the dyes are generally in the 1–5 ng of protein range, which is sufficient protein for MS analysis. Typically, the 2DE gel patterns of the control and experimental samples are compared by image analysis software to identify individual spots that differ in their expression levels or modification. The protein spots of interest can be picked, preferably by automation, as contamination by skin proteins is a frequent problem. The isolated, protein-containing gel fragments are then chemically modified and

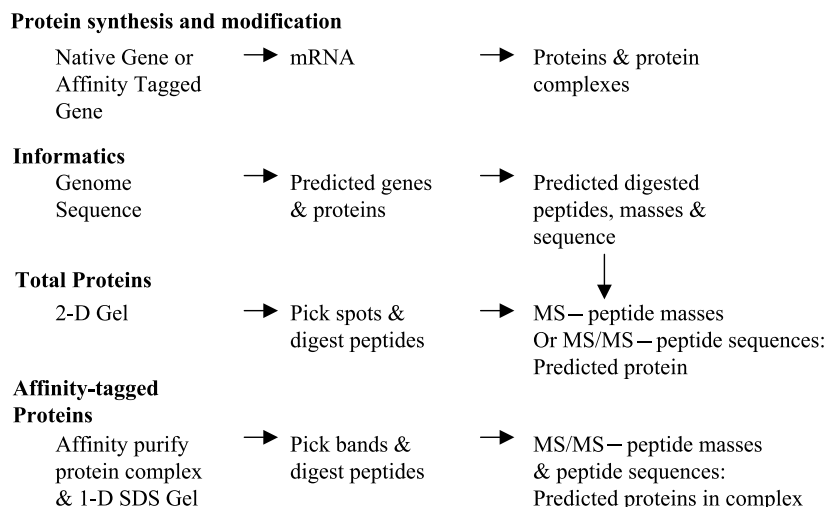

Fig. 1 Mass spectrometry analysis of proteins and affinity-tagged proteins when the genome sequence is known.

digested with site-specific proteases to obtain peptides suitable for MS analysis. Identifying low-abundance proteins still represents considerable separations and sensitivity challenges for current MS instruments, and it is estimated that only 20% of the most abundant proteins are readily detected by these methods. Alternative multistep HPLC fractionation methods that might be more sensitive are emerging.^[7] In either case, quantitative comparisons can be done with isotope-coded affinity tagging (ICAT) methods.^[8]

MASS SPECTROMETRY IDENTIFICATION OF PROTEIN MODIFICATIONS

Much of the regulation of protein activity occurs at the level of covalent modifications and protein–protein interactions. Covalent modifications alter the mass of the digested peptide, and there are over 100 known modifications, including the more common ones such as glycosylation, phosphorylation, acetylation, and methylation. The challenge with identifying protein modifications is that it is rare to identify all the peptides in a digested protein due to different rates of vaporization and detection, with 20% coverage of the peptides being more typical. Additional problems are the occurrence of mixtures of proteins and peptides in the fractionation methods, making it difficult to analyze peptides present in low amounts in the mixture. Therefore, relatively pure proteins are currently needed for covalent modification studies to assign the modified or low-abundance peptides to the protein of interest.^[9] Purifications can be facilitated with either antibody precipitations or by using the high-affinity protein tags described below.

MASS SPECTROMETRY IDENTIFICATION OF PROTEIN INTERACTIONS

The most common separations techniques prior to MS analysis, such as 2DE, destroy protein–protein interactions and are only useful for detecting individual proteins. Additionally, identifying low-abundance proteins still represents considerable separations and sensitivity challenges for current MS instruments. A new approach, which combines affinity-tagged proteins and MS, provides a high level of purification of intact protein complexes. This new approach creates an in-frame fusion of a high-affinity tag to the gene and then transfers the tagged gene back into the cells or the organism. The resulting affinity tag on the fusion protein provides a standard high-affinity, gentle purification method that allows highly purified samples of the tagged protein and any interacting proteins to be obtained as intact complexes. The high degree of purification also allows for processing the large amounts of starting materials necessary to detect low-abundance proteins.

The affinity-tags used have been designed for either single-step or two-step purifications and rely on the copurification of other proteins to be an indication of protein–protein interactions. In the two-step or tandem purifications, a first affinity purification and elution step is followed by a second, different affinity purification and elution step, providing a much higher level of purification than a single-affinity-step purification.^[10] For example, the tandem affinity purification or TAP method^[11] uses IgG beads to bind to a protein A domain in the affinity tag, and then releases the bound protein by using a site-specific protease to cleave at its specific recognition site in the affinity tag eluting the now slightly shorter fusion protein. The second purification step uses a calmodulin

binding protein domain in the remaining portion of the affinity tag to bind to calmodulin beads, in a Ca⁺⁺-dependent manner, followed by elution by chelation of the Ca⁺⁺ with EGTA. The two-step purification provides a higher level of purification and thus more reliable data on the proteins likely to be interacting with the tagged protein, as opposed to those that fortuitously copurify. Single and tandem affinity tags have been used in analyzing large numbers of yeast protein interactions^[12,13] but are still relatively new in plant applications.^[14] In the yeast examples, many of the copurifying yeast proteins found in affinity-tagged protein complexes had been previously identified by genetic or biochemical methods, confirming the validity of the affinity tag method.

It is critical that copurifying proteins are confirmed with additional experiments. The simplest step is to repeat the experiment, as 30% of copurifying proteins are not found again.^[12] Further confirmation can be obtained by epitope-tagging the new interacting protein and confirming its interaction with the first tagged protein by precipitation of the *in vivo* complexes and by verifying that both proteins were precipitated by the presence of the second epitope.^[15] If the function of the tagged gene is known, and therefore provides information about what type of pathway the protein is part of, functionally testing the gene encoding the interacting protein is an excellent method to confirm the interaction, using one of the functional genomics technologies described in this book.

SUMMARY

The 2DE approach can be used to identify proteins in any plant, although it is much more efficient when most or all of the genome sequence is known, as this facilitates the identification of the gene encoding the peptide(s) identified. The affinity-tagging methods can be used for any plant into which genes can be stably transformed. Additionally, in some instances transient expression assays can be conducted in cells that have the responses appropriate for the biology being examined, greatly increasing experimental flexibility and speed.^[14] For example, *Arabidopsis* suspension culture cells can be infected with *Agrobacterium* in sufficient amounts for proteomic analysis^[15,16] and show responses to osmotic and salt stress. We have recently demonstrated that transient expression of several TAP-tagged proteins that are involved in osmotic stress signaling in *Arabidopsis* cells can be purified in amounts sufficient for tandem MS/MS sequencing of the peptides of the isolated and digested proteins.

The post-genome era will herald increasing focus on gene function and biochemical mechanisms. Proteomics tools, particularly mass spectrometry, will play an increasing role in identifying proteins, their modifications, and their protein-protein interactions. Recent results in protein-protein interactions in yeast indicate that an

extensive network of interacting proteins exists in cells that we are only now beginning to understand.^[17]

Mechanisms of Infection: Imperfect Fungi

Gyungsoon Park

Jin-Rong Xu

Purdue University, West Lafayette, Indiana, U.S.A.

INTRODUCTION

Imperfect fungi (deuteromycetes) by definition are fungi that do not have known sexual stages. Although their taxonomic status is no longer valid, many of several thousands of known imperfect fungal species are important plant pathogens. In general, infection starts with the adhesion of fungal propagules (usually asexual spores or conidia) to plant surfaces followed by surface recognition and penetration. Some fungi enter plant hosts through natural openings, such as stomata or wounds, while others directly penetrate through plant surfaces and epidermal cells. After penetration, infectious hyphae colonize plant tissues and induce disease symptom development.

ATTACHMENT AND GERMINATION

Attachment

Adhesion of dispersing propagules to plant surfaces is commonly the first step of infection by fungal pathogens, but the composition of the adhesive materials and the development of adhesiveness vary among fungal species. In some fungi, the adhesive materials are preformed and released upon contact with the plant surface or upon hydration of conidia, such as the spore tip mucilage formed by the rice blast fungus *Magnaporthe grisea* and the adhesion knob formed by the nematode trapping fungus *Drechmeria coniospora*. In some fungal pathogens, the extracellular matrix of conidia may contain adhesive materials or enzymes that assist in attachment and preparation of the infection court.^[1] In fungi with an active adhesion process, respiration and protein synthesis are required before the conidia or their germ tubes become adhesive. Synthesis of adhesive materials may be stimulated by compounds present at plant surfaces or regulated by specific fungal-plant recognition events.^[1]

Adhesion has been recognized as an important step in plant infection, and it is worth noting that fungal adhesion can occur at different stages of infection-related morphogenesis.^[2] Various proteins, glycoproteins, and polysaccharides have been identified in different pathogens, but the exact chemical components of adhesive materials have

not been determined for most fungi. No fungal adhesive compound has been experimentally proved by directed mutagenesis to mediate plant attachment.

Germination

Conidial germination involves activation, swelling, and germ tube emergence.^[3] In a few fungi, such as *Botrytis cinerea* and some *Colletotrichum* species, conidia can remain dormant or quiescent on plant surfaces until host plants produce certain stimulatory compounds (e.g., ethylene produced during fruit ripening). However, in most fungal pathogens, conidia germinate immediately after attachment and produce germ tubes when moisture, nutrients, temperature, and other environmental conditions are favorable. Conidia of a number of fungi contain endogenous self-inhibitors that prevent conidia from germinating when the spore density exceeds a given threshold. Germination occurs only after these compounds are washed off or diluted, or their inhibitory effects are relieved with nutritional supplements or plant surface molecules (such as cutin monomers). In many fungi, adhesive materials are formed surrounding the germ tubes to mediate adhesion and possibly provide protection against harmful environmental factors.

PENETRATION

Penetration Structures

Fungal pathogens have evolved distinct strategies for penetrating plant leaves, stems, or roots. In some fungi, the undifferentiated germ tube or hyphal tip can directly form a penetration peg to invade plant cells. The penetration peg is a thin, tip-growing cellular protuberance that is generally much narrower than somatic hyphae. However, in many fungi, penetration pegs develop from the thin-walled appressorial pores located at the contact area between the appressorium and the plant surface. Appressoria are infection structures formed on the end of germ tubes or hyphae for adhering to host surface and subsequent penetration. The tight adhesion of appressoria to the plant surface is mediated by a ring of appressorium

mucilage. An appressorium can be a simple or multiple-lobed germ tube tip swelling or a specialized swollen body delimited from the germ tube by a septum. Some fungi form multicellular aggregates that are known as compound appressoria or infection cushions. Multiple penetration pegs can arise from a single compound appressorium. Penetration pegs also can develop from a net-like mycelium without well-differentiated appressoria. Another infection structure common among asexual foliar pathogens is the hyphopodium. Hyphopodia formed on epiphytic somatic hyphae may be terminal, lateral, or intercalary, simple or lobed. Many environmental factors, including temperature, pH, nutrients, plant surface molecules and physical features, are known to affect penetration structure formation. Germ tubes can also recognize surface hydrophobicity, hardness, components of the plant surface, and topographical properties to regulate infection-related morphogenesis.

Mechanisms of Penetration

Both physical and enzymatic forces are used by fungal pathogens to invade plant tissues.^[4] In fungi such as *M. grisea*, elevated osmotic pressures within melanized appressoria are used to puncture leaf cuticles physically and plant cell walls.^[2] Blocking melanin synthesis by mutation or inhibitors prevents penetration because the melanin layer is essential for lowering the porosity of the appressorial wall. The turgor pressure in melanized appressoria is as high as 80 bars by accumulation of a high concentration of glycerol.^[2] Pressure generated by turgor is exerted over the restricted area of the appressorial pore where the penetration peg emerges, resulting in penetration of plant tissue. Other fungi, including *Colletotrichum* species, also develop turgor pressures in appressoria as part of the penetration forces.^[4] Forces produced by the cytoskeleton in penetration pegs may also contribute to appressorial penetration, particularly in fungi with low appressorium turgor pressures. A high concentration of cytoskeleton element in penetration peg may also be necessary to compensate for the difference in osmotic pressure between appressorial and host cell protoplasts.

Many fungal pathogens produce degradative enzymes, such as cutinases, laccases, polygalacturonases, and cellulases. For fungi that directly penetrate plant tissue without producing specialized infection structures, it is likely that cell wall-degrading enzymes play important roles in penetration. Some fungi are able to erode the plant cuticle, and localized degradation of plant cell wall materials has been observed along the penetration peg in several fungi. Even in fungi with high appressorium turgor, cell wall-degrading enzymes may be involved in penetration by modifying or softening the plant surface or cell wall. However, determining the importance of

individual cell wall-degrading enzymes in plant penetration is complicated by the genetic redundancy and variable regulation of these enzymes.

INFECTIOUS GROWTH

After penetration of host epidermal cells, infectious hyphae are differentiated from the bulbous primary vesicle. Infectious hyphae are often morphologically distinct from somatic hyphae or germ tubes. In some fungi, infectious hyphae may grow only between the cuticle and cell wall or within epidermal cell walls. Some endophytic fungi can grow extensively in plant tissues without damaging host cells and only cause disease symptoms when host plants are under certain stresses or developmental processes. In biotrophic pathogens, an elaborate structure known as the haustorium is formed within the penetrated cell for nutrient absorption. Most asexual fungi, however, do not produce haustoria. In necrotrophic pathogens such as *Alternaria* and *Rhizoctonia* species, plant cells are killed in advance of the invading hyphae, and the infectious hyphae grow between and into dead and dying cells. Some asexual pathogens are hemibiotrophic. During the initial biotrophic stage, the infectious hyphae can grow without killing plant cells. Switching from the biotrophic to necrotrophic phase occurs in the later stages and results in plant cell death. A few genes that are specifically expressed in the biotrophic phase or involved in the transition from biotrophic to necrotrophic phase have been reported in several *Colletotrichum* species.

During growth within the plant, the infectious hyphae must adapt to the plant environment and produce necessary enzymes for nutrient absorption. Infectious hyphae must also use different strategies to overcome constitutive and induced plant defenses, including degradation of preformed or induced antimicrobial compounds (such as pisatin demethylases or saponin-detoxifying enzymes and enzymes for scavenging reactive oxygen species). Some fungal pathogens produce molecules that suppress induced plant defenses.^[5] For some pathogens with narrow host ranges, the fungal-plant interaction is governed by specific interactions between fungal avirulence and plant resistance genes. Fungal avirulence genes have been identified from several pathogens. These avirulence genes encode proteins with diverse biological functions and do not share common structural features.

Various fungi produce toxins or elicitors to damage plant cells. While some phytotoxins, such as trichothecenes, interfere with general host cellular functions, some toxins are known as host-specific toxins, such as AAL- and HC-toxins produced by *A. alternata* and HC-toxin produced by *Cochliobolus carbonum*. Host-specific toxins are primary determinants of host range and can elicit

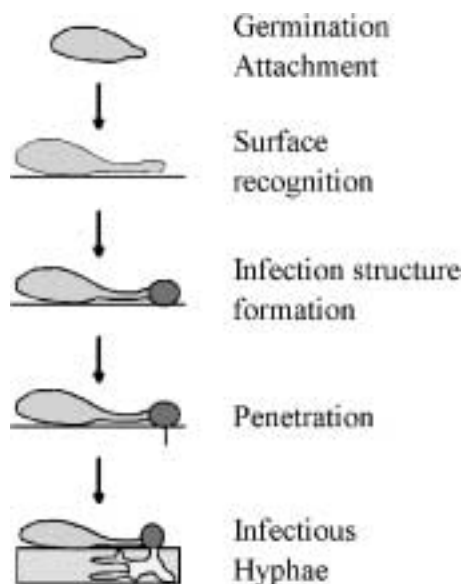

Fig. 1 Major steps of plant infection processes.

disease symptoms with the same specificity as the pathogens. In pathogens causing vascular wilt diseases, such as *Fusarium oxysporum* and *Verticillium* species, the xylem vessels of infected stems and roots may be clogged with hyphae, spores, or polysaccharides produced by the pathogens. Cell wall-degrading enzymes, proteinases, and other enzymes also play important roles during infectious hyphal growth. For example, *B. cinerea* mutants disrupted in the endopolygalacturonase gene BCPG1 are significantly reduced in virulence, and transgenic tomatoes expressing a high level of polygalacturonase inhibitory proteins exhibit increased resistance to *B. cinerea*.^[6]

CONCLUSION

In the past few years, both forward and reverse genetics approaches have been used to characterize genes important for plant infection processes and signal transduction pathways regulating infection-related morphogenesis.^[7] However, our knowledge about molecular mechanisms

involved in the intimate fungal-plant interactions is still very limited, particularly the events after penetration.^[8] Recent advances in imaging techniques and genomics studies will be very helpful to further characterize fungal infection structures and efficiently identify genes critical for fungal pathogenesis (Fig. 1).

Mechanisms of Infection: Oomycetes

Paul R. J. Birch

David E. L. Cooke

Scottish Crop Research Institute, Dundee, U.K.

INTRODUCTION

Oomycetes are a diverse group of organisms that morphologically resemble fungi yet are members of the chromista, more closely related to key organisms in aquatic environments such as brown algae (e.g., kelp), golden-brown algae, and diatoms. The oomycetes include a tremendous range of free-living water molds, as well as saprophytes and pathogens of plants, algae, insects, fish, crustaceans, vertebrate animals, and microbes, including fungi. Plant pathogenic oomycetes cause devastating diseases of crop, ornamental, and native species and are arguably the most important pathogens of dicot plants. This article focuses on the most damaging groups, comprising more than 60 species of *Phytophthora*, several downy mildew genera (the most important being *Peronospora*, *Plasmopora*, and *Bremia*) and more than 100 *Pythium* species.

There is considerable diversity in oomycete infection strategies, from opportunistic or weakly pathogenic necrotrophs with wide host ranges, typified by many soil-borne *Pythium* species, through to the highly specialized, biotrophic, aerially disseminated, foliar *Peronospora* species. The genus *Phytophthora* spans these two extremes, including species colonizing leaf-litter, others that are described as “root-pruning,” and a range of highly specialized pathogenic hemibiotrophs. A common feature, however, is the absolute dependence on living plant tissue to complete their life cycle. Such diversity of pathogenic strategies begs the question of whether similar variation is manifest in infection mechanisms.

Oomycetes undergo many developmental stages throughout a successful infection cycle, including formation of sporangia, release of motile zoospores, their encystment and germination to form hyphae and appressoria, production of primary and secondary infection hyphae, haustoria, and finally sporangiophores. These stages facilitate dispersal, host recognition, adhesion, penetration, and colonization, encompassing biotrophic and/or necrotrophic phases of infection, finally returning to dispersal. In Fig. 1 we present a diagrammatic representation of “typical” oomycete infection structures and mechanisms and discuss the extent to which variation is apparent, using specific examples selected from key genera.

DISPERSAL AND RECOGNITION: SPORANGIA AND ZOOSPORES

Asexual, multinucleate sporangia develop from simple or compound sporangiophores at the apices of hyphae and are the most rapid means of reproduction (Fig. 1). The sporangia of airborne oomycetes, such as the potato late-blight pathogen *Phytophthora infestans*, are, in general, caducous, i.e., released freely from aerial hyphae and dispersed by wind or insects. In oomycetes predominantly colonizing roots or stem bases, sporangia are not freely released (noncaducous) and zoospores provide the main means of dispersal (Fig. 1). Generally, *Pythium* spp. produce noncaducous sporangia and downy mildews produce caducous sporangia. Within the *Phytophthoras* there are groups of species that span both extremes.

Sporangia may germinate directly to form an infection hypha or differentiate, through specialized cleavage vesicles, into between 10 and 30 zoospores that are released.^[1] The mechanism adopted varies, with zoospore production prevalent in *Pythium* species, through to an inability to form zoospores in *Peronospora* species. All *Phytophthora* species form zoospores but direct germination also occurs. The lack of the aquatic zoospore stage in *Peronospora* may reflect a greater adaptation to a terrestrial habitat, and sporangia thus provide the means of dispersal, recognition, and penetration of the host.^[2]

Zoospores are ephemeral, motile, biflagellate cells lacking cell walls and are often the initial agents of contact with the host.^[3] Under certain conditions they remain motile for several hours, although the distances traveled rarely exceed a few centimeters; passive movement in mass flow or surface water is a more significant means of dispersal. They can differentiate to form adhesive cysts, involving detachment or resorption of flagella, formation of a cell wall, and secretion of adhesive materials. *Phytophthora cinnamomi* cysts can differentiate into a sporangium that releases a single, secondary zoospore. This process can be repeated several times to increase the distance traveled to colonize a new host.^[4]

Zoospores respond to both plant exudates (chemotaxis) and to changes in electric currents (electrotaxis), although the pathological significance is unclear, since they are

Fig. 1 Typical oomycete infection cycle in host leaf (upper circle) or root (lower circle) tissues. In each circle, **1** represents mechanisms of dispersal of oomycetes, including wind or insect dispersal (upper circle) of sporangia (sp.), and attraction of zoospores (z) by electrotaxis or chemitaxis (lower circle); **2** direct germination of sporangia, or encystment (c) and germination of zoospores to penetrate the host along anticlinal epidermal cell walls (lower circle), via stomata, or through the periclinal cell wall with the aid of an appressorium (a) and infection hypha (ih) (upper circle); **3** hyphal colonization of host tissues and the development of intracellular haustoria (h); **4** sporulation on the leaf or root surface to complete and reinitiate the infection cycle. (View this art in color at www.dekker.com.)

attracted nonspecifically to roots of host and nonhost plants. However, many oomycetes with restricted host ranges respond to specific host-derived chemicals. For example, *Phytophthora sojae* zoospores are attracted to isoflavones in soybean seeds and root exudates.^[5] Recently, van West et al.^[6] demonstrated that *Pythium aphanidermatum* and *Phytophthora palmivora* differed in their responses to electric currents. *P. palmivora* is anodotactic and attracted to rye grass root tips, whereas *Py. aphanidermatum* is cathodotactic and attracted to a region behind rye grass root tips and to wounds, which are cathodic.

CYST GERMINATION, APPRESSORIUM FORMATION, AND HOST PENETRATION

During zoospore encystment and germination, adhesive materials are secreted that are important in preventing dislodgement of cysts and in providing attachment as physical force is exerted during host penetration. The adhesive materials are unknown, although genes encoding mucin-like proteins, termed *Car*, have been postulated to play a role in attachment and are up-regulated in germinating cysts and appressoria.^[7] Moreover, a protein called CBEL, identified in *Phytophthora parasitica*, contains a fungal-like cellulose binding domain and is required for attachment to cellulose.^[8]

Phytophthora cysts germinate 20 to 30 minutes after encystment, and hyphae directly penetrate host roots either intercellularly along anticlinal cell walls, or intracellularly through the periclinal wall of epidermal cells.^[9] Both forms of penetration are also observed in the *Pythium* spp. Aerial plant parts are similarly infected by *Phytophthora* and downy mildews but with an additional means of direct entry via stomata.

Both root- and leaf-infecting oomycetes can form appressorium-like structures, hyphal swellings that are manifest prior to penetration of host epidermal cells. In contrast to those formed in fungal plant pathogens such as *Magnaporthe grisea*, oomycete appressorium-like structures lack cross-walls separating them from the spore and germ tube. However, there is little doubt that they are involved in host penetration and thus meet one of the important criteria that define appressoria.^[9]

Appressorium-like structures are formed with greater prevalence in oomycetes invading foliar host tissues. Nevertheless, whether in leaf- or root-infecting species, they are more frequently formed when directly penetrating the periclinal wall of epidermal cells, possibly due to the greater demands of overcoming more challenging host cell wall barriers.^[9]

Penetration of host cell walls involves not only exertion of physical pressure but also production of enzymes facil-

itating breakdown of cell wall polymers, including pectin and cellulose. Various extracellular hydrolytic enzymes, including cellulase, β -glucosidases and 1,3- β -glucanases were purified from *P. infestans* culture filtrates,^[10] and genes encoding some of these, and also cutinases and polygalacturonases, have been identified in a range of oomycetes.^[11]

HOST COLONIZATION AND HAUSTORIUM FORMATION

The infection tube that develops from a *P. infestans* appressorium-like structure penetrates a leaf epidermal cell to form a dilated hyphal structure termed a "primary hypha" or "infection vesicle." This "biotrophic" structure is surrounded by the host plasma membrane. One or more secondary hyphae develop that traverse the cell and exit, either penetrating a mesophyll cell or entering intercellular spaces. The hyphae ramify through intercellular spaces, where they form a further "biotrophic" structure within living plant cells, the haustorium (Fig. 1).^[12] Unlike the spherical bodies typical of many true-fungi, those in *Phytophthora* spp., downy mildews, and *Pythium* spp. are fingerlike. As with the infection vesicle, they are surrounded by the host plasma membrane and make no direct contact with host cytoplasm. Their outer cell wall comprises an extra-haustorial matrix, an electron dense substance of unknown function laid down at the initial stage of haustorial penetration of the host cell wall.^[9,12] Interestingly, haustoria of *Phytophthora* spp. are reported to lack nuclei,^[9,12] whereas those in downy mildews may be uninucleate or multinucleate.^[13]

Haustoria are biotrophic, since they are formed within living plant cells and are presumably involved, at least in part, in exchange of nutrients from the host to the pathogen. Subtle penetration of living host cells implies avoidance or suppression of host defences. Doke et al.^[14] proposed the production of a glucan by *P. infestans* that suppresses the hypersensitive response, a form of programmed cell death or host cell suicide to which haustoria would be particularly vulnerable. Furthermore, a family of glucanase inhibitor proteins (GIPS) in *P. sojae* inhibit host endo- β -1,3-glucanases.^[15] GIP inhibition not only prevents host glucanases from directly attacking pathogen cell walls but also prevents their activity leading to release of elicitor-active oligosaccharides that induce additional host defences.

In susceptible hosts, oomycetes acquire sufficient nutrients to ramify through plant tissues and sporulate on the root, stem, or leaf surface, releasing sporangia

and/or zoospores to complete and reinitiate the cycle of infection.

FUTURE PROSPECTS

The cytology of plant infection by oomycetes has been extensively studied over many years. Infection follows a cycle of clearly defined developmental stages. With each cell type that is formed, countless genes will be up- or down-regulated, not only to drive cellular development but also to facilitate host invasion and counteract host defences. The molecular bases of pathogenicity are poorly understood, although the current era of genomic research promises to accelerate our understanding of molecular processes in two key, model oomycetes, *P. sojae* and *P. infestans*.^[5,11]

Mechanisms of Infection: Rusts

Matthias Hahn

University of Kaiserslautern, Kaiserslautern, Germany

INTRODUCTION

Among the various infection strategies used by plant pathogenic fungi, growth in living host tissue (biotrophy) and formation of haustoria are hallmarks of rust fungi. Rust infection is also unique in the ability of a germ hypha to sense surface topography in order to achieve invasion via stomata. Our understanding of biotrophic parasitism and the crucial role of rust haustoria in the uptake of sugars and amino acids from infected host cells has increased significantly using molecular and cytological methods. This article summarizes our knowledge about host invasion and establishment of rust infection.

BIOLOGY AND INFECTION MECHANISMS OF RUST FUNGI

With more than 5000 described species, rust fungi (Uredinales, Basidiomycetes) form a major group of plant pathogens. Named after their noticeable sori, which are often filled with reddish-brown (or yellow, black, etc.) colored spores, rust fungi have destroyed cereal crops since ancient times, and still cause significant damage to a large variety of economically important plants (e.g., legumes, coffee, pines). The most conspicuous property of rust fungi is their highly complex life cycle and their ability to switch hosts. Macrocytic rust species produce up to five different spore forms, but reduced life cycles also exist. Three types of rust spores are infectious, namely uredo- and aecidiospores (dikaryotic) and basidiospores (monokaryotic, haploid). In heteroecious rusts, which need two different host plants to complete their life cycle, dikaryotic spores infect one species and monokaryotic spores infect another. A well-known example is *Puccinia graminis*, which infects wheat as a dikaryon and barberry as a monokaryon. Infection by uredo- and aecidiospores usually occurs via stomata and involves a series of infection structures (see below). In contrast, basidiospores penetrate epidermal cells directly, giving rise to a mycelium which shows a lower degree of cellular differentiation and which often tends to grow toward vascular host tissue.^[1]

SPORE ATTACHMENT, GERMINATION, AND INFECTION STRUCTURE FORMATION

Rust uredospores are spread by air, sometimes over very long distances, to reach their host plants. They have hydrophobic coats, which allow adhesion to aerial hydrophobic plant surfaces. Irreversible attachment, however, requires the release of adhesive gel-like material consisting of carbohydrates and glycoproteins. It accumulates—in the presence of water, by passive hydration and swelling—between spore and host surface. Hydrolytic enzymes such as esterases and cutinases increase the adhesive properties of the secreted material, possibly by “eroding” the hydrophobic cuticular layer and converting it to a hydrophilic one.^[2] Subsequently, the germ tube emerges and grows over the plant surface, with the tip of the hypha being closely attached to the cuticle.

Localization of stomata as entry points for subsequent invasion is achieved by a unique surface-sensing mechanism of the germinated rust uredospore. Growth direction of the germ tube is aligned perpendicular to repetitive features formed by the ridges or grooves of adjacent epidermal cell walls. This increases the chance that the fungus will hit a stoma. Subsequently, when the germ tube tip reaches a stomatal guard cell, a new type of hypha called an appressorium is formed. Allowing rust germ-lings to develop on artificial surfaces with ridges or grooves of defined dimensions proved that topographical features provide the key signals for this differentiation process. For instance, a ridge of approximately 0.5 μm height was most effective in the case of the bean rust *Uromyces appendiculatus*, and this height is similar to the height of the guard cell lip of bean leaves.^[3] Within a few minutes after topographical recognition, germ tube elongation is stopped and appressorium formation is initiated. There is evidence that ion fluxes across the plasma membrane in the tip region of the germ tube, followed by cytoskeletal rearrangements, are involved in transducing the mechanical signal “presence of the stoma” into the response “appressorium formation and invasion.” Invasion of host tissue occurs by means of additional infection structures, i.e., penetration hypha, infection hypha, and haustorial mother cell (Fig. 1). In several rust species, these structures are formed without additional signals. The

Fig. 1 Infection by rust fungi (*Uromyces* spp.). A germ tube (GT) emerges from an uredospore (S) attached to the leaf surface by an adhesion pad (P). Above the stoma, an appressorium (A) is formed, a penetration hypha (PE) grows into the substomatal chamber, and an infection hypha (IH) extends into the apoplastic space. A haustorial mother cell (HM) attaches to the host cell wall and penetrates into the cell, giving rise to a haustorium (H). Unique features of the haustorium are the neckband (NB) and the interfacial, extrahaustorial matrix (yellow) surrounded by the host-derived extrahaustorial membrane (EHM). After formation of the primary haustorium, the infection hypha forms branches and the biotrophic mycelium proliferates within the leaf tissue. (From Ref. 6.) (View this art in color at www.dekker.com.)

formation of infection structures in response to artificial signals has made it possible to study molecular events associated with the early invasion process of rust fungi in the absence of a host plant.

During invasion, rust fungi secrete low amounts of host cell wall degrading enzymes, which is strictly dependent on infection structure formation. For instance, the secretion of several isoforms of cellulases and pectin esterases was not observed until appressorium formation and occurred in a sequential fashion. Another enzyme, pectate lyase, was not produced until haustorium mother cell differentiation. In contrast to the situation in many other fungi, production of these enzymes was not subject to glucose repression, and no substrate induction was observed except for pectate lyase, which was secreted only in the presence of pectate (=polygalacturonate).^[4]

Although it has not been proven, it is plausible that the abovementioned enzymes—together with others—aid in the attachment of the invading hyphae to cells walls of the host and in the subsequent penetration of the walls during haustorium formation. The highly controlled secretion of these lytic enzymes could be important in minimizing damage to the host cell that is invaded during haustorium formation.

HAUSTORIA

In contrast to the infection structures mentioned above, haustoria are formed only within living host cells. This makes their experimental analysis difficult, even more so since rusts are obligate biotrophs which cannot be cultivated (with few exceptions) in artificial media. Therefore, it is not possible to apply powerful molecular genetic experimental tools such as genetic transformation and knockout mutagenesis to rust fungi.

Haustoria certainly play a crucial role for the establishment of biotrophic rust infections. They are part of a parasitic mycelium which grows largely intercellularly. While being formed within host cells, they remain surrounded by a modified plasma membrane. By this means, a highly specialized interface is formed. Extensive cytological studies using light and electron microscopy identified the unique structural properties of haustoria that are likely to be correlated with their function. According to our present view, rust haustoria are centrally involved 1) in biotrophic nutrient acquisition; 2) in vitamin biosynthesis; and 3) in maintaining the biotrophic relationship with the host plant. Whereas only little experimental evidence is available about the last

Fig. 2 Model for uptake of nutrients by a rust haustorium from an infected plant cell. The proton-pumping activity of a plasma membrane H^+ -ATPase in the haustorial plasma membrane generates a proton gradient and membrane potential. They are used by proton-coupled carrier proteins that transport hexose sugars (glucose, fructose) and amino acids into the haustorium. One hexose transporter and three amino acid transporters are known in the broad bean rust. (View this art in color at www.dekker.com.)

aspect, molecular studies have provided significant information about the nutritional and metabolic aspects of haustorium function.

Fig. 3 Immunolocalization of a hexose transporter within the plasma membrane of rust haustoria. A resin-embedded section of a rust-infected broad bean leaf was incubated first with an antibody against a rust hexose transporter, followed by a fluorescence-labeled secondary antibody. Labeling is visible only in the periphery of rust haustoria (H). V, plant vacuole; C, chloroplast; A, apoplast. (From Ref. 6.) (View this art in color at www.dekker.com.)

According to the diagram shown in Fig. 2, nutrients released from the infected host cell into the interface (extra-haustorial matrix) diffuse across the interface layer and the haustorial wall to the haustorial membrane, where they are transported by proton symport carriers into the haustorial cytoplasm. The driving force for metabolite uptake is a proton gradient across the haustorial plasma membrane generated by the activity of a plasma membrane H^+ -ATPase. This model is supported by the following experimental evidence: Genes encoding amino acid and hexose carriers have been cloned from a rust fungus and were found to be transcribed at high levels in haustoria, but not (or only at low levels) in early infection structures and the intercellular hyphae. With immunolocalization, a proton-coupled hexose carrier was detected exclusively in the haustorial plasma membrane, convincingly showing that this is the major site of sugar uptake into the fungus (Fig. 3).^[5] Furthermore, the activity of the rust plasma membrane H^+ -ATPase was shown to be highest in a membrane preparation isolated from rust haustoria, so this enzyme could well be responsible for the generation of the membrane potential required for secondary active nutrient uptake.

Evidence for major metabolic activities in haustoria also came from the identification of two highly expressed genes that encode enzymes required for thiamine biosynthesis. One of these enzymes was detected in

haustoria in high concentrations, but only at low levels in other parts of the rust mycelium. Thus, haustoria appear to be not only the principal sites of nutrient uptake, but also of the biosynthesis of vitamin B1 and possibly other important metabolites that are not provided by the host plant.^[6]

CONCLUSION

The biotrophic lifestyle provides rust fungi with a continuous supply of nutrients and allows them to escape competition with most other herbivorous microorganisms. To achieve this goal, rust fungi need to suppress host cell death, which is usually associated with the most powerful plant defense mechanism—the hypersensitive response. How defense suppression is accomplished remains unknown, but there is evidence that haustoria also play a crucial role in this process.

Medical Molecular Pharming: Therapeutic Recombinant Antibodies, Biopharmaceuticals and Edible Vaccines in Transgenic Plants Engineered via the Chloroplast Genome

Henry Daniell

University of Central Florida, Orlando, Florida, U.S.A.

INTRODUCTION

The daily average income of nearly one billion people is less than one U.S. dollar. Globally, about 170 million people are infected with hepatitis C virus, with 3–4 million new infections each year. WHO Department of Communicable Disease Surveillance and Response reports that more than one third of world population is infected with hepatitis B. In Asia, the prevalence of chronic hepatitis B and C is very high (about 110 million infected by HCV and 150 million infected by HBV). A large majority of hepatitis C–infected patients have severe liver cirrhosis and currently there is no vaccine available for this disease. The annual requirement of human, insulinlike growth factor 1 (IGF-1) per cirrhotic patient is 600 mg (1.5–2 mg per day) and the cost of IGF-1 per mg is \$30,000. Current annual cost of interferon therapy for viral hepatitis is \$26,000 per year. Therefore, agricultural scale production of therapeutic proteins and vaccines is necessary to meet such large demand at a reasonable cost. Recent observation of the potential ability of one acre of transgenic tobacco plants to produce 600 million anthrax vaccines makes this a promising new approach.

CHLOROPLAST-DERIVED THERAPEUTIC PROTEINS

Chloroplast-derived biopharmaceuticals should be inexpensive to produce and store, easy to scale up for mass production, and free of animal or human pathogens.^[1,2] Chloroplast genetic engineering is an environmentally friendly approach and offers biological containment of transgenes.^[3] Expression of thousands of copies of transgenes per plant cell via chloroplast genomes has yielded the highest level of foreign proteins ever reported in transgenic plants.^[1,2] Chloroplast transgene expression is also free of position effect and gene silencing,^[1,2] frequently encountered in nuclear transgenic plants that result in low levels of expression. Oral delivery of phar-

maceuticals should eliminate the purification steps that usually account for most of production costs. Edible vaccines may be the only practical solution to combat bioterrorism agents. The successful engineering of tomato chromoplasts for high-level transgene expression in fruits,^[4] coupled with hyper expression of vaccine antigens^[5] and the use of plant-derived, antibiotic-free selectable markers,^[6] augurs well for oral delivery of edible vaccines or biopharmaceuticals that are currently beyond the reach of those who need them most. However, because of the concerns of dosage and potential for contamination with the food supply, plant derived pharmaceuticals should be prescribed as a freeze-dried powder (with appropriately identified dosage) and fully contained.

PLANT-DERIVED BIOPHARMACEUTICALS AND HUMAN PROTEINS

Generally, levels of pharmaceutical proteins expressed in nuclear transgenic plants have been less than the levels needed for commercial feasibility, if the protein must be purified. Recombinant hepatitis B surface antigen (HBsAg) expressed via the nuclear genome induced only a low-level serum antibody response in a small human study, probably reflecting the low level of expression (1–5 ng/g fresh weight) in transgenic lettuce. Recent studies increased the level of expression up to 8.35 µg/g fresh tuber (0.000835% fresh weight). Despite such low levels of expression, adequate primary antibody response was observed in animals fed with uncooked potato tubers, but this response was lost when tubers were cooked.^[7] Similarly, Norwalk virus capsid protein expressed in potatoes caused oral immunization when fed to mice, but expression levels were too low for large-scale oral administration. Similar to viral proteins, expression of genes encoding several human proteins in transgenic plants has been disappointingly low, e.g., human serum albumin, 0.02%; human protein C, 0.001%; human epidermal growth factor, 0.001% and erythropoietin,

0.0026% of total soluble protein; human interferon- β was 0.000017% of fresh weight.^[8-10] Therefore, there is a great need to increase expression levels of human, viral, or bacterial proteins or antigens in order to enable commercial production of pharmacologically important proteins in plants.

CHLOROPLAST TRANSGENIC SYSTEM

Chloroplast genetic engineering was conceived as a novel approach to increase expression levels and overcome problems of nuclear genetic engineering.^[11-13] Foreign genes have been integrated into the chloroplast genome of several crop plants, including tobacco, tomato, and potato (up to 10,000 copies of transgenes per cell), resulting in accumulation of recombinant proteins several hundred-fold higher than nuclear transgenic plants (up to 47% of the total soluble protein).^[14] Targeted integration of transgenes at specific sites into the chloroplast genomes eliminates the "position effect" frequently observed in nuclear transgenic plants resulting from random integration of transgenes.^[1,2] In addition, gene silencing has not been observed in transgenic chloroplasts, in spite of extraordinarily high levels of transgene expression, whereas it is a common phenomenon in nuclear transformation.^[2] Because of these reasons, expression and accumulation of foreign proteins is uniform in independent chloroplast transgenic lines.^[5] It has been shown that multiple genes can be engineered in a single transformation event via the chloroplast genome, regulated by a single promoter; this facilitates coordinated expression of multisubunit proteins or multicomponent vaccines, or engineering new pathways. This was demonstrated by successful expression and assembly of monoclonal antibodies^[15] or multigene bacterial operons^[14] in transgenic chloroplasts. Yet another advantage is the lack of toxicity of foreign proteins to plant cells when they are compartmentalized within chloroplasts.^[5,16] Chloroplast genetic engineering is an environmentally friendly approach, minimizing several environmental concerns, including transgene containment.^[3] Most importantly, chloroplasts are able to process eukaryotic proteins, including correct folding and formation of disulfide bridges. Accumulation of large quantities of a fully assembled form of human somatotropin with the correct disulfide bonds provides strong evidence for hyperexpression and assembly of pharmaceutical proteins using this approach.^[17] In addition, functional assays showed that chloroplast-synthesized cholera toxin β subunit (CTB) binds to the intestinal membrane GM1-ganglioside receptor, confirming correct folding and disulfide bond formation of the plant-derived CTB pentamers.^[5] Such folding and assembly of foreign proteins should eliminate the need for

highly expensive in vitro processing of pharmaceutical proteins produced in recombinant organisms. For example, 60% of the total operating cost for the commercial production of human insulin in *Escherichia coli* is associated with in vitro processing (formation of disulfide bridges and cleavage of methionine).^[18]

Expression of Human Serum Albumin in Transgenic Chloroplasts

Human serum albumin (HSA) accounts for 60% of the total protein in blood serum and it is the most widely used intravenous protein. Currently, HSA is produced primarily by the fractionation of blood serum. Because of unique advantages of the chloroplast genetic engineering approach, HSA was expressed in transgenic chloroplasts.^[19,20] Regulation of HSA under the control of a Shine-Dalgarno sequence (SD), 5' *psbA* region, or the *cry2Aa2* untranslated region (UTR) resulted in different levels of expression in transgenic chloroplasts from seedlings: 0.8, 1.6, and 5.9% of HSA in total protein (tp), respectively. On the other hand, a maximum of 0.02, 0.8, and 7.2% of HSA in tp was observed in transgenic potted plants regulated by SD, *cry2Aa2* UTR, or 5' *psbA* region, respectively, demonstrating excessive

Fig. 1 Electron micrograph of immunogold labeled inclusion bodies of human serum albumin (HSA) in transgenic chloroplasts (magnification $\times 6300$). HSA is the most widely used intravenous protein in human therapies.

proteolytic degradation, unless compensated by enhanced translation. The psbA-HSA expression was subject to developmental and light regulations, with the lowest expression observed in seedlings and maximal expression (11.1% tsp) under continuous illumination. This is the highest expression of HSA so far and five hundred-fold higher than previous reports of HSA expression in leaves of nuclear transgenic plants. Accumulation of HSA was so high that inclusion bodies were observed within transgenic chloroplasts (Fig. 1). Formation of HSA inclusion bodies not only offered protection from proteolytic degradation but also provided a simple method of purification from other cellular proteins by centrifugation. HSA inclusion bodies could be readily solubilized to obtain monomeric form using appropriate reagents. The *cry2Aa2* UTR-mediated expression in seedlings and chloroplasts, although as efficient as 5' *psbA* region, is independent of light regulation and should therefore facilitate expression of foreign genes in nongreen tissues, thereby enabling oral delivery of pharmaceuticals. The regulatory elements used in this study should serve as a model system for enhancing expression of foreign proteins that are highly susceptible to proteolytic degradation and provide advantages in purification.

Optimization of Codon Composition and Regulatory Elements for Expression of Human Insulinlike Growth Factor 1 in Transgenic Chloroplasts

Human insulinlike growth factor 1 (IGF-1) is a potent multifunctional anabolic hormone produced by the liver. IGF-1 polypeptide is composed of 70 amino acids with a molecular weight of 7.6 kDa and contains three disulfide bonds. IGF-1 is involved in the regulation of cell proliferation and differentiation of a wide variety of cell and tissue types, and plays an important role in tissue renewal and repair. One cirrhotic patient requires 600 mg of IGF-1 per year and the cost of IGF-1 per mg is \$30,000.^[21] In the past, IGF-1 has been expressed in *E. coli* but the protein cannot be produced in the mature form, because *E. coli* does not form disulfide bonds in the cytoplasm. In order to increase the expression levels, a synthetic IGF-1 gene with chloroplast optimized codons was made. The integration of the IGF-1 gene into the tobacco chloroplast genome was confirmed using Polymerase chain reaction (PCR) and Southern analyses. The IGF-1 protein was detected in large quantities in transgenic chloroplasts by western blot analysis. The ELISA performed on the transgenic lines showed expression levels up to 32% IGF-1 of the total soluble protein, both in the native and synthetic genes. This is the highest level of pharmaceutical protein reported in transgenic plants.^[19,22]

Most importantly, these observations show that the chloroplast translation machinery is quite flexible, unlike the bacterial translation machinery that translated only the synthetic chloroplast codon-optimized IGF-1 gene.

Expression and Functionality of Human Interferon in Transgenic Chloroplasts

Interferon alphas (IFN α s) are known inhibitors of viral replication and cell proliferation. In addition, they are potent enhancers of the immune response and have many uses in the clinical treatment. A specific subtype, IFN α 2b, was first approved in 1986 for the treatment of hairy cell leukemia by the Food and Drug Administration and has shown efficacy in a growing number of treatments for various viral and malignant diseases. However, the recombinant IFN α 2b now on the market is being produced through an *E. coli* expression system and due to necessary in vitro processing and purification, the average cost of treatment is \$26,000 per year. Recently, recombinant IFN α 2b is used to treat patients suffering from West Nile virus. The 2 week treatment costs \$2500 per patient. This drug is usually administered by injection, but the development of severe side effects is quite common. Also, up to 20% of patients produce anti-IFN α antibodies when the IFN α 2b aggregates with human serum albumin in the blood. These antibodies are an undesirable response and lessen the effectiveness of the treatment. Evidence links the negative side effects to route of administration and dosage parameters. In fact, oral administration of natural human IFN α has proven to be therapeutically useful in the treatment of various infectious diseases.

Oral delivery of IFN α 2b expressed via the chloroplast genome may eliminate some of these problems. Therefore, a recombinant IFN α 2b containing a polyhistidine purification tag and a thrombin cleavage site was generated and integrated into the chloroplast genome of petit Havana and into a low nicotine variety of tobacco, LAMD-609.^[15,19,23] Chloroplasts correctly process and fold human proteins as well as form the requisite disulfide bonds. In addition, bioencapsulation in plants cells can protect recombinant proteins from degradation in the mammalian gastrointestinal tract, and plant-based production systems are free of human pathogens. Western blots detected monomers and multimers of IFN α 2b in both tobacco varieties using interferon alpha monoclonal antibody (MAB). Southern blots confirmed stable, site-specific integration of transgenes into chloroplast genomes and determined homoplasmy or heteroplasmy in the T₀ generation. In the petit Havana transgenic lines, homoplasmy of chloroplast genomes occurs in the first generation, and this corresponds to the highest level of IFN α 2b expression. ELISAs were used to quantify up to 18.8% of total soluble protein in petit Havana and up to

12.5% in LAMD-609. IFN α 2b functionality was determined by the ability of IFN α 2b to protect HeLa cells against the cytopathic effect of encephalomyocarditis virus (EMC) and RT-PCR. Chloroplast derived IFN α 2b was as active as commercially produced Intron A. The mRNA levels of two genes induced by IFN α 2b: 2'-5' oligoadenylate synthase and STAT-2, were tested by RT-PCR using primers specific for each gene. Chloroplast derived IFN α 2b induced expression of both genes similar to commercial IFN α 2b. These expression levels and functionality are ideal for purification and further use in oral IFN α 2b delivery or preclinical studies.

Expression of *Bacillus anthracis* Protective Antigen in Transgenic Chloroplasts for an Improved Vaccine Against Anthrax

Bacillus anthracis is the causative agent for the anthrax disease, which has become a serious threat due to its potential use in bioterrorism and recent outbreaks among wild-life in the United States. CDC lists *B. anthracis* as a category A agent and estimates the cost of an anthrax attack to exceed \$26 billion per 100,000 exposed individuals. Concerns regarding vaccine purity, the current requirement for six injections followed by yearly boosters, and a limited supply of the key protective antigen (PA), underscore the urgent need for an improved vaccine. Therefore, the gene coding for PA (*pag*) was cloned into a chloroplast vector along with the *psbA* regulatory signals to enhance translation. Chloroplast integration of the transgenes was confirmed by PCR and Southern blot analyses. Crude plant extracts contained up to 2500 μ g PA/g of fresh leaf tissue. Exceptional stability of full length PA in leaves stored for several months or in crude extracts was observed, even in the absence of protease inhibitors. PA expression was light-regulated, and maximal expression was observed under continuous illumination. Co-expression of the ORF 2 chaperonin from *Bacillus thuringiensis* did not increase PA accumulation or fold it into cuboidal crystals in transgenic chloroplasts. Both trypsin and chymotrypsin proteolytic cleavage sites present in PA were protected in transgenic chloroplasts. Furin or furinlike proteases are absent in chloroplasts because only PA 83 was observed. Both CHAPS and SDS detergents extracted PA with equal efficiency and PA was observed in the soluble fraction. Chloroplast-derived PA efficiently bound to anthrax toxin receptor, underwent proper cleavage, heptamerized, and bound lethal factor, resulting in macrophage lysis; up to 25 μ g functional PA per ml crude extract was observed. With anticipated expression level up to 6.24 kg PA per acre (three cuttings), assuming 50% loss of PA during purification from plant extracts and at 5 μ g PA per dose (the current vaccine contains 1.75–7 μ g/ml PA),

600 million doses of vaccine (free of contaminants) could be produced per acre of transgenic tobacco.^[15,24] This opens a new approach to combat bioterrorism.

Expression of Monoclonals in Transgenic Chloroplasts

Owing to their remarkable specificity and therapeutic nature for defined targets, monoclonal antibodies are emerging as therapeutic drugs at a fast rate. The chloroplast genome was chosen for transformation with antibody genes due to tremendously high levels of foreign protein expression, the ability to fold, process, and assemble foreign proteins with disulfide bridges, and simpler purification and transgene containment via maternal inheritance. To enhance translation, a codon-optimized gene under the control of specific 5' untranslated regions (UTRs) was used. IgA-G, a humanized, chimeric monoclonal antibody (Guy's 13) has been successfully synthesized and assembled in transgenic tobacco chloroplasts with disulfide bridges.^[25] Guy's 13 recognizes the surface antigen *Streptococcus mutans*, the bacteria that causes dental cavities. In this study, integration into the chloroplast genome was confirmed by PCR and southern blot analyses. Western blot analysis revealed the expression of heavy and light chains individually, as well as the fully assembled antibody, thereby suggesting the presence of chaperonins for proper protein folding and enzymes for formation of disulfide bonds within transgenic chloroplasts.

Expression of Anti-Microbial Peptides (AMP) to Combat Drug-Resistant Pathogens

There are several human pathogenic bacteria that are drug resistant or have acquired resistance over a period of time. There is an urgent need to explore alternate ways of combating such bacteria. Magainin and its analogues have been investigated as a broad spectrum topical agent, a systemic antibiotic, a wound-healing stimulant, and an anticancer agent. Magainin's analogue MSI-99, a synthetic lytic peptide, has been recently expressed via the chloroplast genome.^[26] This AMP is an amphipathic alpha helix molecule and possesses affinity for negatively charged phospholipids found in the outer membrane of all bacteria. The probability of bacteria adapting to the lytic activity of this peptide is very low. It was observed that the lytic peptide is expressed at high levels, i.e., 21.5% of tsp. A multidrug-resistant gram negative bacteria, *Pseudomonas aeruginosa*, which is an opportunistic pathogen for plants, animals, and humans, was used for in vitro assays to test for the effectiveness of the lytic peptide expressed in the chloroplast. Cell extracts prepared from T1 generation plants resulted in 96% inhibition in growth

of this pathogen. This result is highly encouraging in the exploration treatments against drug-resistant bacteria in general and to cystic fibrosis patients in particular because of their high susceptibility to *P. aeruginosa*.

Pharmaceutical companies are exploring the use of lytic peptides as broad-spectrum topical antibiotics and systemic antibiotics. It has been reported that the outer leaflet of melanoma and colon carcinoma cells express three- to seven fold more phosphatidylserine than their noncancerous counter parts. Previous studies have reported that analogues of magainin 2 were effective against hematopoietic, melanoma, sarcoma, and ovarian teratoma lines. Given the preference of this lytic peptide for negatively charged phospholipids, MSI-99 shows potential as an anticancer agent. The minimum inhibitory concentration of MSI-99 was investigated. Based on total inhibition of 1000 *P. syringae* cells, MSI-99 was most effective against *P. syringae*, requiring only 1 µg/1000 bacteria.^[26] Because the lytic activity of antimicrobial peptides is concentration dependent, the amount of antimicrobial peptide required to kill bacteria was used to estimate the level of expression in transgenic plants. Based on the minimum inhibitory concentration, it was estimated that transgenic plants expressed MSI-99 at 21.5–43% of the total soluble protein.

Oral Delivery of Recombinant Proteins via Cholera Toxin B Subunit (CTB)

CTB has previously been expressed in nuclear transgenic plants at levels of 0.01 (leaves) to 0.3% (tubers) of the total soluble protein. To increase expression levels, the chloroplast genome was engineered to express the CTB gene.^[5] Expression of oligomeric CTB at levels of 4–5% of total soluble plant protein was observed. PCR and Southern blot analyses confirmed stable integration of the CTB gene into the chloroplast genome. Western blot analysis showed that transgenic chloroplast-expressed CTB was antigenically identical to commercially available purified CTB antigen. Also, GM1-ganglioside binding assays confirm that chloroplast synthesized CTB binds to the intestinal membrane receptor of cholera toxin.^[5] Transgenic tobacco plants were morphologically indistinguishable from untransformed plants and the introduced gene was found to be inherited stably in the subsequent generation as confirmed by PCR and Southern blot analyses. In addition to establishing unequivocally that chloroplasts are capable of forming disulfide bridges to assemble foreign proteins, the increased production of an efficient transmucosal carrier molecule and delivery system, such as CTB, in plant chloroplasts makes plant-based oral vaccines and fusion proteins with CTB needing oral administration a much more feasible approach.

Spontaneously forming CTB pentamers have exhibited intact transcytosis to the external basolateral membrane of intestinal epithelium and have been widely used as oral vaccine vehicles. It is thus feasible to produce CTB fusion proteins for oral delivery.

CONCLUSION

The first pharmaceutical protein expressed in transgenic chloroplasts was a protein-based polymer with varied biomedical applications, including prevention of postsurgical adhesions/scars, use in wound coverings, artificial pericardia, tissue reconstruction, and programmed drug delivery.^[27] Since then several biopharmaceutical proteins have been expressed in transgenic chloroplasts. Hyperexpression of several human blood proteins, including human serum albumin, Magainin, interferons, somatotropin and insulinlike growth factors in transgenic chloroplasts for mass production and purification, makes chloroplast genetic engineering an invaluable approach to realize the full potential of plant-derived biopharmaceuticals. The successful engineering of tomato chloroplasts for high-level transgene expression in fruits, coupled with hyperexpression of vaccine antigens (for anthrax, cholera, plague) and the use of plant-derived, antibiotic-free selectable markers, augurs well for the oral delivery of edible vaccines or biopharmaceuticals that are currently beyond the reach of those who need them most.

Meiosis

Wojciech P. Pawlowski

Lisa C. Harper

W. Zacheus Cande

University of California, Berkeley, California, U.S.A.

INTRODUCTION

Meiosis is the specialized pair of cell divisions that alter the genetic content of the nucleus from $2n$ (diploid) to $1n$ (haploid) and lead to the production of gametes. Following a premeiotic S phase, homologous chromosomes pair and synapse. This is followed by meiotic recombination and subsequent chiasmata formation between the paired homologous chromosomes. Chromosome pairing and the formation of chiasmata ensure the bipolar attachment of homologous chromosomes to the spindle, which is required for the reductional division of meiosis I that leads to the separation of homologs. This is followed by a modified cell cycle lacking an S phase. A second, equational division leads to the separation of sister chromatids and a halving of the chromosome number per cell. The general progression of meiosis is highly conserved, and is thus similar in yeast, humans, and plants.

PLANTS AS MODEL SYSTEMS FOR STUDYING MEIOSIS

The availability of large numbers of cells undergoing meiosis (meiocytes) in anthers has made plants excellent models for studying meiosis. Maize is one of the few organisms with a large genome where pairing and synapsis is amenable to analysis by a combination of cytological, genetic, and molecular techniques. The features of meiosis in *Arabidopsis*, at least at a cytological level, are conventional and comparable to those of other plants, but it has been the ease of gene discovery in this organism that has led to the adoption of *Arabidopsis* for meiosis research.

CHROMOSOME BEHAVIOR DURING MEIOTIC PROPHASE

The accurate segregation of chromosomes at the first division of meiosis requires that homologous chromosomes pair and recombine with each other to form bivalents (Fig. 1). The pairing and crossing over of

homologous chromosomes occurs in the extensive prophase of meiosis. Dramatic changes in chromosome behavior and morphology during meiotic prophase have been used to subdivide the prophase into stages: leptotene, zygotene, pachytene, diplotene, and diakinesis.^[1–3] In leptotene, the decondensed clouds of chromatin are organized into long, thin fibers by the assembly of a proteinaceous core—the axial element—onto the chromosomes. During zygotene, homologous chromosomes pair and begin to tightly associate, or synapse, along their length when the central element of the synaptonemal complex (SC) is installed between the homologous chromosomes. By pachytene, SC formation is complete and meiotic recombination between homologs is resolved. In diplotene, the synaptonemal complex disassembles and chiasmata, which are responsible for holding the homologous chromosomes together, are visible. Finally, in diakinesis, the chromosomes undergo a final stage of chromosome condensation just prior to metaphase.

TELOMERES CLUSTER ON THE NUCLEAR ENVELOPE AT THE BEGINNING OF MEIOTIC PROPHASE

Before chromosomes synapse during zygotene, the nucleus becomes highly polarized by the formation of the telomere bouquet (Fig. 1). The ends of the chromosomes become tightly clustered together on the inner surface of the nuclear envelope, resulting in a structure resembling a bouquet of flowers. The close relationship between the telomere clustering and chromosome pairing has led to the suggestion that the bouquet may help to facilitate pairing. By coaligning the ends of the chromosomes, homologous regions of the chromosomes are vectorially aligned and within the same region of the nucleus. In addition, the clustering of telomeres on the nuclear envelope may serve to restrict the homology search to a much smaller volume of the nucleus. Consistent with this potential role is the general observation that synapsis is typically initiated near the telomeres. Mutants defective in bouquet formation show delay in the progression of meiosis and severe defects in pairing and synapsis.^[4]

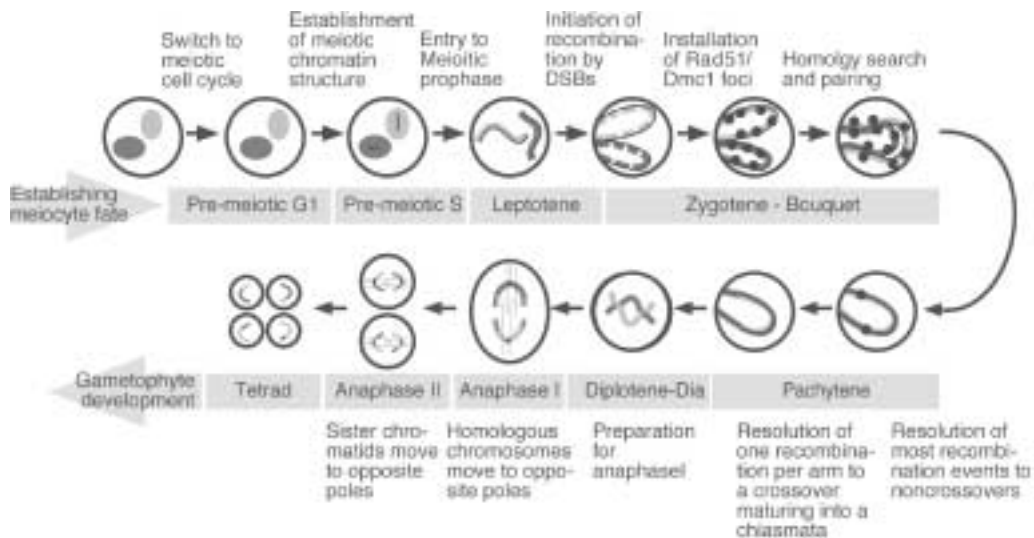

Fig. 1 A diagram showing the key stages and main molecular events in meiosis. Only one homologous chromosome pair is shown, and each homologous chromosome (two sister chromatids) is a different shade of gray. The Rad51/Dmc1 foci are shown as nodules on the extended prophase chromosomes.

CHROMOSOME PAIRING AND SYNAPSIS

In some organisms, such as the hexaploid wheat and *Drosophila*, the pairing of homologous chromosomes occurs prior to meiosis. However, in many other organisms such as maize, oat, humans, and mice, homologous chromosomes are not associated with each other until zygotene. Regardless of when chromosomes pair, a major question in meiosis is, how do the homologous chromosomes identify and associate with each other? The axial cores of the synaptonemal complex do not appear to contain the information for distinguishing homology because they will synapse randomly in a haploid organism undergoing meiosis.^[3] The general consensus is that the homology search is DNA-based, which accounts for the correct pairing of chromosome inversions, translocations, and alien chromosomes. In most organisms, including plants, a successful homologous chromosome pairing is linked to the progression of the meiotic recombination pathway, initiated by the action of the topoisomerase Spo11 to generate DNA double-strand breaks (DSBs).^[2] Mutants lacking Spo11 or other components of the meiotic recombination pathway that act at subsequent steps show serious defects in homologous chromosome pairing.

In a number of species, the chromosome homology search and synapsis are closely coupled during the zygotene stage. Electron microscopy has revealed the presence of large numbers of small, electron-dense spheres associated with synapsing chromosomes during this stage. These nodules, called early recombination nodules,

contain recombination enzymes and are predicted also to function in the chromosome homology search.^[2,3]

MEIOTIC RECOMBINATION

Homologous recombination fulfills a number of critical biological functions, including maintaining genetic diversity, repairing DSBs. Stabilizing interactions between homologous chromosomes in the form of chiasmata, promoting proper disjunction, healing a number of types of DNA damage, and removing undesirable mutational load. Because meiosis is a specialized type of cell division and the meiotic recombination machinery is largely derived from the machinery responsible for mitotic recombination and DNA repair in somatic cells, the meiotic and somatic recombination pathways share many components. However, a number of meiotic recombination-specific components also have been identified. Meiotic recombination is initiated by the introduction of DSBs on chromosomes by the topoisomerase Spo11 (Fig. 1). The DSBs are then resected and subsequently repaired by a protein complex containing two homologs of the *E. coli* RecA protein, Rad51 and Dmc1. These two recombination proteins are some of the most studied elements of meiotic recombination and have also been proposed to play roles in the pairing of homologous chromosomes.^[5] The Rad51/Dmc1 complex forms distinct foci on chromosomes during the meiotic prophase I, which are thought to mark the positions of DSBs. In maize, there are about 500 Rad51 foci in zygotene when

chromosomes are pairing, located mostly on unpaired chromosomes. By early pachytene, when pairing and synapsis are complete, there are only about 10–20 foci, which corresponds well to the number of meiotic cross-overs in maize.

METAPHASE I AND II CHROMOSOME SEGREGATION

The reductional separation of homologous chromosomes at the first division of meiosis (MI) requires that homologous chromosomes recombine with each other and form bivalents. Since chiasmata hold the homologs together until the metaphase/anaphase transition during MI, failure to undergo recombination results in the inappropriate attachment of chromosomes to the spindle and their inaccurate segregation, leading to aneuploidy. Sister chromatid cohesion at the centromere and arms proximal to the chiasmata is maintained during the first meiotic division (MI) but is dissolved during the second meiotic division (MII), permitting the separation of sisters. During the MI reductional division, the kinetochores of both sister chromatids face the same spindle pole, and the kinetochores of one homolog face toward one pole while the kinetochores of the other homolog face the other pole. Often, sister kinetochores are fused to form a single structure. Following anaphase of MI, the two sisters end up at the same spindle pole. During the MII equational metaphase, sister kinetochores face the opposite spindle poles, ensuring that when sister chromatid cohesion is released at anaphase, the sister chromatids will move to opposite spindle poles and end up in different daughter cells.^[3]

THE IMPORTANCE OF UNDERSTANDING MEIOSIS FOR THE CROP SCIENTIST

Meiosis requires DNA replication and chromosome condensation, homologue pairing and recombination, sister chromatid cohesion and homologue attachment, and spindle assembly and chromosome segregation. Many genes are expected to participate in these events, some of which will be unique to meiosis, whereas others are likely to be involved in other cellular processes. Therefore, understanding gene functions in meiosis will provide new insights into the molecular control of many basic cellular events in plants. Furthermore, knowledge about the genes controlling meiosis also has several potential applications in plant breeding. Such applications would include: 1)

developing strategies for acquiring apomixis in maize and other grasses; 2) allowing manipulation of the level of genetic recombination in breeding programs, for example in wide hybrid crosses and for the introgression of quantitative trait loci (QTL) from exotic germplasm; 3) altering genetic incompatibility between species, thus permitting wide hybrid crosses and making it possible to select for desired traits from a broader gene pool; and 4) developing new methods for manipulating transgene integration in random or homologous transformation methods.

CONCLUSION

Meiosis is a highly specialized cell cycle leading to halving of the chromosome number per cell, which is required for the formation of gametes. Homologous chromosomes must pair and recombine, forming bivalents, in order for meiotic chromosome segregation to occur properly.

Metabolic Engineering of the Plant Phenylpropanoid Pathway

Oliver Yu

Donald Danforth Plant Science Center, St. Louis, Missouri, U.S.A.

INTRODUCTION

Starting from amino acids phenylalanine or tyrosine, the phenylpropanoid pathway produces the majority of phenolic compounds found in nature. It has been estimated that approximately 20% of the carbon fixed by photosynthesis is directed into this pathway. More than 100,000 phenylpropanoid compounds have been identified from various species, making them one of the largest natural product families in the world. Many of these compounds are essential for normal plant growth and development. They also play important roles in defense against pathogens and plant-microbe/animal interactions. Some of the phenylpropanoid compounds have significant economic value that is important to human health or modern industries. Like metabolic engineering in other pathways, the majority of phenylpropanoid engineering research is aimed at achieving one of these three goals: 1) engineering as part of the effort to understand the metabolic pathway; 2) engineering to increase or decrease one or more specific compounds; and 3) engineering to introduce *de novo* biosynthesis of novel compounds in a particular species. This brief review has been focused on four directions of phenylpropanoid engineering based on their applications.

ENGINEERING TO ALTER FLOWER COLORS

Anthocyanins synthesized by the phenylpropanoid pathway are major components of flower and fruit colors. Because colored compounds serve as visual markers, many major discoveries in the history of plant biology were driven by studies related to the phenylpropanoid pathway. Examples include the purple pigment trait studied by Gregor Mendel in early genetic works during the 1900s; the red aleuron trait investigated by Barbara McClintock for her Nobel prize-winning discovery of transposons; and cosuppression of the chalcone synthase gene in petunia flowers that led to the flourishing of gene silencing and micro-RNA research (Fig. 1).

Silencing the expression of key anthocyanin biosynthetic enzymes resulted in white flowers or patches of white in various ornamental species that were normally colored. This novelty increased their market value. More economically significant has been the hunt for a blue rose since 1840, when the horticultural societies of Britain and Belgium offered a prize to the first person to produce a truly blue rose. A flavonoid 3′5′-hydroxylase (F3′5′H) is required for synthesizing purple and blue delphinidin-based pigments. Some species, such as roses and carnations, lack this enzyme in their genome. Therefore, it is impossible to produce a blue flower by traditional breeding despite the enormous efforts by generations of breeders. By introducing a petunia F3′5′H gene and a helper protein into a carnation through genetic transformation, Brugliera et al. produced a deep purple carnation in 2000.^[1] Currently, different variations of blue-color carnations dominate North American markets. Recently, Australian and Japanese researchers introduced three transformation constructs simultaneously into roses: a pansy F3′5′H gene to produce delphinidin, an anti-rose dihydroflavone reductase (DFR) gene that silences the endogenous DFR to produce a white background, and an iris DFR gene to make specific modifications of delphinidin. With this approach, the group announced a successful production of the world first blue rose in April 2005, claiming the Holy Grail of horticulture after a 165-year-long pursuit.

ENGINEERING TO IMPROVE FIBER QUALITIES

Lignins are phenolic polymers found primarily in secondary cell walls that add to the rigidity of stem tissue in terrestrial plants. Lignins constitute a significant proportion of plant biomass. Because the composition and structure of cell walls have a dramatic impact on the commercial value of raw materials, especially for the bio-ethanol and pulp industries, numerous strategies have been developed to reduce lignin contents in both woody plants and grasses. Reducing lignins will significantly reduce the energy cost, chemical input,

(Adapted from Ref.^[6])

and toxic waste of pulp making, or increase the conversion efficiency of biomass used for fuel ethanol production.

The biosynthetic mechanisms of lignin monomers are well studied (Fig. 2). They are produced by a branch of the phenylpropanoid pathway involving enzyme *p*-coumarate 3-hydroxylase, hydroxycinnamoyl CoA:shikimate hydroxycinnamoyltransferase (CST), caffeic acid/5-hydroxyferulic acid O-methyltransferase (COMT), cinnamoyl CoA reductase (CCR), cinnamate 4-hydroxylase (CAD) and others. Together, they convert *p*-coumaroyl CoA to *p*-coumaryl, coniferyl, and sinapyl alcohols. These monomers are transported to cell walls and crosslinked to form long chain lignins.

Many lignin modifications thus targeted one or more of these enzymes (for a review, see Refs.^[2,3] and references therein). For example, silencing of CST led to a 15% decrease in lignin content. Down-regulation of COMT by transformation with antisense constructs in alfalfa enhanced feed digestibility. Using transcription factors that coordinately regulate multiple steps of the pathway has also been carried out. One of the xylem-specific transcription factors (*EgMyb2*) isolated from

Eucalyptus recognizes a conserved DNA motif in the CCR and CAD gene promoters. Over expression of *EgMyb2* altered the lignin content in transgenic plants.

To target the crosslinking step, down-regulation of a tobacco cationic peroxidase in cell walls exhibited up to 50% reductions in lignin content without deleterious effects on plant development. In addition to manipulating plant enzymes, a fungal feruloyl-esterase that reduces the crosslinking of lignin polymers has been used to improve fiber quality as well. Genetically engineered trees with reduced lignin contents are currently in commercial production.

ENGINEERING TO ENHANCE PLANT DEFENSE

The majority of secondary metabolites produced by plants function as phytoalexins, which are inducible defense chemicals deterring bacterial and fungal pathogens. Engineering novel phytoalexins in heterologous plants provides a unique strategy to enhance plant innate defense systems. Previous experiments indicated that native pathogens may have difficulty in detoxifying novel phytoalexins (for a review, see Ref.^[4] and references therein). For example, heterologous expression of stilbene synthase (STS) resulted in accumulation of the phytoalexin resveratrol in both tobacco and alfalfa and improved disease resistance toward the fungal pathogens *Botrytis cinerea* and *Phoma medicaginis*, respectively. On the other hand, silencing of key isoflavone biosynthetic enzyme isoflavone synthase (IFS) in soybean abolished isoflavonoid phytoalexin accumulation, and led to a drastic increase of disease symptoms after fungal pathogen *Phytophthora sojae* infection.^[5] Not surprisingly, increasing flavonoid content in rice leaves and corn silks also significantly increases their resistance to a fungal and an insect pathogen, respectively.^[4] Taken together, these results indicate that boosting crop phenylpropanoid phytoalexin production can reduce the use of chemical fungicide/insecticide, and may prepare crops to fight uncommon and novel pathogens.

ENGINEERING TO INCREASE FOOD NUTRITION

Many phenylpropanoid compounds have direct but complex effects on human health. For example, flavonoids and anthocyanins are strong antioxidants; epigallocatechin gallate and related catechins in green tea have been shown to reduce heart disease and strokes. Additionally, increasing condensed tannins in forage

stocks such as alfalfa may reduce the bloating of ruminant animals thus is useful in animal feed applications.

Isoflavones are predominantly produced by legumes and have been linked with alleviating postmenopausal symptoms and reducing breast and colon cancers by consumption of soybeans. The entry point enzyme IFS was used to transform non-legume species to initiate isoflavone production in cereal crops.^[6] A corn transcription factor was also transformed into soybean to alter isoflavone compositions. When combined with silencing of the F3H gene to block the competing pathway, this transcription factor increased soybean isoflavone levels by up to sixfold.^[7]

Similarly, to increase the antioxidant content of tomato, overexpression of a petunia chalcone isomerase in tomato skins led to a more than 80-fold increase in flavonoid levels.^[8] More interestingly, the above-mentioned resveratrol, which is found in red wine, was shown to function not only as an antioxidant, but also as a regulator of metabolism and longevity. Among a group of phenylpropanoid compounds tested, resveratrol most significantly extended life span of yeast, round worms, and fruit flies. Previously, Becker et al. coexpressed a poplar 4-coumaroyl CoA ligase and a grape STS in yeast. When fed with proper substrates, the transgenic yeast was able to produce resveratrol directly.^[9] It will be interesting to see whether engineering de novo resveratrol biosynthesis in yeast or animal cells will lead to extended longevity.

CONCLUSIONS

The phenylpropanoid pathway is the best-studied and most engineered plant secondary pathway. In general, understanding the mechanism and regulation of biosynthetic processes is the foundation for engineering

works. The rapid progress of genomics and metabolomics will certainly bring more scope and targets than the current handful of genes. However, metabolic pathways inside a cell are interconnected and may have complicated crosstalks. For example, tobacco lines with significantly reduced CCR expression resulted not only in an expected decrease in lignin content, but also in an increase in wall-associated xylose and glucose content,^[2] suggesting that the carbon flux between the two major cell-wall components maintains certain balances. Consequently, these pathway crosstalks may complicate the outcome of engineering attempts.

Adding another layer of complexity is the macromolecular organization of biosynthetic enzymes. In metabolic pathways, specific interactions between sequential enzymes occur as dynamic complexes sometimes called “metabolons.” These multienzyme assemblies localize the accumulation of pathway intermediates and regulate competition for metabolites among branch pathways. Therefore, protein–protein interactions may regulate metabolic pathways beyond simple enzyme kinetic parameters and transcriptional controls. Metabolic channeling in the phenylpropanoid pathway has been demonstrated at various steps.^[10] These enzyme interactions play major roles in pathway regulation, and have to be taken into account to achieve optimum engineering results.

Metabolism, Primary: Engineering Pathways

Alberto A. Iglesias

Instituto Tecnológico de Chascomús (IIB-INTECH), Buenos Aires, Argentina

INTRODUCTION

Plants are traditional sources of organic materials used by humans for food and many industrial purposes.^[1] The relevance of plants as food producers is clear, since their photosynthetic capacity ultimately represents the basis of life on our planet. Main industrially important compounds obtained from plants are (among others) wood, cotton, cork, and latex. Despite advances in chemical synthesis of organic molecules (i.e., plastics), many plant products are still unique. Thus, production of rubber of a certain quality only utilizes latex as a raw material.

In this scenario, the relevance of manipulating plants to improve their synthetic ability is clear. For years, selective breeding allowed increased productivity of crops, but with limitations. The development of genetic engineering expanded possibilities for improvement, as modification of plant metabolic pathways would allow the manipulation of the quantity and quality of natural products and also the synthesis of novel or heterologous compounds.^[1,2]

The feasibility of plant transformation was firstly utilized for the production of genetically modified crops with enhanced resistance to herbicides and pathogens or with longer postharvest life.^[3,4] These transgenic plants importantly affected agriculture, because they allowed reduced production costs and increased yields.^[4] After these advances, efforts centered on modifying specific plant metabolic routes related to the synthetic proficiency of a particular crop.^[3,4]

PLANTS AND METABOLIC ENGINEERING

Plant metabolic engineering is in the period of initial development. The rationale of genetic transformation of organisms requires the understanding of metabolism within the framework of metabolic control analysis, an issue not completely elucidated in plants.^[2] Additionally, plant cells are highly compartmentalized, and the whole organism possesses both phototrophic and heterotrophic tissues. These facts determine complex metabolic networks, with partitioning of metabolites (and metabolic routes) intracellularly and between source and sink

organs.^[5] Despite this complexity, plant metabolic engineering has reached relevant goals and (more important) shows a highly promising future.^[1,2] Key issues in the subject are the type of tissue (source or sink) and the intracellular compartment targeted for transformation.

PLANT PRODUCTIVITY IMPROVEMENT

Autotrophy of plants for fixing CO₂ into carbohydrates makes this process a key target for engineering in order to improve productivity. Possibilities include not only improving the carbon fixation process itself (in source tissues, see Fig. 1), but also increasing the carbon demand at sink organs where the product is finally accumulated (Fig. 2). Table 1 details the possibilities and advances made in the manipulation of carbon partitioning and allocation in plants.

Engineering Source Tissues

About 95% of plants (including many crops) are C₃ species that assimilate atmospheric CO₂ via the Calvin cycle or the C₃ photosynthetic pathway. C₃ plants utilize CO₂ with relatively low efficiency, since primary carbon fixation in the C₃ pathway is catalyzed by the chloroplastic enzyme ribulose-1,5-bisphosphate carboxylase/oxygenase (Rubisco), which also utilizes O₂ as a substrate, leading to photorespiration that reduces (by up to 40%) photosynthetic efficiency (Fig. 1).^[6]

Engineering of Rubisco to increase its ratio of carboxylase/oxygenase activity seems very unlikely, as predicted from the enzyme's catalytic mechanism. The strategy to increase the carbon photoassimilation efficiency is now following the path traced by natural evolution: the addition of enzymatic steps to increase the CO₂ to O₂ ratio in the chloroplast (Fig. 1). Indeed, C₄ plants evolved a biochemical device that masters photorespiration.^[2,6] Briefly, it comprises annexation of a metabolism (C₄ pathway) that pumps atmospheric CO₂ to the chloroplast. Additionally, leaves of C₄ plants have two types of photosynthetic cells (mesophyll and bundle sheath cells) that play a role in the integration of the C₃ cycle and the auxiliary pathway.^[2,6]

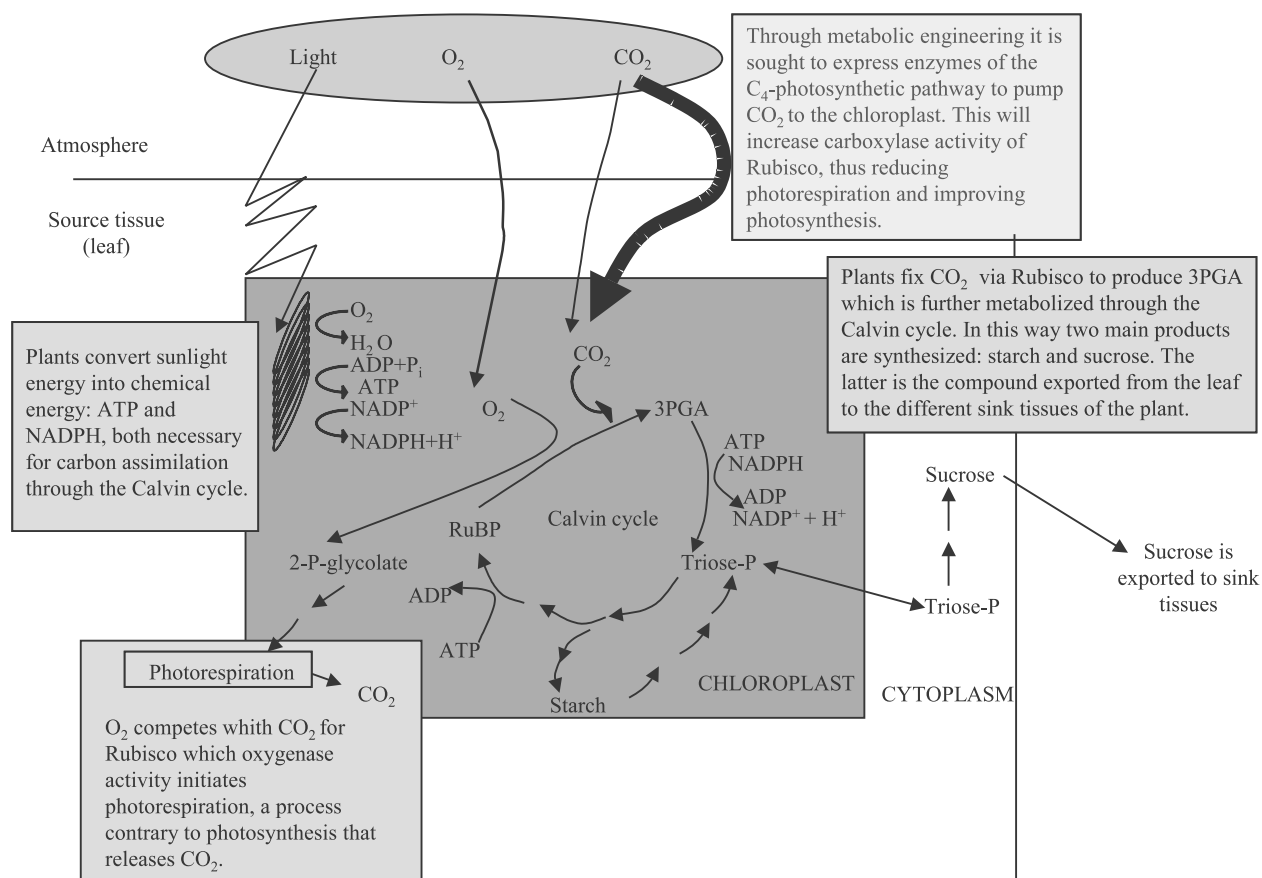

Fig. 1 Carbon photoassimilation in source tissues of plants. Atmospheric CO_2 is converted to 3P-glycerate (3PGA) by the reaction with ribulose-1,5-bisphosphate (RuBP), catalyzed by Rubisco. 3PGA is further metabolized via the Calvin cycle, which consumes ATP and NADPH. Intermediates from the Calvin cycle are utilized for the synthesis of starch and sucrose, the latter being the compound exported to other plant tissues. Strategies to improve carbon assimilation are centered on increasing the CO_2 to O_2 ratio within the chloroplast to reduce photorespiration. (View this art in color at www.dekker.com.)

The technology to introduce genes encoding enzymes of the C_4 pathway into C_3 plants was recently developed.^[6] Transgenic plants expressing C_4 enzymes at different levels exhibited alterations in carbon metabolism (Table 1). The overall view shows engineering of carbon photoassimilation metabolism at the starting point, with many questions to address in the near future about metabolic fluxes in transformed plants. Anyway, results obtained so far support the possibility of creating efficient CO_2 -concentrating mechanisms, via metabolic engineering, to enhance photosynthetic efficiency of crops.^[6]

Engineering Sink Tissues

Metabolic engineering in plant sink tissues (Fig. 2), improving production of primary compounds, has successful examples in the manipulation of starch and fatty acid biosynthesis.^[1,2]

Engineering Starch Metabolism

Starch, a major product of photosynthesis, is synthesized in plastids of photosynthetic and nonphotosynthesizing cells from glucose-1-phosphate by the consecutive reactions of ADPglucose pyrophosphorylase (producing ADPglucose, the donor of glucosyl residues), starch synthase, and branching enzyme.^[5] The pathway is controlled at the level of ADPglucose pyrophosphorylase through allosteric regulation by 3-phosphoglycerate (activator) and Pi (inhibitor).^[2,5]

A significant rise in starch accumulation in sink tissues was obtained by increasing ADPglucose pyrophosphorylase activity in plants transformed via the expression of an unregulated mutant of the enzyme from *Escherichia coli*^[2,7,8] (Table 1). This is a good example of the relevance of the understanding of enzyme kinetics and regulation for metabolic engineering. Based on the knowledge

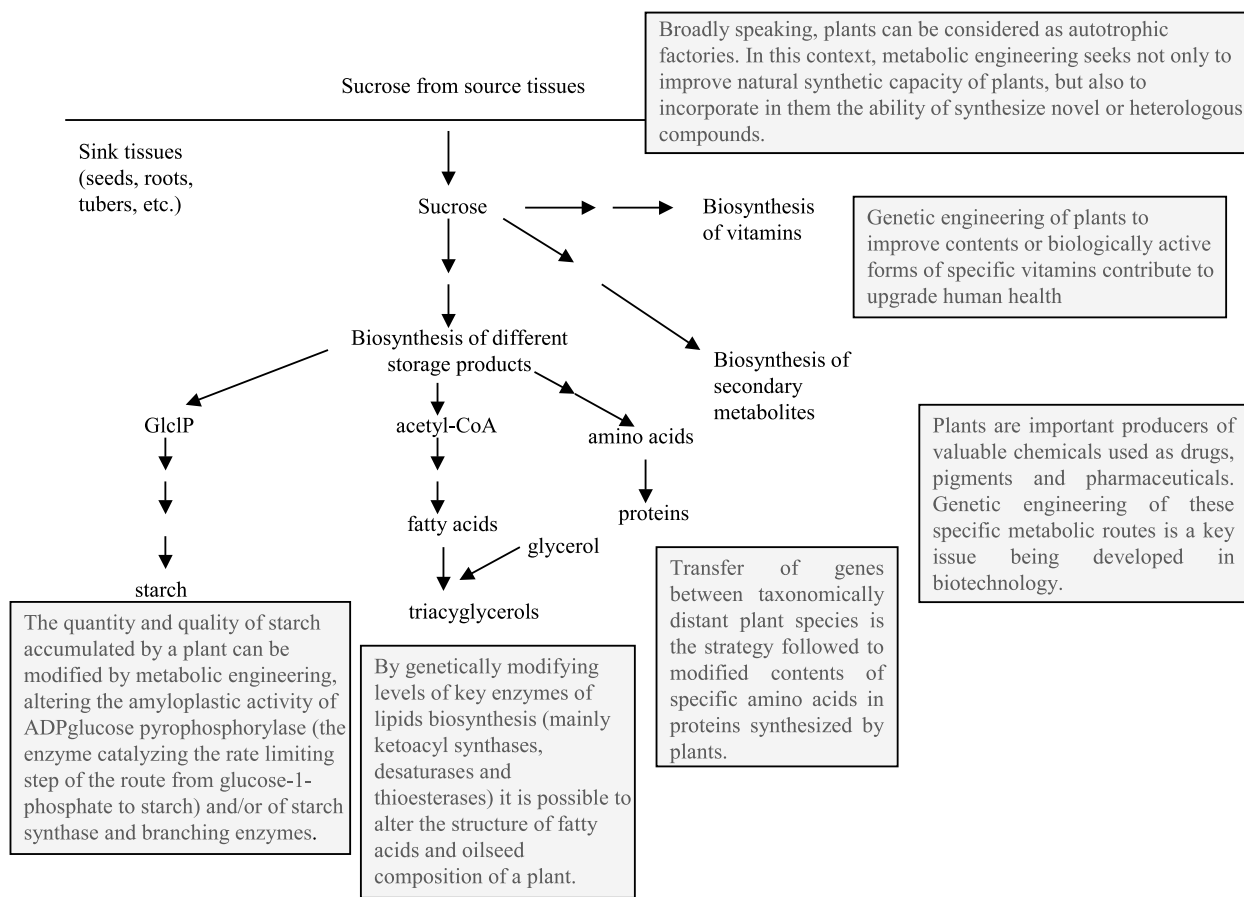

Fig. 2 The pathway of carbon in plant sink tissues and different strategies to be followed by metabolic engineering. Sink tissues synthesize different storage products as well as secondary metabolites and vitamins, representing relevant producers of key natural chemicals. Through metabolic engineering, it is sought to improve the synthetic capacity of plants by modifying the quantity and quality of the compounds they produce. (View this art in color at www.dekker.com.)

that this metabolic route is regulated at the level of ADPglucose pyrophosphorylase, its activity was permanently increased by expressing a mutant enzyme (lacking activator requirement for maximal activity) and thus enhancing ADPglucose and starch production.^[2,7] Additionally, expression of the foreign gene was induced in storage tissue amyloplasts by using a tuber-specific promoter, as detailed in Table 1.^[2,7,8]

Transgenic products obtained by this methodology exhibited substantial improvement in their food quality traits. Thus, potato tubers with more starch (and solids) increased processing efficiency and resistance to cold storage, whereas transformed tomato fruits showed improved flavor.^[1,8] Another objective is to engineer starch metabolism to modify the polysaccharide structure. Current strategies propose manipulating starch synthase and branching enzyme levels to alter contents of amylose

and amylopectin and the branching degree in the latter polymer.^[2,3]

Engineering Lipid Biosynthesis

Plants accumulate oils as triacylglycerols, with properties determined by the type of fatty acids they contain. Fatty acid biosynthesis occurs within plastids, by two-carbon elongation steps (initially derived from acetyl-CoA) catalyzed by a multienzyme complex. Length and desaturation, level of the product is determined by ketoacyl synthases, desaturases, and thioesterases, which render the final fatty acid that is exported to the cytoplasm for triacylglycerol biosynthesis.^[8]

Cloning of genes encoding enzymes involved in fatty acid biosynthesis allowed the modification of oilseed

Table 1 Metabolic engineering in plant source and sink tissues to improve biosynthetic pathways

Objective (O)/Strategy (S)	Results
SOURCE TISSUES	
(O) To increase carbon photoassimilation by reducing photorespiration.	— Transgenic tobacco and potato plants, overexpressing phosphoenolpyruvate carboxylase, exhibited better capacity to assimilate CO ₂ at high temperatures than nontransformed plants. ^[6]
(S) Expression of enzymes of the C ₄ photosynthetic pathway in C ₃ plants, to concentrate CO ₂ at the intracellular site where Rubisco is operative. The increase of CO ₂ over O ₂ will reduce photorespiration.	— Transgenic rice, expressing high levels of phosphoenolpyruvate carboxylase in the leaves, showed no alteration in the rate of CO ₂ assimilation, but significant reduction in O ₂ inhibition of net carbon fixation. ^[2,6] — The expression of phosphoenolpyruvate carboxykinase into chloroplasts of leaf cells in rice significantly increased the production of C ₄ acids and the synthesis of sucrose from these compounds. ^[6]
SINK ORGANS	
(O) To improve carbon allocation by increasing the accumulation of reserve products.	— Potato plants transformed with <i>glgC16</i> gene [from <i>Escherichia coli</i> , encoding a mutant ADPglucose pyrophosphorylase less dependent on the activator (fructose-1,6-bisphosphate) and relatively insensitive to inhibition by AMP] accumulated up to 30% more starch in tubers, when the foreign gene was introduced under the control of a tuber-specific patatin promoter. Constitutive expression of the gene was detrimental to plant growth, because excess accumulation of polysaccharide in leaves diminished sucrose synthesis, which decreased export of carbon to growing parts of the plant. ^[2,7,8]
(S) To increase synthesis of ADPglucose in amyloplasts by expressing ADPglucose pyrophosphorylase, the limiting regulatory enzyme in starch biosynthesis. Expression of a mutant enzyme, insensitive to regulation, to ensure constant levels of activity in plastids.	— Tomato fruits with higher starch content during the green stage of development and canola seeds with low ratio oil/starch were obtained by transformation of plants with identical strategy as above indicated. ^[8]
(O) To alter oilseed composition by manipulating length and desaturation degree of fatty acids.	— Seed-directed expression of specific antisense desaturase genes rendered transgenic soybean and canola plants with higher content of oleic acid (18:1) and reduced levels of natural polyunsaturated oils [mainly linoleic acid (18:2)]. ^[4,8]
(S) To manipulate activity levels of ketoacyl synthases, desaturases, and/or thioesterases in plastids.	— <i>Arabidopsis</i> and canola plants transformed by seed-specific expression of lauroyl-acyl carrier protein thioesterase accumulated up to 50% laurate. Plants further manipulated to express lysophosphatidic acid acyltransferase from coconut accumulated triacylglycerols with three laurate substituents. ^[8]
(O) To improve plant protein quality.	— Expression of FatB class thioesterases produced large amounts of C8 and C10 fatty acids in canola. Transformation with oleyl-acyl carrier protein thioesterase increased accumulation of palmitate and stearate. ^[4,8,9]
(S) Expression of genes coding for proteins with high content of selected amino acids.	— Seed-directed expression (by using phaseolin promoter) of a gene encoding a methionine-rich protein (from Brazil nut) into tobacco and rapeseeds rendered transgenic plants with enhanced contents (up to 30%) of sulfur amino acids. ^[8]
(O) To improve vitamin content in plant products used for food purposes.	— <i>Arabidopsis</i> plants engineered by expression of the gene coding for γ -tocopherol methyltransferase converted γ -tocopherol pools into α -tocopherol, with the respective increase in vitamin E activity. ^[9]
(S) Expression of genes coding for enzymes of vitamin metabolism to drive its biosynthesis.	— Carotenoid biosynthetic enzymes (two from plants and one from <i>Escherichia coli</i>) were simultaneously expressed in rice endosperm. Transgenic rice contained increased levels of provitamin A (β -carotene) visualized by the yellow color of the endosperm and named “golden-rice.” ^[8,9]

composition of certain plants by overexpression, antisense, and cosuppression technologies (Table 1).^[1,8,9] By this approach, oilseeds more resilient to oxidation, healthier for human consumption, or with industrial applications were obtained. This demonstrates the potentiality of plant metabolic engineering for managing production of renewable and biodegradable compounds.^[1,9] The next step envisions the modification of fatty acids to produce specific chemical structures, such as compounds containing epoxy functions or conjugated double bonds^[1,2,4]

Improving Protein Quality and Vitamin Content

Plants produce about 65% of the protein utilized for food by humans and livestock. Plant proteins are deficient in certain essential amino acids, mainly lysine, tryptophan, cysteine, and methionine.^[8] Table 1 shows strategies developed to correct this deficiency, by transferring genes between taxonomically distant plant species.

Manipulation of vitamin content in plants is an important issue where metabolic engineering may contribute to upgrading human health.^[1,9] Table 1 describes increases in vitamin E levels obtained in natural oils. This vitamin is an antioxidant whose presence in the human diet is relevant, especially under stress conditions such as those affecting populations in the developed world.^[7] Transgenic rice with high β -carotene content (Table 1) will also contribute to improving human health, mainly in developing countries where deficiency of vitamin A would be alleviated with the use of a major staple containing it.^[7]

CONCLUDING REMARKS AND FUTURE PERSPECTIVES

The wide metabolic diversity and the autotrophy exhibited by plants made them key tools in biotechnology. In the framework of metabolic engineering, this relevance is enhanced, as plants can be considered as potential factories for the production of compounds useful for food and industrial processes.^[1,2] Examples of the goals already reached and the potentiality of genetic manipulation for improving the quantity and quality of compounds synthesized and accumulated by plants have been detailed and are summarized in Table 1.

Two additional fields need consideration because of their current and future relevance in plant metabolic engineering (Fig. 2). First is production of secondary metabolites, as certain plants synthesize valuable chemicals

(including alkaloids, anthocyanins, anthraquinones, polyphenols, steroids, and terpenoids) widely utilized as drugs, pigments, and pharmaceuticals.^[1,2,7] Secondly, plants are important biological systems for the production of heterologous compounds; they exhibit advantages for the production of recombinant proteins used for different industries (mainly pharmaceutical), as they synthesize fully folded functional products with low costs while avoiding ethical and safety problems.^[2]

Considering that the above analysis represents a relatively novel field, the future of plant metabolic engineering can be visualized as very promising. It is tempting to envision that the complete development of the technology and the better understanding of the biological process will make it possible to widely manipulate amounts and types of carbohydrates, oils, proteins, and many other compounds synthesized by plants.

Purdue University, West Lafayette, Indiana, U.S.A.

INTRODUCTION

The term engineering refers to metabolic engineering, a field pioneered by microbial systems biologists and chemical engineers. Metabolic engineering is defined as “the directed improvement of product formation or cellular properties through the modification of specific biochemical reactions or the introduction of new ones through the use of recombinant DNA technology.” This field has a strong foundation in mathematical analysis of metabolic fluxes and control in biochemical systems. Its emphasis is on understanding the function of biochemical reaction networks *in vivo*, thereby synthesizing information on the interactions of the various system components. Frequently this synthesis is achieved by an iterative cycle of genetic engineering, and by metabolic flux analysis using isotopic labeling. Metabolic modeling is employed to organize and conceptualize the data, facilitating the generation of new hypotheses guiding the next round of engineering. Plant metabolic engineering is in its infancy, but is receiving increased attention, as highlighted in the recent special issue of the journal “Metabolic Engineering,” which is devoted to plants.

SECONDARY METABOLISM TERMINOLOGY

Secondary metabolism is a loose term generally referring to pathways that have no essential role in plant growth and development. Secondary metabolism is thus distinguished from primary metabolism, which refers to the network of catabolic and anabolic reactions essential for growth and development.^[1] Plant metabolites typically referred to as secondary metabolites include a diverse array of alkaloids, phenylpropanoids, terpenoids, glucosinolates, and cyanogenic glucosides that may play roles in plant defense against pathogens and herbivores.^[1–3] Their synthesis is often restricted to distinct plant taxonomic groups. The term natural products is preferred to describe this array of compounds.^[1] Many are of great potential value as pharmaceuticals and/or precursors in the synthesis of industrial chemicals.^[1,3] Because secondary metabolites

are invariably derived from primary metabolites, effective engineering of secondary pathways cannot be readily undertaken without careful consideration of the competition between primary and secondary pathways.^[4,5]

EXAMPLES OF METABOLIC ENGINEERING OF PATHWAYS OF PLANT SECONDARY METABOLISM

Recent advances in the metabolic engineering of plant secondary pathways will be illustrated by considering the natural products derived from tryptophan, tyrosine, and phenylalanine, the three aromatic amino acids (Fig. 1).

Alkaloids, Glucosinolates, and Cyanogenic Glucosides

Alkaloids, glucosinolates, and cyanogenic glucosides are strongly implicated in plant herbivore and pathogen defense.^[1] Manipulation of fluxes to these compounds is of interest not only in modulating herbivore and pathogen resistance, but also in improving the nutritional quality of plants. Early successes in plant metabolic engineering involved overexpressing tryptophan decarboxylase (TDC) in canola, in order to divert flux away from the bitter indole glucosinolates, thus improving the quality of canola oil and making the product more palatable as an animal feed^[1] (Fig. 1). Conversely, antisense down-regulation of TDC has been used to eliminate indole alkaloid biosynthesis.^[5] Overexpression of TDC in combination with other enzymes of the indole alkaloid pathway (e.g., stricosidine synthase) is being vigorously pursued as a strategy to manipulate flux to important terpenoid indole alkaloid compounds such as vinblastine.^[1,3,5] Promising approaches also involve overexpression of transcription factors, resulting in induced levels of a number of genes of the pathway.^[3,5] Daunting challenges in engineering metabolic flux to the terpenoid indole alkaloids will involve coordinating the supply of the indole moiety (derived from tryptophan) with the supply of

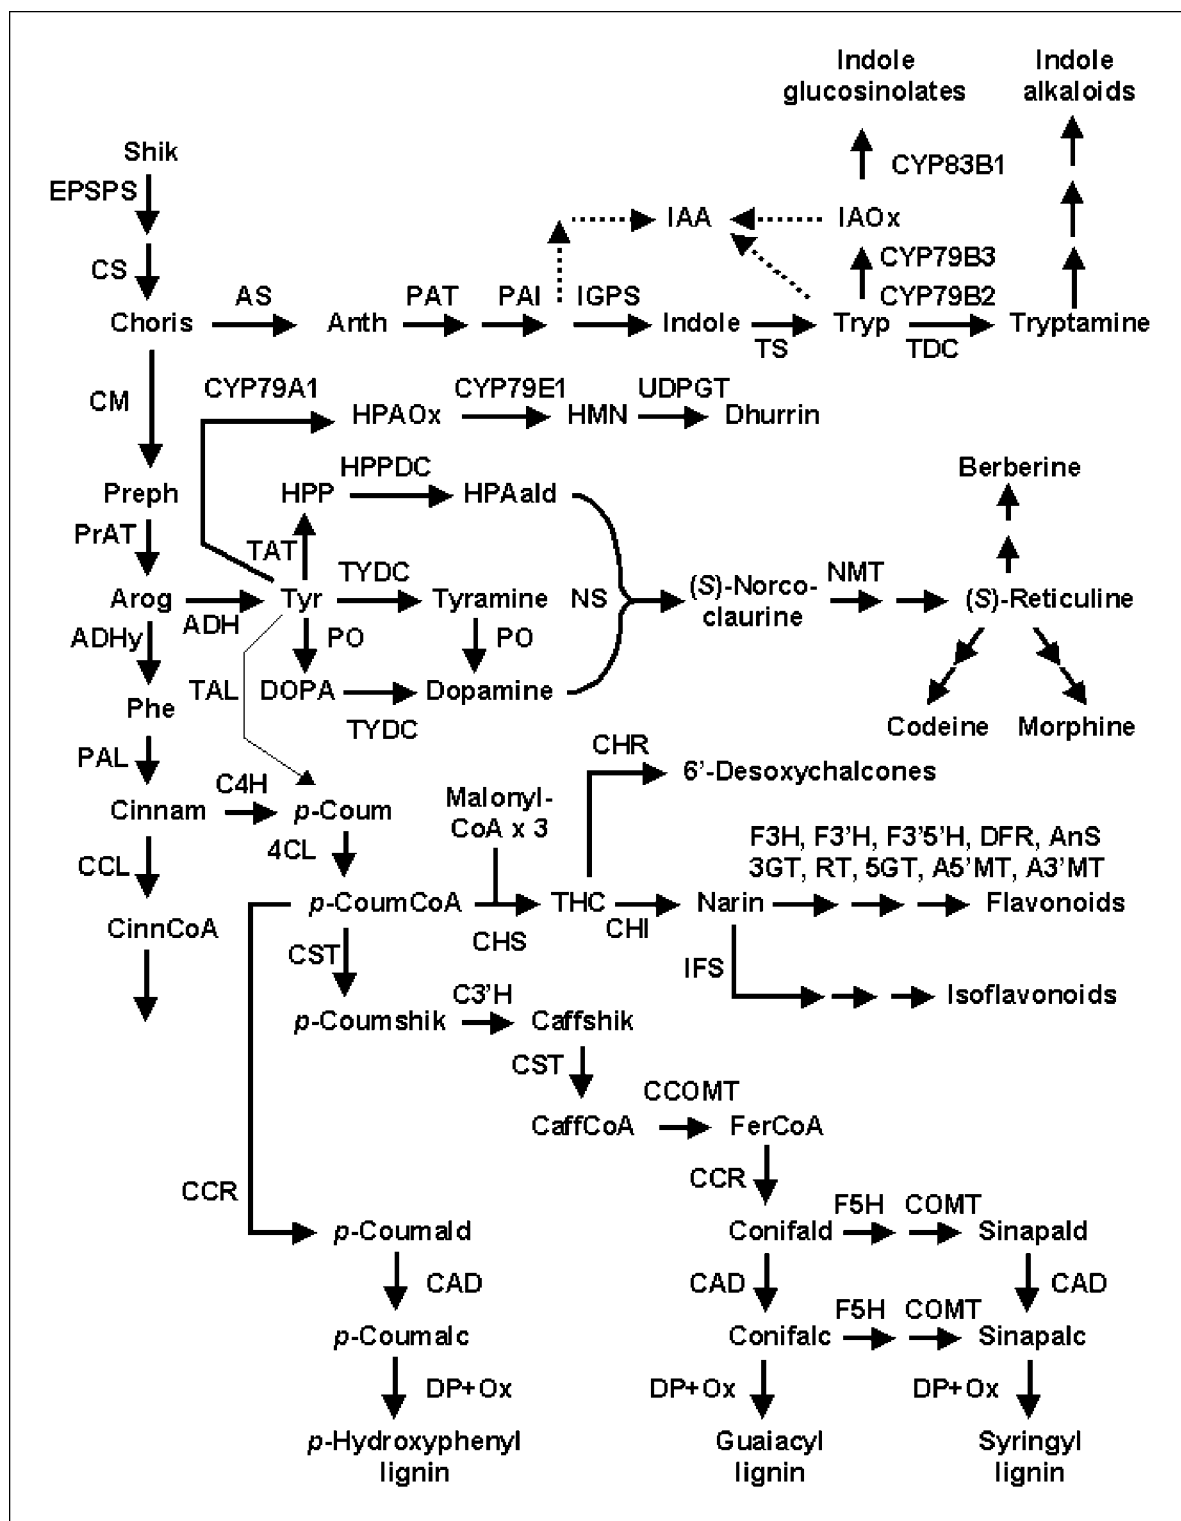

Fig. 1 Plant secondary products derived from the amino acids tryptophan (Tryp), tyrosine (Tyr), and phenylalanine (Phe). Intermediate abbreviations appear on the next page.

the terpenoid precursors (derived from geraniol via the nonmevalonate pathway), and ensuring appropriate intracellular compartmentation and tissue-specific expression of the numerous pathway enzymes.^[1,5]

The pathway of synthesis of the indole glucosinolates in *Arabidopsis thaliana* proceeds via the catalytic action of O₂ and NADPH-dependent cytochrome P450s acting on tryptophan and indole-3-acetaldoxime.^[6] CYP79B2 and CYP79B3 N-hydroxylate tryptophan, converting it to indole-3-acetaldoxime. CYP83B1 subsequently N-hydroxylates indole-3-acetaldoxime to its N-oxide^[6] (Fig. 1). Mutants (*superroot2* (*sur2*); *runt1*) of *Arabidopsis* are defective in CYP83B1 and have elevated levels of IAA, and decreased levels of indole glucosinolates. In contrast, overexpression of CYP83B1 causes a bushy, short phenotype consistent with reduced levels of IAA, suggesting that the glucosinolate pathway competes with the auxin biosynthesis pathway for the indole-3-acetaldoxime intermediate.^[6] These engineering efforts illustrate the difficulty in manipulating fluxes around the tryptophan node of metabolism without detrimental effects on plant growth via perturbations of auxin levels. This is further complicated by the existence of multiple pathways of auxin biosynthesis (both tryptophan-dependent and -independent) which may operate at different stages of plant development, as indicated by the dashed lines at the top of Fig. 1.^[6]

The cytochrome P450 catalyzing the conversion of tyrosine to *p*-hydroxyphenylacetaldoxime in the biosynthesis of the cyanogenic glucoside dhurrin in sorghum, has been designated CYP79A1. *p*-hydroxyphenylacetaldox-

ime is subsequently converted to *p*-hydroxymandelonitrile by a second multifunctional P450 monooxygenase, CYP71E1. The final step in dhurrin synthesis in sorghum is the transformation of the labile cyanohydrin into a stable storage form by O-glucosylation of (*S*)-*p*-hydroxymandelonitrile at the cyanohydrin function, by a UDP-glucose:*p*-hydroxymandelonitrile-O-glucosyltransferase^[7] (Fig. 1). The entire pathway for synthesis of dhurrin has been transferred from sorghum to *Arabidopsis thaliana* by expressing CYP79A1, CYP71E1 and UDP-glucose:*p*-hydroxymandelonitrile-O-glucosyltransferase.^[7] The accumulation of dhurrin in the transgenic plants confers resistance to the flea beetle.^[7] This clearly demonstrates the importance of cyanogenic glucosides in plant defense against insect herbivores, and it illustrates the potential for introduction of multiple genes to install a complete pathway in plants. Interestingly, when only CYP79A1 is expressed in *Arabidopsis*, the transgenic plants produce *p*-hydroxybenzyl glucosinolates.^[7] This is presumably because the intermediate *p*-hydroxyphenylacetaldoxime is recognized as a substrate by native glucosinolate-forming enzymes normally involved in indole and/or alykl glucosinolate biosynthesis.

Considerable progress has been made in identifying the enzymes and genes involved in the production of pharmaceutically important isoquinoline alkaloids derived from tyrosine, including berberine, codeine, and morphine.^[1,3] Engineering of this pathway is currently focused on manipulating expression of tyrosine/DOPA decarboxylase (TYDC) and fluxes around the (*S*)-reticuline node.^[3]

Phenylpropanoids

Phenylalanine is the starting point for the synthesis of a large number of phenylpropanoid secondary products, including flavonoids, isoflavonoids, and lignin. Examples of successful engineering of these pathways in plants include the introduction of chalcone reductase (CHR) in acyanic petunia to generate a novel, yellow flower color due to the accumulation of 6'-desoxychalcones^[81] (Fig. 1), and the overexpression of transcription factors to globally activate or repress anthocyanin biosynthesis.^[3] However, recent attempts to engineer isoflavone synthesis in *Arabidopsis* by introducing the soybean isoflavone synthase (IFS) gene have encountered a problem. It seems that IFS does not compete effectively with flavanone 3-hydroxylase (F3H) for the naringenin substrate, perhaps because chalcone synthase (CHS), chalcone isomerase (CHI), and F3H may exist as a multienzyme complex, causing metabolite channeling.^[9]

Lignin biosynthesis is a key branch-point from the phenylpropanoid pathway.^[1,2] The lignin biosynthetic pathway has been recently clarified, and is now proposed to involve a 3'-hydroxylase (C3'H) acting on *p*-coumaroyl shikimate or *p*-coumaroyl quinate as substrates^[10] (Fig. 1). The revised metabolic scheme for lignin biosynthesis is beginning to explain some of the phenotypes of altered lignin composition of mutants defective in the various metabolic steps, although our understanding of metabolic control in the pathway remains far from complete.^[4] A detailed analysis of transgenic plants and mutants suggests that PAL, C4H and C3'H may be especially important in regulating carbon allocation in the pathway, with CCOMT, 4CL, CCR, F5H, and COMT playing subsidiary processing roles.^[2]

FUTURE PROSPECTS

A significant number of the genes of plant primary and secondary metabolism have now been cloned, and they are being used in metabolic engineering experiments. Urgently needed are mathematical models that integrate the stoichiometric coefficients of the pathways with the kinetic properties of the enzymes encoded by these genes, and with the regulatory circuits that control both gene expression and enzyme activity. Such models will con-

siderably aid future efforts devoted to rational flux manipulations of these pathways.

Milkweed: Commercial Applications

Herbert D. Knudsen

Natural Fibers Corporation, Ogallala, Nebraska, U.S.A.

INTRODUCTION

Milkweed, especially the *Asclepias syriaca* and *Asclepias speciosa* varieties, has excellent potential for commercialization as a new crop. Milkweed raw materials include pod floss, seed, and stem fiber. This article reviews the progress over the last 15 years in developing milkweed production, products, and markets to create a new agricultural business.

HISTORICAL

Asclepiadaceae is the milkweed plant family native to many countries in the world.^[1] The various species range from small shrubs, to vine covers, to plants ten feet tall. Two varieties—*Asclepias syriaca* and *Asclepias speciosa*—are particularly of interest because they are native to many areas in the United States, have erect stems four to six feet tall, and bear multiple large milkweed pods per stem.

Small-volume use of milkweed raw materials from native stands is widely reported. North American Indians used bast fibers from milkweed stems in clothing more than 1000 years ago. Flowers, sprouts, pods, and seeds have been used as food and medicine.

Boris Berkman, president of Milkweed Floss Corporation of America, organized the first effort to produce milkweed floss on a large scale.^[2] In 1943, the U.S. Government built a milkweed processing plant in Petoskey, Michigan as part of the war effort. This plant produced over two million pounds of milkweed floss for military life jackets in its one year of operation. Pods for the production facility were hand-collected in onion bags and shipped to Michigan. War volunteers throughout the United States collected milkweed pods under the slogan “Two bags save one life.” Berkman envisioned great potential for milkweed raw materials in industrial products, but no record of significant milkweed floss production or commercial use of milkweed in products after World War II has been found.

Standard Oil of Ohio conducted extensive research on growing milkweed and extracted the total harvested milkweed biomass with hexane to produce a crude oil substitute. Technically, the process was feasible, but the yield in terms of barrels per acre was too low to make the process economical. Standard Oil also worked with Kimberly-Clark to develop nonwoven products from milkweed floss, but no commercial products were produced.

In 1987, Standard Oil sold its milkweed venture to Natural Fibers Corporation (NFC), a privately held corporation formed to commercialize milkweed as a new crop. In 1990, a consumer products company, Ogallala Down Comforter Company, was formed as a subsidiary of NFC to make and sell goose down/milkweed floss comforters to specialty bedding stores in the United States and to the Four Seasons Hotels throughout the world.

MARKETS

The raw materials from milkweed are floss, seed, pod hulls, and stems, and markets for milkweed as a raw material needed to be created. The options are 1) to sell raw materials to others for their use in products they would develop; or 2) to develop, produce, and sell value-added products with these new raw materials. The downlike qualities of milkweed floss allowed for application in the down industry. Because of the up to 30-fold increase in value of down bedding compared to the milkweed floss content and because of the need to ensure a base load of floss demand, goose down/milkweed floss comforters and pillows as a new consumer product were produced by NFC internally and sold commercially.

Companies, research centers, and organizations have worked to develop milkweed raw material demand. Current projects include 1) working with Monarch butterfly organizations to expand milkweed habitat; 2) pressing milkweed seed to produce oil useful in cosmetics; 3) chopping milkweed floss to a fine powder for body care products; 4) developing milkweed floss nonwoven pads for bedding; 5) researching pulp made from milkweed for paper products; and 6) experimenting with milkweed biomass for nematode control in soil.

PRODUCTION FACILITY

To create a business at startup, a processing system for milkweed pods and a facility for manufacturing consumer products were needed. These issues were more important than cultivating milkweed, because wild collection of milkweed pods could produce enough dry pods to start and run the business for a number of years.

The processing system goal was to develop continuous mechanical separation of milkweed raw materials from dried pods. Boris Berkman's plant in Michigan appeared to be continuous, but all production of milkweed raw materials for Standard Oil was done in a laborious batch process.

For the processor, information about Boris Berkman's cylinder production system was collected, but experiments in similar, but smaller, cylindrical processing systems were not successful. A lower-technology approach of modifying a 1940 John Deere harvester, however, *did* work. See U.S. Patent 4,959,038. Since 1992, an automatic pod feeder was added, the floss hopper was eliminated in favor of direct bagging, and the footprint of the processor was reduced in a move to a new facility. The processor now operates to produce 40 pounds of floss per hour while recovering over 95% of the floss and seed. This processor is more than adequate for current needs, and the unit can be duplicated or modernized as raw material demand increases.

A second mechanical challenge was the blender. The fill developed for comforters and pillows was an intimate blend of milkweed floss and goose down. From bench scale data, a commercial-size blender was invented from wood and blowers. The blender was later upgraded to a cylindrical plastic chamber.

A final manufacturing issue was the production of comforters and pillows. A major issue was developing dependable comforter and pillow shell vendors and down suppliers.

CULTIVATED PRODUCTION

Cultivated production is still in the experimental stage, so milkweed pods are collected by hand from native stands in Nebraska, Wyoming, and Illinois. Wild sources provide time for our agricultural production research to develop proven farming practices. The estimated break-even point between the economics of wild collection and cultivated production is a cultivated yield of 50 pounds of floss per acre.

Cultivated production focused on maintaining milkweed in rows until 1996. However, because milkweed is a perennial plant that spreads through rhizomes, cultivation between rows disrupts the milkweed's natural growing mechanism. With this understanding and the newly available preemergence herbicides that do not affect established milkweed, a change was made to plant broadcast stands of milkweed. Planting milkweed seed in stubble after early July wheat harvest protects the fragile seedlings from strong western Nebraska winds. The goal is to establish enough growth in half of a growing season so that the milkweed plant will produce pods the following year.

Systems for harvest and drying of milkweed pods were developed primarily by Kenneth Von Barga and David

Jones at the University of Nebraska.^[3] A row crop harvester for milkweed was modified from a New-Idea Uni-System ear corn harvester. The row crop harvester achieves 80% pod recovery in the broadcast stands of experimental fields.

Pods are generally harvested in September. During harvest, the harvester strips whole, green pods from the milkweed plant. The stalks are left behind and can be harvested by swathing and baling the dried stems. The pods are air dried and processed into raw materials. Raw materials can be stored under warehouse conditions for years.

A field life of 5–10 years is expected. Development of Roundup-ready soybeans is a major step forward in cultivated milkweed production. Before this development, a fallow year was required to eradicate the milkweed field before planting soybeans. Now milkweed can be eradicated while soybeans grow, and a production year is not lost.

Target economics provide the milkweed grower at least the same revenue as corn, with variable farming costs less than with corn. Contract farming would supply milkweed seed and technical advice to the farmer and would guarantee the purchase of the field's output.

CONCLUSION

Increasing the demand for milkweed raw materials is the key challenge in developing the milkweed business. The strategy is to concentrate on higher-value (>\$5 per pound of milkweed floss) and lower-volume uses. On the agricultural side, the goal is to develop growing technology to the point where innovative farmers can profitably grow the crop.

Minor Nutrients

Wolfgang Schmidt

Humboldt University, Berlin, Germany

INTRODUCTION

In contrast to major (macro) mineral nutrients, which (according to their function in osmoregulation, electrochemical equilibria, or as constituents of organic molecules) are required in relatively large amounts, micronutrients are needed in relatively small quantities; in some cases in only minute amounts. Micronutrients serve mainly as catalytic components of enzymes and play a structural role that is indispensable for enzymic function. Mineral nutrients that are required by higher plants for specific functions—such as Fe, Mn, Zn, Cu, B, Mo, Cl, and Ni—can be distinguished from those that have beneficial effects but are not needed by plants to complete a full life cycle and can be substituted by other nutrient elements or are needed by only few taxa, such as Na, Si, and Co. Research into micronutrients serves several goals. Knowledge of how micronutrients are acquired and transported helps in ameliorating the effects of reduction in crop yield caused by nutrient deficiencies, and improves our understanding of the distribution of species in natural habitats. In edible plant products there is a need for an adequate supply of those micronutrients essential for human and animal nutrition in order to eliminate the requirement for dietary supplements and postharvest treatments. Thus, increasing the metal content of our food helps to decrease health-threatening human deficiencies. A further aspect of the study of micronutrients concerns the use of plants for extracting metals from soil, for either phytoremediation or phytomining. Cleaning soils contaminated with trace metals by plants is an inexpensive method of soil remediation. Similarly, plants engineered to accumulate metals return an economic profit from waste rock.

Concerning the molecular background of micronutrient uptake and homeostasis, most knowledge comes from investigations into iron, zinc, manganese, and copper. Therefore, and due to space limitation, this article focuses on these nutrients. For a detailed overview of micronutrients, see the excellent textbook by Marschner and the recent review by Reid.

FUNCTION OF MICRONUTRIENTS IN PLANTS

Iron and copper are essential redox components in photosynthetic and respiratory electron transport and an indispensable cofactor in fundamental cellular processes. Due to its ability to pass readily between the divalent and trivalent oxidation states, iron participates in a wide range of electron transfer reactions that are essential for almost all organisms. Besides electron transport, copper is involved in free radical elimination, lignification, pollen formation, and hormone perception and signaling. Iron and copper metabolism appears to be interlinked in various respects. High levels of free Cu^{2+} causes iron deficiency, possibly by competition between Fe^{2+} and Cu^{2+} for binding sites on proteins or complexing compounds. In yeast and *Chlamydomonas*, copper deficiency also results in iron deficiency because copper is required for the synthesis of a multicopper oxidase that oxidizes ferrous iron prior to uptake of iron.^[1] The valency of zinc cannot be changed and the biological role of zinc is based on its tendency to form tetrahedral complexes. Zinc functions in the regulation of gene expression and is essential for a large number of enzymes, including alcohol dehydrogenase, carbonic anhydrase, and CuZn-superoxide dismutase. Manganese is required for a variety of essential processes, including light-induced oxygen evolution in photosynthesis and CO_2 fixation in C4 and Crassulacean acid metabolism (CAM) plants via phosphoenol-pyruvate carboxylase. In addition, manganese is important for the detoxification of free oxygen radicals via Mn-superoxide dismutase. The function of molybdenum is related to valency change. Molybdenum plays an essential role in nitrate reduction and nitrogen fixation via nitrogenase. Chloride is essential for water splitting in PSII. A further function of chloride is associated with stomatal regulation. In species that lack functional chloroplasts for malate synthesis, Cl^- is transported as a counter anion for K^+ . Due to the ubiquitous presence of chloride in soils, toxicity is much more frequent than deficiency. Nickel is required in extremely low

amounts and is the most recent plant nutrient to be included in the list of essential elements. The only nickel-containing enzyme is urease. Boron has been implicated in a diverse array of functions and is dealt with in a separate article. Despite the fact that the requirement for boron is highest among the micronutrients on a molar basis, the role of boron is still not completely understood.

UPTAKE AND TRANSPORT OF MICRONUTRIENTS

Several classes of transporters that mediate the uptake of micronutrients from the soil solution and their distribution around the plant have been identified by sequence similarities and functional complementation.^[2,3] IRT1, the founding member of the ZRT-IRTlike proteins (ZIP) family, mediates iron uptake in *Arabidopsis*, and orthologs have been subsequently identified in other taxa. AtIRT1 can also transport manganese, zinc, and cobalt but not copper. Interestingly, the substrate specificity of IRT1 is defined by only few residues, offering the possibility of constructing plants with altered selectivity. Depending on the species, iron is either taken up as a divalent cation after reduction of the ferric form that prevails in most soils (strategy I),^[4] or as ferric chelate, complexed with plantborne siderophores with high affinity to ferric ions (phytosiderophores, PS, strategy II). Transporters of the natural resistance-associated macrophage protein (Nramp) family participate in iron uptake and iron homeostasis and have potential roles in the distribution of other metal cations, but their physiological functions are not yet clearly defined.^[5] Zinc is taken up as a divalent ion and accumulates in high amounts by some hyperaccumulators, such as *Thlaspi caerulescens*. ZIP proteins confer zinc uptake in yeast and appear to represent the major route of entry for zinc into plants. ZIP1 and ZIP3 are expressed in roots in response to zinc deficiency.^[6]

Copper enters the cell either complexed by organic ligands or as a free metal ion. Uptake of copper is mediated by a family of transporters named COPT1-COPT5, some members of which are repressed by excess copper.^[7] In yeast, Cu^{2+} must be reduced before uptake. Whether such a reduction is also required for copper uptake by plants is unclear. Manganese is taken up mainly as the free Mn^{2+} ion; a transporter specific for manganese has not been identified. Less is known concerning the uptake of those micronutrients that are taken up as anions. Molybdenum is transported across the plasma membrane as the MoO_4^{2-} anion. Chloride is taken up as a monovalent Cl^- , most likely by an active process in symport with protons. No specific transporters involved in the uptake of micronutrient anions have been identified to date. Boron crosses membranes as an uncharged mole-

cule. Besides simple permeation, boron is thought to be taken up by a transporter or via aquaporins.^[8]

CELLULAR TRAFFICKING AND HOMEOSTASIS OF MICRONUTRIENTS

The availability of micronutrients in the environment varies, necessitating regulated uptake systems to ensure that adequate amounts of essential ions are required. Knowledge of the mechanisms for maintaining cytoplasmic homeostasis of micronutrients is still fragmentary. The regulation of transporters mediating the uptake of metal cations appears to be complex, including both transcriptional and posttranslational control. For example, in transgenic plants overexpressing the iron transporter gene *IRT1*, the IRT1 product is rapidly degraded and represents a safety module when the iron concentration is increased rapidly.^[9] Moreover, IRT1, which is not expressed in zinc deficient plants, can be downregulated by high zinc levels, indicating interaction between signalling cascades of various nutrients. Such cross talks have also been revealed by cDNA microarrays with plants grown in the absence of different essential nutrients, showing that several genes with potential regulatory roles are induced by deficiencies in various nutrients.^[10]

To prevent toxicity, metal cations have to be chelated after entering the cells. This is mainly achieved by peptides such as phytochelatin and metallothioneins, organic acids, polyphenolics, and an array of yet unidentified low molecular weight anionic ligands. A specific role in the distribution of heavy metals has been suggested for the amino acid nicotianamine (NA). In some plants, NA concentrations are considerably increased by high external copper and iron, pointing to the role of NA in the detoxification of excess metals. Immunostaining of the NA-Fe complex has revealed that labelling density was highest in the cytoplasm under adequate iron supply, whereas most of the labelling was present in the vacuole when the plants were iron loaded.^[11] Accordingly, sequestration of iron and possibly other metals into the vacuole appears to represent a mechanism regulating the cytoplasmic level of metal ions. Besides Nramps, members of the cation diffusion facilitator (CDF) family, yellow stripelike (YSL) transporters, and heavy metal (CPx-type) ATPases have been implicated in the uptake, efflux, and sequestration of metal cations, but (with few exceptions) a specific physiological function of these transporters has not yet been proven.

LONG-DISTANCE TRANSPORT

Little is known about how metals are transported over long distances, either from roots to the shoot after uptake

from the soil via the xylem or, during remobilization, from source to sink in the phloem. Generally, metal micronutrients are complexed by ligands to decrease interaction with charged groups during transport. In the xylem, iron is complexed with citrate as the FeCit_2^{3-} ion in a 1:1 ratio. Zinc and manganese are also most likely bound by citrate during xylem transport. Unlike other heavy metals, copper appears to be bound by NA during translocation, a complex with an extremely high stability constant. Other low molecular-weight ligands that have been suggested to function in xylem transport are histidine and phytosiderophores of the mugineic acid family. Co-loading of NA and micronutrients into the phloem supports a role for NA in this process, but a function of NA as a ligand for phloem transport has not been confirmed. A protein with high affinity for iron that can also complex copper, zinc, and manganese *in vitro* has recently been isolated from *Ricinus* phloem exudates, representing the first identified micronutrient ligand mediating phloem-mediated long-distance transport.^[12]

CONCLUSION

Although unravelling the intra- and intercellular transport of micronutrients has recently begun at the molecular level, many important questions concerning the mechanisms underlying uptake, trafficking, and sequestration still remain unanswered. Little is known about how the level of micronutrients—either within the cell or in its immediate vicinity—is sensed and how this signal is translated to adjust uptake and transport within the cell. The elucidation of the mechanisms that determine the concentration and distribution of micronutrients in plants opens new avenues to deepen our understanding of both basic and applied aspects of plant mineral nutrition as diverse as the autecology of species and the improvement of human nutrition.

Mitochondrial Respiration

Agepati S. Raghavendra

University of Hyderabad, Hyderabad, India

INTRODUCTION

Respiratory metabolism occurs in two compartments of plant cells: cytoplasm and mitochondria. Cytoplasm is the site of glycolysis, which produces pyruvate from glucose. The mitochondria carry out further oxidation of pyruvate to CO_2 and H_2O , and they produce adenosine triphosphate (ATP).

Mitochondria are threadlike or rod-shaped organelles, enveloped by an outer and an inner membrane. The space between these two membranes is called intermembrane space. The outer membrane is unselective in permeability, but may be regulatory because of porins (pore-forming proteins). The inner membrane is highly selective and directs metabolite movement through translocators. The inner membrane encloses the granular matrix and has invaginations called cristae. Besides the enzymes of the tricarboxylic acid (TCA) cycle, the matrix contains mtDNA and machinery for protein synthesis and fatty acid metabolism. The components of oxidative electron transport and phosphorylation are located in the inner membrane.

Mitochondrial respiration is most important in terms of contribution, complexity, regulation, and interaction with other organelles. Of about 64 molecules of ATP generated from the oxidation of one molecule of sucrose, 56 molecules of ATP are produced in mitochondria. Besides meeting cellular energy demands, mitochondrial respiration provides the carbon skeletons for primary and secondary metabolism, forms a link in interorganelle interaction, and helps in the homeostasis of redox in cytoplasm.^[1,2]

SUBSTRATES AND PRODUCTS

Mitochondrial respiration consists of three steps: the TCA cycle, electron transport, and oxidative phosphorylation.^[1,2] The first step is oxidation of substrates like pyruvate or malate through the TCA cycle to generate reduced nicotinamide adenine dinucleotide (NADH) and reduced flavin adenine dinucleotide (FADH_2), which are oxidized through electron transport to generate a proton electrochemical gradient across the inner membrane. In the last step, the energy from the proton gradient is used for ATP formation through oxidative phosphorylation.

The substrates for mitochondrial respiration in plant cells range from pyruvate, malate, glutamate, succinate, and glycine, coming from the cytoplasm, chloroplasts, glyoxysomes, or peroxisomes.^[2,3] The predominance of substrate depends on the developmental stage of the organ, the type of tissue, and the presence of light. Pyruvate, malate, or succinate is oxidized through the TCA cycle to yield NADH or FADH_2 , CO_2 , and H_2O . Glutamate is converted to 2-oxoglutarate and fed into the TCA cycle. Glycine is oxidized to serine and sent into peroxisomes. NADH and FADH_2 generated during the oxidation of substrates are utilized in the electron transport to produce ATP.

The final products of mitochondrial respiration are ATP, CO_2 , and H_2O . However, intermediates of the TCA cycle are exported to provide carbon skeletons for nitrate assimilation and other processes.

TCA CYCLE

The major activity of mitochondria is to form citrate, by condensation of acetyl CoA (from pyruvate) and oxaloacetate, and oxidize it through the TCA cycle (Fig. 1). Pyruvate is oxidized (to acetyl CoA) by pyruvate dehydrogenase, a multienzyme complex composed of three components: pyruvate dehydrogenase, dihydrolipoyl transacetylase, and dihydrolipoyl dehydrogenase. Acetyl CoA condenses with oxaloacetate to form citrate, an irreversible reaction catalyzed by citrate synthase. The enzyme aconitase isomerizes citrate to isocitrate, which is oxidized to 2-oxoglutarate by isocitrate dehydrogenase. Another multienzyme complex, 2-oxoglutarate dehydrogenase oxidizes 2-oxoglutarate to succinyl CoA. The hydrolysis of succinyl CoA by succinyl CoA thiokinase yields succinate and ATP. The next step of succinate oxidation to fumarate is catalyzed by succinate dehydrogenase (also known as Complex II), an enzyme bound to the inner membrane. Fumarate is converted to malate by fumarase. Malate is oxidized to oxaloacetate by NAD-malate dehydrogenase to complete the cycle.^[1,2]

The complete operation of the TCA cycle does not always occur, because some intermediates are exported to meet the carbon demands of cytoplasm.^[2,3] For example, citrate and 2-oxoglutarate are needed for nitrate assimilation. It becomes essential to replenish the intermediates

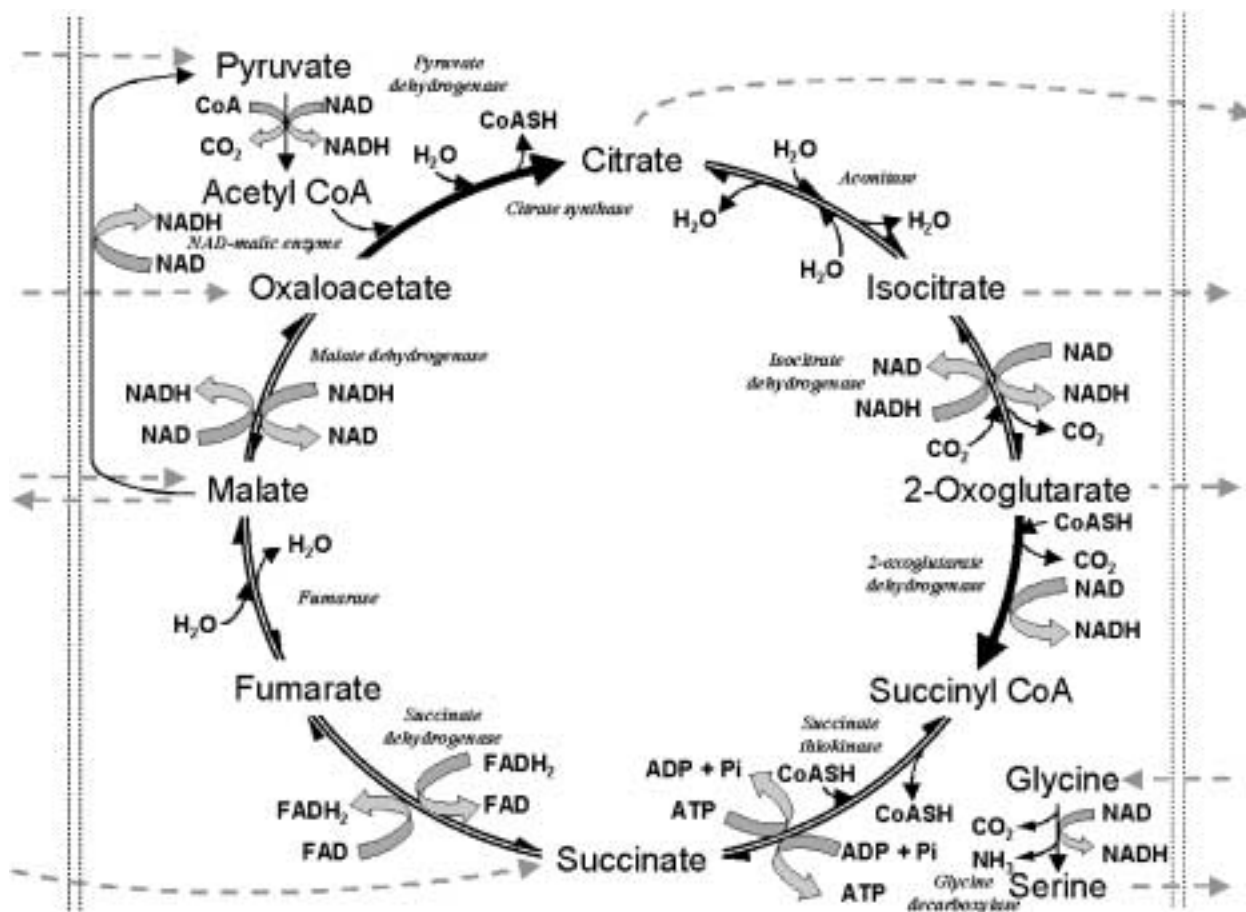

Fig. 1 Overview of the oxidation of pyruvate through the TCA cycle. The dotted lines represent the boundaries of mitochondria; enzymes are indicated by italics; and the inputs and outputs are indicated by gray broken arrows.

of the TCA cycle. Mitochondria, therefore, import malate (formed from oxaloacetate through PEP carboxylase), glutamate (formed from nitrate assimilation and present in high quantities in the cytoplasm), and glycine (formed in photorespiration). Glycine is the major substrate for mitochondrial respiration in leaves under light.

ELECTRON TRANSPORT CHAIN

The oxidative electron transport chain, located in the mitochondrial inner membrane, is formed of complexes, as in chloroplasts.^[2,3] The mitochondrial electron transport chain consists of four modules: NADH-dehydrogenase complex (Complex I), the cyt-b/c complex (Complex III), and the terminal cyt-a/a₃ complex (Complex IV). The oxidation of succinate is initiated by the succinate dehydrogenase (Complex II), and the electrons pass through Complexes II and IV (Fig. 2).

Complex I accepts electrons from NADH and passes them on to ubiquinone within the membrane. The ubiquinone is reduced and traverses across the inner membrane to reduce the cyt-b/c complex and to pull protons from the matrix side into the intermembrane space. The NADH dehydrogenase complex is made up of more than 40 subunits. Complex II is the smallest and has 4 subunits. The cyt-b/c complex is made up of 9–11 subunits. The reduced cytochrome c diffuses along the surface of the inner membrane to reach and reduce Complex IV (earlier known as cyt-a/a₃, consisting of 7–9 subunits), which is in turn oxidized by O_2 . Protons move from the matrix into the intermembrane space during the reduction/oxidation of cyt-a/a₃.

Plant mitochondria can oxidize NAD(P)H on the cytoplasmic side, by an external NAD(P)H dehydrogenase, distinct from Complex I. The external NAD(P)H dehydrogenase is regulated by calcium and the levels of NADH/NADPH.^[4]

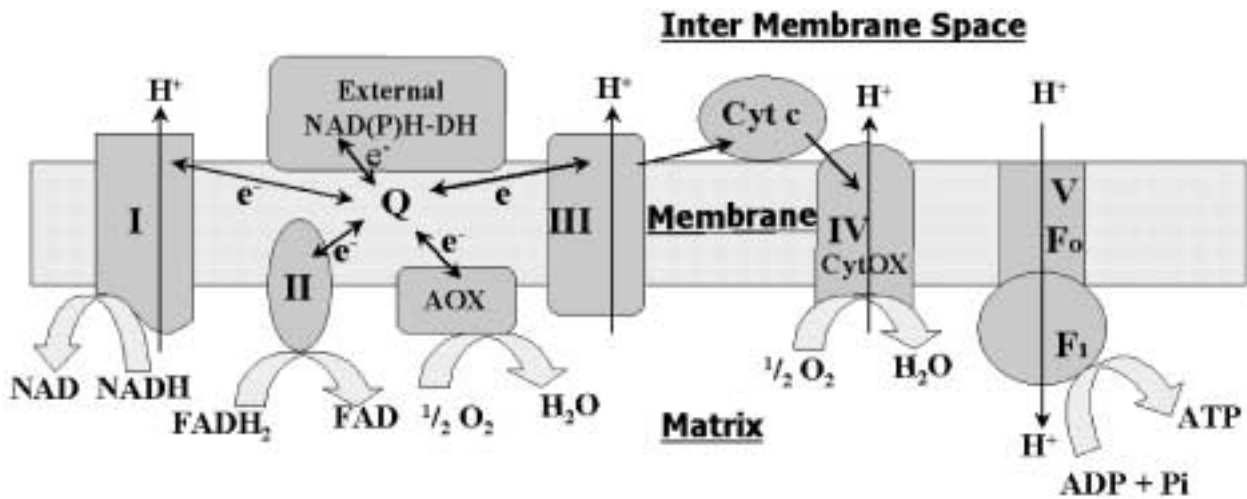

Fig. 2 Electron flow from NADH or FADH through the mitochondrial electron transport chain involving either the cytochrome pathway (Complex IV or CytOX) or the alternative pathway (alternative oxidase, AOX). Plant mitochondria also have an external NAD(P) dehydrogenase.

OXIDATIVE PHOSPHORYLATION

The mitochondrial electron transport creates an electrochemical proton gradient and facilitates ATP formation, as in chloroplasts. The oxidation of NADH/FADH drives protons from the matrix into the intermembrane space, creating a strong proton gradient (the intermembrane space being acidic) and depolarizing the membrane.^[2,4] Protons diffuse back into the matrix through the F_0 - F_1 -ATP synthase complex. The F_0 - F_1 -ATP synthase of mitochondria is a multienzyme complex with two major components. The F_0 is membrane-embedded and is the proton channel. The F_1 is peripheral, extends as a stalk into the matrix, and is the site of ATP formation. F_1 contains five different subunits in a ratio of $\alpha_3\beta_3\gamma_1\delta_1\epsilon_1$, while F_0 has three, with a composition of $a_1b_2c_{10-12}$.

The function of F_0 - F_1 is quite fascinating. F_1 can synthesize ATP from ADP and Pi without additional energy, but a change in conformation driven by H^+ transport across the complex is needed to release ATP bound to the ATP synthase. The oxidation of each NADH molecule through the electron transport and phosphorylation yields 2.5 molecules of ATP and the oxidation of each of FADH molecule yields 1.5 of ATP.

ALTERNATIVE PATHWAY OF OXIDATIVE ELECTRON TRANSPORT

The mitochondrial respiration in plants is not completely inhibited by compounds such as cyanide, because their electron transport occurs through two different routes: the

cyanide-sensitive cytochrome path and a cyanide-insensitive alternative path. The alternative pathway is facilitated by an alternative oxidase (a 32 kDa polypeptide), which has been isolated, cloned, and characterized in detail.^[5,6]

Both pathways use Complex I/II and diverge at the site of ubiquinone (Fig. 2). Since these electrons do not use Complex III or IV, the extent of ATP formed from NADH through the alternative pathway is much less than that through the cytochrome pathway. Most of the energy is released as heat. The main function of the alternative electron transport is to oxidize surplus NADH (even if without ATP formation) and to produce heat. Since the alternative oxidase expression is boosted under environmental stress, it also may have other functions.

FUNCTION AND REGULATION OF MITOCHONDRIAL RESPIRATION

Unlike chloroplasts, mitochondria export ATP to the cytoplasm at high rates through an adenylate translocator, complemented by a phosphate translocator. The translocators are specialized proteins of the inner membrane of mitochondria that facilitate the movement of key metabolites. Among the translocators (and the compounds translocated) present on the inner membrane of mitochondria are malate or dicarboxylate (malate/Pi), 2-oxoglutarate (2-oxoglutarate/malate), citrate/tricarboxylate (citrate/dicarboxylate), oxaloacetate (oxaloacetate/malate), pyruvate (pyruvate/OH⁻), and glutamate (glutamate/aspartate). The presence of a glycine/serine translocator is expected.

Table 1 Metabolic inhibitors that block mitochondrial electron transport, phosphorylation, or other associated processes

Site of action	Inhibitor
Complex I	Rotenone, Amytal A, Piericidin
Complex II	Malonate
Complex III	Antimycin A, Myxothiazol
Complex IV	Cyanide, Azide, Carbon monoxide
Alternative oxidase	Salicylhydroxamic acid, Propyl gallate
F ₁ of F ₀ -F ₁ -ATP synthase	Oligomycin
F ₀ of F ₀ -F ₁ -ATP synthase	Dicyclohexyl carbodiimide
Proton gradient	2,4-dinitrophenol, Carbonyl cyanide-m-chloro-phenylhydrazone, Carbonyl cyanide p-trifluoromethoxy-phenylhydrazone, Ammonium chloride, Methyl amine
Oxaloacetate translocator	Phthalonate
Malate translocator	Butyl malonate
Adenylate translocator	Bongkrekic acid, Carboxyatractyloside

The operation of the TCA cycle and oxidative electron transport are highly regulated^[1,2,4] by the energy status (relative levels of ATP and ADP) of the cell and the redox status of mitochondria (the levels of NADH) and acetyl-CoA. Increase in ATP promotes the phosphorylation and inactivation of pyruvate dehydrogenase. Similarly, increase in NADH causes feedback inhibition of dehydrogenases. Thus the turnover of the TCA cycle depends on the rate of NADH reoxidation by electron transport and the balance between ATP production and utilization. The availability of substrates (e.g., carbohydrate) is important. The regulation of oxidative electron transport by the availability of ADP and Pi is well known ('respiratory control'). Further, the movement of ATP/ADP/Pi into and out of mitochondria is modulated by the electrochemical proton gradient.

The alternative oxidase facilitates a distribution of electrons through the oxidative electron transport. The extent of flow through cytochrome or alternative pathways is modulated by metabolites such as pyruvate and reducing agents such as dithiothreitol.^[5,6] The operation of alternative pathways is regulated by environmental stresses and factors modulating the carbon metabolism. Several metabolic inhibitors are available which block or inhibit different steps of the TCA cycle, translocators, oxidative electron transport, or ATP formation (Table 1).

IMPORTANCE IN PHOTOSYNTHESIS AND INTERORGANELLE INTERACTION

In plants, photorespiration is essential for retrieving half of the carbon diverted through the Rubisco oxygenase activity, with mitochondrial oxidation of glycine as the

key. Mitochondria are the site of malate decarboxylation in NAD-malic enzyme type C₄ and CAM plants. Thus, mitochondrial respiration is essential for C₃-, C₄-, and CAM photosyntheses.^[2,3]

Mitochondria interact beneficially with chloroplasts and peroxisomes.^[7] Chloroplasts supply the substrates for mitochondria, which in turn dissipate the excess reductants generated in chloroplasts. Such cooperation optimizes the photosynthetic carbon assimilation and protects chloroplasts against photoinhibition. Another process, which involves the cooperation of mitochondria with chloroplasts and cytoplasm, is nitrate assimilation.

CONCLUSION

The focus of plant science research has shifted from physiology and biochemistry to the areas of molecular biology and biotechnology. Stupendous progress has occurred in understanding the molecular biology of the function and regulation of mitochondrial respiration. Genomics of plant mitochondria are well known, and the present focus is on proteomics.^[8] Genetic manipulation of enzymes, such as citrate synthase, has been done.^[9] Mutants (e.g., those deficient in some components of F₀-F₁) have long been used to analyze the mitochondrial function.^[10] The mitochondrial transformation is bound to catch up soon with chloroplast transformation.

Mitosis

Dénes Dudits

Attila Fehér

Hungarian Academy of Sciences, Szeged, Hungary

INTRODUCTION

Duplication of somatic plant cells by mitotic division is a fundamental cellular function that provides a continuous supply of cells to create the plant body during the life cycle. Mitosis ensures the faithful transmission of genetic information by packaging replicated DNA strands into high-order chromatin structures leading to the condensation of mitotic chromosomes that are distributed into the daughter cells. Chromosome organization is an active condensation/decondensation process that depends on histone H3 phosphorylation and the functions of topoisomerases and condensin complexes. Parallel with chromosome condensation, organization of microtubule (MT) arrays, such as the plant-specific preprophase bands (PPB), the phragmoplast, and the mitotic spindle provide the apparatus for chromosome separation and new cell plate formation in cytokinesis. The MT function is dependent on the dynamic structure of tubulins and the large number of MT-associated proteins (MAPs). Cyclin-dependent kinases (CDKs) and various members of plant mitogen-activated protein kinases (MAPKs) act as mitotic regulators in cooperation with phosphatases (PP2A). The transition from metaphase to anaphase is controlled by the degradation of cohesin by separase. This cysteine protease can be activated by degradation of an inhibitor protein securin, through the anaphase-promoting complex (APC) as a specific ubiquitin ligase complex. During cytokinesis, the phragmoplast serves as a scaffold for the maturation of the vesicle fusion-generated network binding of the new cell wall.

VISUALIZATION OF STRUCTURAL CHANGES IN THE NUCLEUS AND MICROTUBULES OF MITOTIC PLANT CELLS

The series of micrographs in [Fig. 1](#) highlight the major mitotic events and reveal the coordination between chromosome dynamics and MT organization. The DNA was stained by DAPI and the MTs were visualized by fluorescent labeled antitubulin antibodies.

The interphase nucleus is accompanied by cortical and cytoplasmic MTs. In preprophase (late G₂), chromatin condensation is significantly advanced, as shown by dot formation or organization of chromatid strands. Concurrent with the organization of chromatin, MTs assemble to form the preprophase band. This cytoskeletal structure is a unique characteristic of dividing plant cells. The PPB appears transiently and its position determines the organization site of the phragmoplast and the new cell plate. Condensed chromosomes can be recognized during prophase inside the nuclear envelope surrounded by assembled MTs. The nuclear envelope breaks down during prometaphase, and microtubules attach to the kinetochore at the centromeric region of chromosomes. Simultaneously with the start of mitotic spindle construction, the chromosomes move to the spindle equator. In metaphase cells the chromosomes align at the spindle equator and the barrel-shaped mitotic spindles are formed from the spindle and kinetochore. The MTs follow a bipolar organization with several microtubule-nucleation sites. At anaphase, the replicated sister chromatids separate synchronously and chromosomes move to the poles that subsequently separate. The chromosome movement is dependent on MT depolarization. Between the two spindle poles, the phragmoplast is formed from microtubules, actin, and myosin during late anaphase. Phragmoplast formation in telophase occurs when chromosomes decondense in daughter nuclei and the newly formed nuclear envelope develops. At this time, the mitotic spindle breaks down and the phragmoplast serves as a scaffold for the collection of Golgi-derived vesicles containing materials required for the construction of the cell plate. Cytokinesis in plant cells is completed by the formation of a new wall between daughter cells.

GENE EXPRESSION PROFILES DURING G₂-M PROGRESSION

The identification of transcriptionally active genes in mitotic cells provides essential information about the functionally important molecules and their roles in mitosis.

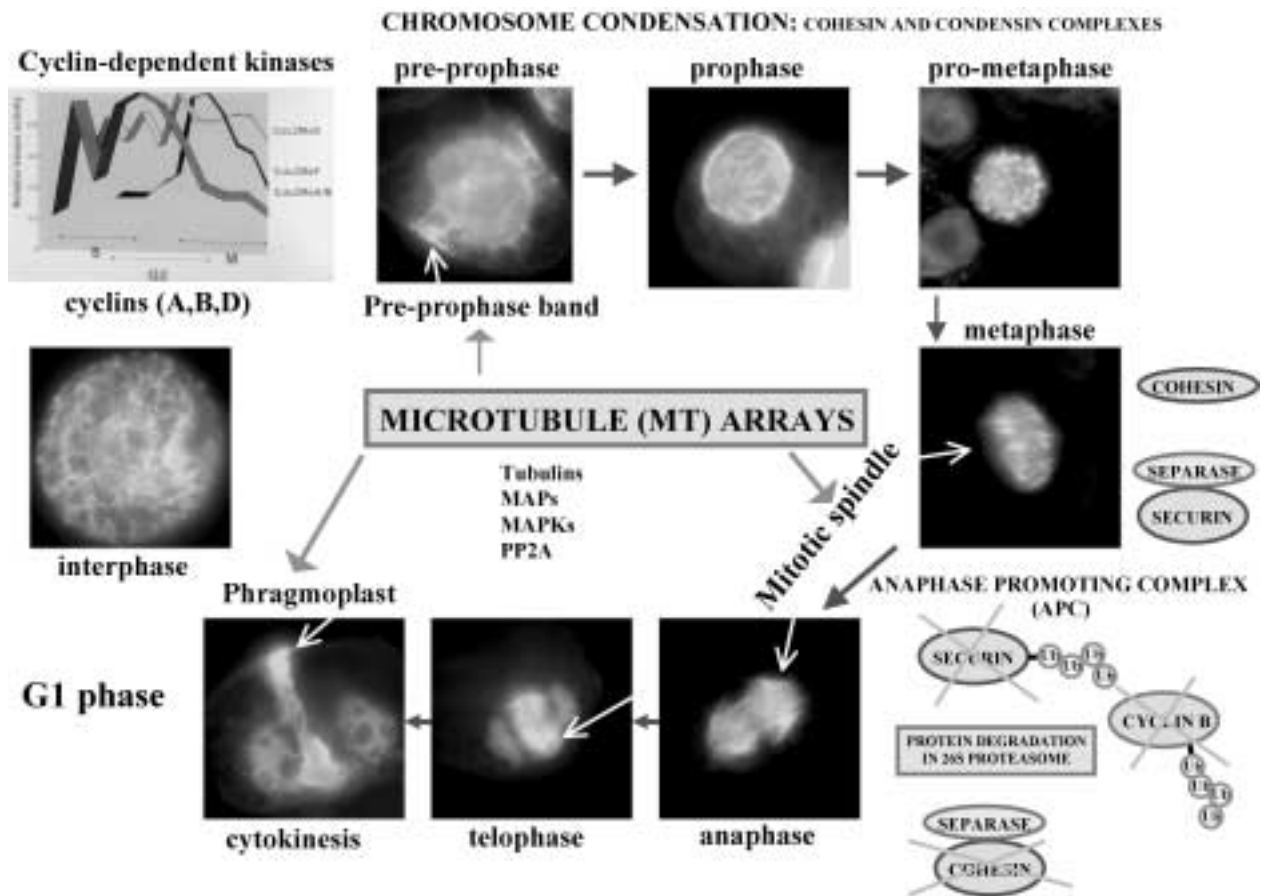

Fig. 1 Components of mitotic events in plant cells. In alfalfa cells the DNA is stained with DAPI (orange) and the microtubules are visualized by fluorescent-labeled antitubulin antibodies (green). MAP: microtubule-associated protein; MAPK: mitogen-activated protein kinase; PP2A: phosphatase. (Photos by Ferhan Ayaydin, Ph.D.) (View this art in color at www.dekker.com.)

The recent genomewide transcriptome analysis of synchronized tobacco and *Arabidopsis* cells highlighted a set of genes that are preferentially expressed in G2 and mitotic phases of the cell cycle. In tobacco cells, the cDNA-AFLP-based transcript profiling revealed more than 1300 transcript tags with significant modulation during the cell cycle.^[1] The G2 cells exhibited 16% of these tags enriched in transcriptional factors. Mitotic cells provided the largest group of cell cycle tags (53%) representing genes with functions in cell cycle control (4.17%), RNA processing (5.37%), protein synthesis (8.65%), protein phosphorylation (5.67%), proteolysis (5.07%), cytoskeleton (11.34%), cell wall (7.46%), and transport secretion (6.26%). A large portion (33.43%) of tags corresponded to proteins with unknown function. By the use of an Affymetrix Gene Array in synchronized *Arabidopsis* cells, nearly 500 gene signals (12% of total expressed genes) were identified that have a significant cell cycle phase-dependent fluctuation in expression.^[2] A high portion (30%) of these genes showed a peak of expression

in the G2 phase and mitosis. These data convincingly show that transcriptional control has a critical role in regulation of mitotic functions. Furthermore, the list of genes expressed during mitosis and the prediction of the encoded proteins can provide a comprehensive insight into mitosis at the molecular level. In addition to mitotic B-type cyclins, plant-specific CDKs (in *Arabidopsis*: CDKB1 and CDKB2; in alfalfa: *cdc2MsD*, *cdc2MsF*) with unique cyclin-binding motifs (PPTALRE, PPTTLRE) exhibit clear transcript accumulation in G2/M cells. Plants differ from yeasts and animals in this feature. Similarly, the β -tubulin genes from plants are highly induced in G2 and early M-phase, whereas the tubulin-gene expression fluctuates moderately during the yeast cell cycle. The class of kinesin genes showed mitosis-linked expression profiles. The *Arabidopsis* homologue of the CDC20 gene from budding yeast was actively transcribed in mitotic cells. The encoded protein is involved in the activation of the anaphase-promoting complex. The mitotic function of various kinases such as NPK1, MAPKs with a role in

phragmoplast and cell plate growth, or the homologue of Aurora kinase involved in chromosome segregation and cytokinesis, can be inferred from the gene expression profile. The regulatory role of protein phosphorylation is also emphasized by the activity of genes encoding various phosphatases (e.g., protein phosphatase 2C). Activity of the ubiquitin-proteasome complexes during mitosis can be seen from expression of genes of the M-phase-specific, protein-degradation system. The hormonal control of mitosis can be related to the high level of expression of histidine kinase gene encoding the cytokinin receptor CRE1. The mitotic peak in expression of auxin-related genes (IAA17; At2g46690) is in accordance with the auxin dependence of this cell cycle phase.

As extended analyses of cell cycle, phase-dependent gene that expression patterns demonstrate, significant number of plant genes are under a tight transcriptional control. The Mitosis-Specific Activator (MSA) *cis* element in promoters of various B-type cyclins and the tobacco kinesin-like protein genes (NACK 1,2) has been identified as responsible motif for the G2/M phase-specific gene expression. The Myb-related transcription factors (NtmybA1 and A2) with three imperfect repeats in the DNA-binding domain can activate while the Ntmyb factor represses transcript accumulation from genes with MSA-promoter element.

MOLECULAR MECHANISMS UNDERLYING SISTER CHROMATID COHESION AND CHROMOSOME CONDENSATION

The two initial phases in chromosome organization include cohesion and condensation—both events based on distinct, yet structurally similar proteins forming the cohesin and condensin complexes. These components of mitotic chromosome dynamics and functions show high evolutionary conservation from yeast to vertebrates, and recent studies on the titan (*ttn*) mutants of *Arabidopsis* demonstrate the functional significance of plant cohesin and condensin as well.

The duplicated sister chromatids produced by replication of chromosomal DNA are tightly paired, at both the centromere and along the arms throughout the G2 phase and during condensation of chromosomes. The cohesin complex, which physically holds sister chromatids together, involves the SMC1 and SMC3 proteins (structural maintenance of chromosomes) in yeast, *Aspergillus*, *Xenopus*, and humans. In *Arabidopsis*, a single orthologue of these genes has been identified and the SMC1 (*ttn8*) and SMC3 (*ttn7*) knockouts show a strong titan phenotype with defects in embryo and endosperm development.

In mitotic plant chromosomes, condensation is a highly ordered and active process that starts during early prophase from the centromeric region. The complete remodelling of the chromatin structure results in a high degree of DNA packing into tightly folded chromatin.^[3] The condensation process depends on histone modifications (phosphorylation, de-ubiquitination) and the activity of topoisomerases and condensin complexes. In mitotically dividing cells, the process of chromosome condensation has been shown to be coupled with phosphorylation of histone H3. Mitotic CDK complexes and serine/threonine phosphatases can alter the degree of chromosome condensation, as demonstrated by experiments based on the microinjection of kinase complexes or treatment with phosphatase inhibitors (endothall, sodium vanadate, cantharidin).^[4] The phenomenon of premature chromosome condensation (PCC) can be induced by fusion of mitotic and interphase plant protoplasts or by exposing cells to phosphatase inhibitors.

The functional role of topoisomerase II during the condensation process is to induce super coils into the DNA helix that allow an increase in the packing density of DNA. Treatment of plant cells with inhibitors of this enzyme aborted the chromosome condensation. The presence of an other topoisomerase (type I) is required for the function of the multisubunit condensin complex that organizes the topology of DNA loops in the chromosomes. The core condensin complex consists of two structural maintenance of chromosome (SMC) subunits—SMC2 and SMC4—that form the 13S condensin complex, and includes three other proteins (Cnd1–Cnd3). The SMC core complex can bind to naked DNA and exhibits ATPase activity that is increased in association with regulatory subcomplex formed by Cnd proteins. In *Arabidopsis*, the *TTN3* gene corresponds to a SMC2 condensin homologue expressed in most of the plant organs. Apart from CDKs, other enzymes such as the Aurora B kinase can be required for condensin activity during metaphase. A plant orthologue of this kinase gene has been found in transcript-profiling experiments with cultured tobacco cells.

As shown by electron micrographs in Fig. 2., condensed mitotic plant chromosomes are organized into chromosome arms separated by a centromeric region. Sister chromatids of metaphase chromosomes are joined at the centromere where the centromeric DNA is closely associated with a protein-rich structure called the kinetochore, the attachment site for MTs. At the end of the linear chromosome, telomeres protect the chromosome from shortening. The length of repeated telomeric sequences (TTAGGG in *Arabidopsis*) may change during development. Telomerases can copy several telomere repeats with the help of complementary RNA molecules.

MODES OF MICROTUBULE FUNCTIONS

In coordination with the condensation of chromosomes, the highly dynamic structure of the MTs is organized in dividing plant cells to serve as one of the key functional components for segregation of chromosomes. The heterodimers of α - and β -tubulin subunits constantly assemble, disassemble, and rearrange (polymerize/depolymerize) during the organization of MT arrays such as the preprophase bands, the mitotic spindle and the phragmoplast (Fig. 1). The MT organization and dynamics require the functional contribution of a large number of MT-

associated proteins.^[5] The ATP-dependent motor proteins move unidirectionally along the surface of MTs and function as transporters or MT organizers. The kinesin-like motor proteins such as KCBP/2-WICHEL can induce the transient and local stabilization of MTs to be rearranged or focused. Mutation in the TANGLED1 (TAN1) gene causes misorientation of MT arrays. This protein is associated with mitotic MT arrays and repeats in cytokinesis.

The central role of different MAPs in phragmoplast organization and cytokinesis is shown by the characteristics of cell division mutants or immunolocalization studies.^[6] The *Arabidopsis* Microtubule Organization (MOR1) protein and its homologue, the tobacco MT-bundling protein (TMBP200), participate in the organization of MT arrays (e.g., by cross-bridging between phragmoplast MTs). Inhibition of a motor protein called TKRP15 interferes with translocation of phragmoplast MTs. One of the phragmoplast-localized, kinesin-related proteins of *Arabidopsis* (AtPAKRP2) has been suggested to act as transporter of Golgi-derived vesicles to the newly forming division plate.

Several essential mitotic events including MT dynamics are under a defined phosphorylation control, based on a series of kinases and phosphatases with regulatory and/or coordinatory function.^[7] The pivotal role of CDKs in mitotic plant cells can be concluded from G2/M phase-specific expression of the corresponding genes, identification of mitotic kinase complexes, protein interaction, and immunolocalization studies. In synchronized G2/M alfalfa cells, at least three types of Cdc2-related kinase complexes can be detected with characteristic timing of activity peaks (Fig. 1). The Cdc2MsA/B kinases are highly active in mid-G2 phase, whereas the Cdc2MsD kinase activity peaks before the start of mitosis. The CdcMsF kinase represents a typical mitotic kinase.

The alfalfa Cdc2MsD and F kinases have *Arabidopsis* orthologues (CDKB1 and CDKB2) and exhibit plant-specific, cyclin-binding motives (PPTALRE or PPTTLRE) instead of the PSTAIRE sequence element. The alfalfa Cdc2MsF mitotic kinase was shown to be colocalized with MTs in all mitotic stages.^[8] In general, the B-type cyclins are considered regulators of mitotic CDKs; however, a role for A-type and D-type cyclins can be inferred from protein-interaction studies. Gene predictions based on sequence data of the *Arabidopsis* genome suggest 10 A-type cyclins, 9 B-type cyclins, and 10 D-type cyclins. As far as the number of cyclin gene variants and kinase complexes is concerned, the mitotic cell cycle control machinery in plants shows higher complexity than in animals; however, the specificity and redundancy in cyclin gene functions have not been elucidated so far. The formation of active CDK complexes is dependent on the

phosphorylation of selected amino-acid residues of the interacting partners. The CDK-activating kinases (CAKs) and inhibitory phosphorylation by the Wee1 (Mik1-type) kinases can alter the CDK functions that are also controlled by the set of inhibitor proteins. The Kip-related proteins (in *Arabidopsis*, KRP1-KRP7) can differentially regulate the various CDK complexes. The list of kinases involved in the control of mitosis is not restricted to the CDKs. Various members of plant mitogen-activated protein kinase (MAPK) cascades can contribute to the establishment and function of the phragmoplast during cytokinesis. Nucleus- and phragmoplast-localized Protein Kinase 1 (NPK1) activity is required for expansion of both the cell plate and the phragmoplast. Other MAPKs, such as p43^{Ntf6} from tobacco and MMK3 from alfalfa, are activated during cytokinesis. The *Arabidopsis* HINKEL (HIK) protein and its orthologue in tobacco, the Nicotiana protein kinase 1 (NPK1)-activating kinase-like protein 1 (NACK1), can initiate a signaling cascade involved in the cytokinesis.

An increasing number of experimental data support the significance of phosphatases as counteracting enzymes of kinases in regulating mitotic events in plant cells. The formation of active CDK complexes requires the removal of inhibitory phosphate from the Tyr-14 and Thr-15 residues of the CDKs. Cdc25-related phosphatases can activate CDKs in yeast, *Drosophila*, and in mammalian cells. Attempts to identify plant orthologues of these phosphatases are expected to be successful. However, expression of the yeast Cdc25 enzyme in tobacco transformants caused cytokinin-independent premature mitosis, reduced cell size, and altered lateral root development. In general, cytokinins are needed to form an active CDK complex. The role of serine/threonine phosphatases (e.g., PP2A) in MT organization can be concluded from inhibitor experiments. In endothall-treated alfalfa cells, the formation of PPBs and the phragmoplast is disturbed, and the premature polarization of the mitotic spindle is coupled with the early activation of mitotic Cdc2M_SF kinase.^[4] Mutation in the *Arabidopsis* TONNEAU2 (TON2)/FASS gene encoding a putative B-regulatory subunit of PP2A phosphatases causes similar abnormalities in mitosis.

METAPHASE-TO-ANAPHASE TRANSITION AND CYTOKINESIS

The release of cohesin-mediated chromosome cohesion at the metaphase plate is a prerequisite for the chromosome segregation in anaphase.^[9] The dissolution of cohesion between sister chromatids can be induced through degradation of cohesin by separases belonging to the

CD clan of cysteine proteases. The precise timing of separase activation is crucial, because it can occur only after the formation of bipolar attachments between the sister chromatids and the spindle MTs. This tightly controlled regulatory process includes an inhibitory protein called securin that blocks separase activity until the Anaphase-Promoting Complex (APC), a specific ubiquitin-ligase complex, links a polyubiquitin chain to securin and targets it for degradation by the 26S proteasome. The composition of APC has not been identified in plants, but we expect functional conservation with the 10 subunits of mammals and 13 subunits of yeasts. The APC activity also regulates cyclin degradation in mitosis. In plants, both the B-type and A-type cyclins can carry a short peptide motif of nine amino acids called the destruction (D)-box, which serves as a recognition site for APC. Reduction in the availability of cyclins could contribute to the loss of CDK activity at the end of mitosis. The APC function is under complex regulatory control, including an association with activator WD-repeat proteins such as Cdc20p (Fizzy) or Cdh1 (Fizzy-related) proteins that recruit substrates to APC. Components of the mitotic spindle checkpoint such as MAD (mitotic arrest deficient) and BUB (budding uninhibited by benomyl) proteins can inhibit APC activity. The APC is also regulated by cell cycle-specific phosphorylation; both kinases (Polo-like kinase, Plk1) and phosphatases (PP1) can activate APC.

After completion of mitosis, the phragmoplast serves as a scaffold to direct the movement of Golgi-derived vesicles containing cell wall components to form the new cell wall between the daughter nuclei.^[10] The phragmoplast complex is composed of two bundles of antiparallel MTs and actin filaments that are colocalized with number of kinesins. The process of phragmoplast expansion by reorganization from a solid cylinder into a ring-shaped structure is dependent on MT depolymerization in the center and reassembly-polymerization of MTs on the outside of phragmoplast. This lateral expansion of the phragmoplast can be arrested by brefelding treatment, which prevents the establishment of a ring-shape and MT disassembly. Caffeine can disrupt cell-plate formation by interfering with the maturation of the fusion-generated vesicle membrane network into a wide tubular network in the phragmoplast. The cell plate grows outward by incorporating vesicles into the edge until it reaches the parental cell walls. The primary cell walls consist of cellulose, cellulose-binding hemicellulose, and pectins. Cellulose is generated at the plasma membrane in the form of paracrystalline microfibrils, whereas hemicellulose and pectins are synthesized within Golgi cisternae. After the formation of a new primary cell wall, the division procedure is complete and the separated daughter cells can either enter into a new division cycle or undergo differentiation.

CONCLUSION

Our present knowledge about the major regulatory mechanisms of mitotic events is increased by the use of improved cytological techniques, based mainly on immunolocalization of key proteins. Detailed characterization of cell division mutants (primarily in *Arabidopsis*), and the cloning of the responsible genes provide essential functional information about control of the mitotic cell cycle. Overexpression of genes encoding proteins with roles in mitosis can be an alternative approach in functional analysis. In the future, detailed characterization of protein complexes and outlining cascades of phosphorylation/dephosphorylation during the perception of developmental or environmental signals will be needed. The DNA damage checkpoint will attract more attention. Discovery of the major controlling elements in endoreduplication is expected to highlight plant-specific elements in mitosis. Activity of meristems as major foci of mitotic events is under the precise control of a developmental program that can be altered by environmental influences.

Molecular Analysis of Chromosome Landmarks

James A. Birchler

Juan M. Vega

Akio Kato

University of Missouri, Columbia, Missouri, U.S.A.

INTRODUCTION

The major landmarks of a plant chromosome include the primary constriction, which represents the centromere; the ends of the chromosomes or telomeres; and blocks of heterochromatin, which, depending on the circumstances, can be rather discrete or diffuse. In many plant species a secondary constriction that represents the nucleolus organizer regions (NORs) is observed in one or more pairs of chromosomes. This secondary constriction encodes the major species of ribosomal RNA. The different landmarks consist of various types of repetitive sequences. This fact allows their molecular analysis to be facilitated by visualizing them using hybridization of probes to the mitotic metaphase or meiotic pachytene chromosomes.

CENTROMERES

The centromere is the structure present at the primary constriction of a chromosome.^[1] At this site, the proteins are organized in a complex called the kinetochore, which serves to move the chromosome to the poles at mitosis and meiosis. Moreover, at meiosis I, it serves to hold the two sister chromatids together during anaphase.

Among plant species, early molecular studies were of the B-specific repeat of the B chromosome centromere of maize^[2] and of the satellite repeat in Arabidopsis.^[3] The B-specific unit is approximately 1.4 kilobases in length and is only found in the centromere of the supernumerary B chromosome.^[2] Its location in the centromeric region was confirmed by analysis of B chromosome derivatives that have suffered from misdivision of the centromere. This process results when a centromere is present as a univalent in meiosis. The spindle attaches from both poles and ruptures the centromere transversely instead of separating it lengthwise. A number of misdivision derivatives have been studied and all change the restriction pattern identified by the B-specific repeat probe

confirming the location of this unit within the B centromere.^[4]

The B centromeric repeat arrays extend over approximately 9 megabases in length. The misdivision derivatives reduce this size to as small as a few hundred kilobase pairs.^[5] Although other sequences are also included, the B-repeat cluster is likely to be throughout the centromere, based on the fact that misdivision can fracture this sequence and both fractured centromeres of the broken chromosome can still function.^[4]

The centromeric satellite sequence of Arabidopsis is 180 base pairs in length and is repeated many times at the site of the primary constriction of each of the five chromosomes of Arabidopsis. The length of the repeat cluster ranges from 1–2 megabases.^[3] The satellite cluster falls within the genetically defined centromere as determined by tetrad analysis.^[6]

For the A chromosomes of maize, there are other repeats present at the primary constriction of the respective chromosomes.^[7,8] One of the more prominent is the CentC unit^[8] (see Fig. 1). It is present at the primary constriction of all of the ten chromosome pairs to varying degrees. Another element, CentA, is present and variable as well. A third related element is CRM.^[9] The latter two repeats are retrotransposons that are specific in their location to the centromeric regions.

The centromeres of rice are also composed of a collection of repeats that are quite similar to those of maize.^[10] The satellite sequence referred to as CentO is a small repetitive element that contributes to slightly more than 1% of the rice genome. The representation of CentO in different centromeres of the twelve chromosomes is highly variable. Interspersed among the CentO repeats are copies of the CRR retroelement. Thus, a common feature of cereal centromeres is the presence of both conserved retrotransposons and species-specific tandem repetitive sequences. Functional centromeres are associated with a particular version of histone 3.^[11] A portion of the amino acid sequence of this histone is highly conserved relative to the normal version present in nucleosomes outside the centromere. However, one end of the molecule has

Fig. 1 Fluorescent in situ hybridization of maize root tip metaphase chromosomes illustrating the locations of the centromeres (red) and the knob heterochromatic sites (yellow green). A probe for CentC was used to mark the centromeres. (View this art in color at www.dekker.com.)

evolved very rapidly. To date, antibodies have been produced against the centromere histone 3 from Arabidopsis and from maize.^[9,11]

NUCLEOLAR ORGANIZER REGIONS (NORS)

The ribosomal RNA genes are clustered by the hundreds or thousands of copies, often spanning millions of basepairs of chromosomal DNA at loci known as nucleolus organizer regions (NORs).^[12] The number of NORs in a haploid chromosome set is characteristic of a species.^[13,14] As a rule, at least one NOR is present per genome. During metaphase of mitosis, the NOR is usually observed as a secondary constriction on the chromosome. Upon exit from mitosis, transcription of the rRNA genes initiates the formation of a nucleolus. In interspecific hybrids, the NORs of one progenitor species are often inactivated, regardless of whether that species served as the maternal or paternal parent.^[15] In this phenomenon, known as nucleolar dominance, silenced rRNA genes

can be efficiently derepressed by chemical inhibitors of DNA methylation or histone deacetylation, implicating chromatin modifications in the maintenance of nucleolar dominance.

TELOMERES

The ends of chromosomes are capped by a specific sequence, called the telomere, which appears to stabilize the terminus. Typically broken chromosome ends will fuse with each other to generate chromosomal changes in structure. Alternatively, sister chromatids of a broken chromosome fuse at the ends after replication to initiate a bridge–breakage–fusion cycle. The addition of a telomere at the broken site will prevent such fusions.^[16,17] Moreover, the presence of a telomere allows complete replication of the chromosome ends. Telomeres also cluster in meiosis before homologue synapsis.^[18]

The first telomere sequence isolated from plants was from Arabidopsis.^[19] The sequence is composed of the

repeat TTTAGGG in many tandem copies. Most plant species have the same structure.^[20] Adjacent to the telomere repeats are telomere-associated sequences that consist of degenerate versions of the repeats. Some few plant species, including members of Alliaceae and Aloe spp. (Asphodelaceae), were found to lack the Arabidopsis-type telomeric repeats.^[21]

Mutations in telomerase—the enzyme that synthesizes telomeric DNA—cause telomere shortening.^[22] This ultimately limits cell proliferation capacity because uncapped chromosome ends activate DNA damage checkpoints. Arabidopsis mutants that lack telomerase have unstable genomes, but manage to survive up to 10 generations with increasingly shortened telomeres and cytogenetic abnormalities.^[22]

HETEROCHROMATIN

Pericentric Heterochromatin

Most plant chromosomes have deeply staining heterochromatin surrounding the centromeres that displays gradual transition to more lightly staining regions called euchromatin. There are species, however—tomato being a prime example—in which the demarcation between centric heterochromatin and the euchromatin is very distinct. Typically there are few genes located in the pericentric regions and recombination values are low. Consequently the majority of genes are placed distally on the chromosome. The centric heterochromatin is likely composed of retrotransposon copies.^[23] In maize, some retroelements such as PREM^[24] are preferentially distributed around the centromeres.

Knob Heterochromatin

Some plant chromosomes contain blocks of heterochromatin within the chromosome arms that are referred to as knobs.^[1] The most thoroughly studied knobs from the molecular point of view are those of maize (see Fig. 1). These chromosomal landmarks were first used as a means to distinguish the members of the maize karyotype in meiosis.^[1] Subsequently, they were found to act as neocentromeres and cause preferential segregation of linked markers through the female side.^[25]

This neocentromeric activity only occurs during meiosis. The knobs proceed to the poles ahead of the true centromeres. For preferential segregation to occur, heterozygosity is necessary for the presence or absence of a knob or at least for the size of knobs. A recombination event must occur between the true centromere and the

knob to generate a heteromorphic dyad that pulls the knobbed chromatid to the outer poles during female meiosis. Because the most basal megaspore gives rise to the female gametophyte, the knob containing chromatid is recovered more often than random in the egg. The knobs act as neocentromeres only in the presence of an abnormal version of chromosome 10, which itself has a novel large knob near the end of the long arm.

Peacock et al.^[26] identified a repeat of 180 base pairs in length that is limited to knob heterochromatin. These units are arranged in tandem arrays interrupted by retroelements.^[27] Subsequently, another version was found (referred to as TR1) that is the major component of a few knobs.^[27] The neocentric activity in the knobs is not associated with the presence of the centromeric version of histone 3. Moreover, their attachment to the spindle is at an angle, in contrast to the perpendicular nature of spindle attachment to a normal centromere.^[28]

Constitutive Heterochromatin

Constitutive heterochromatin refers to chromosome regions that remain condensed and transcriptionally inactive during interphase. They are enriched in tandemly repeated sequences of which the heterochromatic state is a heritable chromosomal trait. These regions include the already cited knobs and other heterochromatic blocks that reside in interstitial and terminal positions in many plant chromosomes. They can be visualized by conventional staining methods and a number of chromosomal banding techniques.

In plants, the first systematic analysis of the relationship between different heterochromatic bands and repetitive DNA sequences was done in rye.^[29] Several repeats arranged in tandem arrays, with repeating units of a few hundred base pairs, are located within the blocks of telomeric heterochromatin that can be observed on all seven pairs of rye chromosomes by C-banding. Most heterochromatic blocks contain more than one class of repeated elements. The size of the blocks varies among different rye accessions, indicating that the copy number of the DNA sequences may change extensively.

The heterochromatic state is highly stable. However, an interstitial C-band present in rye 5R chromosome is unusually decondensed when this chromosome is added to wheat. In the wheat background, this region appears as a constriction, which coorients with the true centromere and shows neocentric activity at meiosis.^[30] This phenomenon resembles the situation observed with maize knobs. However, whereas maize neocentromeres interact with spindle microtubules in a lateral manner, the 5R neocentromere shows end-on contact with microtubules, in a way similar to the binding of true centromeres. Tandem arrays

of a 118 base pair monomeric unit are present at the 5R neocentromere.

CONCLUSION

The major landmarks of plant chromosomes are typically composed of repeated units of one type or another. The telomeres are synthesized by an enzyme (telomerase) that adds the appropriate sequence to the ends of the chromosomes. The basis for the maintenance of the centromeric repeats, especially considering their uniformity on nonhomologous chromosomes, is unknown. Also unknown are the exact sequence requirements to specify a centromere. Because the putative *cis*-acting centromeric sequences are not conserved, even in closely related species, it is possible that centromeric identity is not determined by DNA sequence but rather by chromatin assembly during replication. The accumulation of some repeated sequences under these sites might be unrelated to the specification of the centromere location. Future work is needed to reveal the nature of the centromere determination.

Molecular Biology Applied to Weed Science

Patrick J. Tranel
Federico Trucco

University of Illinois, Urbana, Illinois, U.S.A.

INTRODUCTION

Weed science is a very practical discipline that has the general goal of improving weed management. To achieve this goal, however, weed scientists historically have relied on many basic scientific disciplines, such as plant physiology, biochemistry, chemistry, and genetics. In more recent years, the tools afforded by molecular biology techniques also have been brought to weed science. In fact, among the first and most widely adopted outcomes of biotechnology were weed science products, namely herbicide-resistant crops. Molecular biology tools are also being widely used in weed science to investigate fundamental questions regarding the biology, ecology, and evolution of weeds. The application of molecular biology tools to weed science is described and illustrated with several examples.

RECENT EVENTS IN THE HISTORY OF WEED SCIENCE

Although humans have contended with weeds for millennia, rapid growth of weed science as a discipline did not occur until the middle of the 20th century, after the discovery of the first synthetic herbicides. Throughout much of the latter half of the 1900s, weed science was focused on herbicide discovery and herbicide physiology. Weed scientists were tremendously successful, increasing the efficacy and range of new herbicidal chemistries and thereby simplifying and improving weed management. As a result, soil conservation practices expanded and yields improved. Herbicides also aided basic biological research. For example, much of what we now know about the shikimic acid pathway (which is disrupted by the herbicide glyphosate) and photosynthetic electron transport (disrupted by triazine and other herbicides) was discovered by weed scientists investigating herbicide phytotoxicity.

Herbicide-Resistant Weeds

A repercussion of the wide adoption of herbicides for weed management was the evolution of herbicide-resistant

weed populations. This phenomenon continues to be an area of intense weed science research, and is greatly aided by molecular biology. Illustrative of this point are investigations of resistance to herbicides that inhibit the enzyme, acetolactate synthase (ALS).

The ALS enzyme is necessary for the production of certain amino acids, so inhibition of this enzyme leads to plant death. Numerous herbicides, most of which belong to either the sulfonylurea or imidazolinone chemical group, target this enzyme and have been widely used since the early 1980s. Although these herbicides have been very effective, populations of more than 70 weed species have evolved resistance to these herbicides.^[1] In most cases in which it has been investigated, resistance was determined to be due to an altered target site. More specifically, mutations in the gene encoding ALS result in the production of herbicide-insensitive versions of the ALS enzyme. Multiple mutations have now been identified from resistant weed populations and are being catalogued.^[2] Identification of these mutations and the corresponding patterns of resistance to the various ALS-inhibiting herbicides has greatly improved our understanding of how these herbicides interact with their target site.

Herbicide-Resistant Crops

In recent years, application of molecular biology research methods to herbicide physiology and herbicide resistance in weeds has furthered our understanding in these areas. Taking this idea a step further, our understanding of herbicide phytotoxicity at the molecular level has enabled the most recent revolution in weed science: the development and commercialization of herbicide-resistant crops.

Herbicide-resistant crops are perhaps the most consequential outcome of molecular biology applied to weed science. Among these, glyphosate resistance technology stands as the best example. Glyphosate's ability to control a broad spectrum of weeds, its low toxicity to humans and other nontarget organisms, and its limited environmental persistence have made it a good candidate for efforts at engineering herbicide-resistant crops.

Glyphosate targets the enzyme 5-enolpyruvylshikimate-3-phosphate synthase (EPSPS). First attempts to

engineer glyphosate resistance involved overexpression of the gene encoding EPSPS and expression of mutated forms of the gene encoding glyphosate-insensitive variants of the enzyme.^[3] Although marginally successful, such attempts did not result in commercially acceptable levels of glyphosate resistance. The screening of microorganisms resulted in identification of a second type of EPSPS enzyme (Class II EPSPS) that was highly resistant to glyphosate. A Class II EPSPS gene was cloned from *Agrobacterium* spp. strain CP4 and expressed in crop plants. Success in using the CP4 EPSPS gene led to the commercialization of glyphosate-resistant soybean in the United States in 1995, followed by canola and cotton in 1997 and corn in 1998.^[4] Since 1996, the worldwide adoption of glyphosate-resistant crops has been immense (Fig. 1).

Transgenic approaches also have been used to obtain other commercial forms of herbicide-resistant crops. Additionally, mutagenesis has been used with success in nontransgenic attempts to obtain herbicide resistance. In this approach, resistant variants are selected from a population of the crop of interest. To improve the chance for success, genetic variation in the population is increased by using one of several techniques to induce mutations in the plants.

Regardless of the specific technique used, the development of herbicide-resistant crops has increased options for weed management, and several such crops are now commercially available (Table 1). Although often criticized by environmental groups, such crops—if used wisely—offer great promise for reducing detrimental impacts of weeds and for developing more sustainable weed management systems.

Fig. 1 Glyphosate-resistant soybean hectares as a percentage of total soybean hectares. The United States, Argentina, and Brazil produce 90% of the world's soybean exports. Note the high adoption in Brazil, despite the fact that glyphosate-resistant soybean is not legal in that country. (From <http://soystats.com>, accessed March 2003.)

Table 1 Partial list of herbicide-resistant crops obtained using molecular biology tools

Herbicide	Resistance mechanism	Crops
Bromoxynil	Herbicide detoxification	Cotton
Glufosinate	Herbicide detoxification	Corn, canola
Glyphosate	Altered herbicide target site	Cotton, corn, canola, soybean
Imidazolinones/sulfonylureas	Altered herbicide target site	Corn, canola, sunflower, wheat
Sethoxydim	Altered herbicide target site	Corn

MOLECULAR BIOLOGY APPLIED TO THE BIOLOGY, ECOLOGY, AND GENETICS OF WEEDS

Weed scientists have often wondered what the underlying mechanisms are that contribute to the success of weeds. Tools of molecular biology offer novel ways of approaching this question.

Tools to Study Genetic Diversity

It is often hypothesized that large genetic diversity in weed species allows them to survive and adapt to changing agroecosystems. In the past, phenotypic markers were used to measure such diversity. However, because such markers may be influenced by environmental conditions, they do not always reflect genetic diversity. Molecular markers are a significant improvement for the study of genetic diversity.^[5]

The first widely used molecular marker system used isozymes. Different versions of a particular enzyme can be separated by electrophoresis, due to different migration rates, and thus can provide a scoreable genetic marker. The discovery of restriction endonucleases (enzymes that cleave DNA) led to development of DNA markers based on restriction fragment length polymorphisms (RFLPs). The RFLP system detects genetic diversity based on the presence or absence of specific nucleotide sequences that are recognized by the restriction endonucleases.

Development of polymerase chain reaction (PCR) technology led to the improvement of DNA-based molecular markers into finer-scale genetic assessment techniques, such as amplified fragment length polymorphism (AFLP) and random amplified polymorphic DNA (RAPD). In general, AFLPs are based on the same principles as RFLPs, but with enhanced resolution provided by PCR amplification. RAPD markers rely on random amplification

of DNA by means of short, arbitrary primers. Other variants of these PCR-based techniques have been used to target extremely diverse regions of genomes constituted by tandemly repeated sequences. Genetic diversity can be examined at the finest possible level by comparing nucleotide sequence information (i.e., by direct DNA sequencing).

Application of Genetic Diversity Tools: Studying Gene Flow

Studies that explore the mechanisms by which genetic diversity is acquired gained new force with the use of molecular biology tools. In particular, molecular biology has been invaluable in research examining gene flow among populations of the same species and between different species. Interspecific gene flow has been studied between some crops and their weedy relatives and among weed species themselves.^[6] In most cases, gene flow has been studied in the context of herbicide resistance transmission. Hybrid intermediates between herbicide-susceptible and herbicide-resistant populations have been detected using a variety of molecular techniques. Such studies have made it possible to understand the significance of gene flow in the evolution of weed species. Furthermore, such studies are instrumental in predicting the risk that a herbicide-resistant crop may outcross with a weedy relative.

Gene Expression Profiling

Molecular biology can greatly facilitate understanding of how weeds respond to their environment, whether it be growing in competition with crops, surviving herbicide treatment, or initiating flowering after an early frost. In particular, a variety of techniques that can be loosely grouped in a category called gene expression profiling are ideally suited for such studies. The aim of gene expression profiling is to determine what genes are “turned on” or “turned off” in response to a particular treatment or environment. Results from such studies could provide insight at the molecular level as to how a weed responds to a particular treatment.

Modern gene expression profiling techniques (e.g., DNA microarrays) allow monitoring of thousands of genes simultaneously.^[7] Such so-called “genomics” analyses have been adopted recently with model organisms—including plants such as *Arabidopsis* and several crop species—but have seen scant use in weed science research. As this technology becomes more commonplace, it likely will be applied to several aspects of weed

science. Basic questions regarding biological phenomena important to weediness, such as induction of flowering, seed dormancy, and control of vegetative reproduction could be readily addressed with genomic techniques.

CONCLUSION

As illustrated by the foregoing examples, molecular biology research techniques provide many opportunities for advancements in weed science. In the future, molecular approaches will continue to provide new tools for managing weeds and will provide new information about the weeds themselves.

Molecular Evolution

Michael T. Clegg

University of California, Riverside, California, U.S.A.

INTRODUCTION

The field of molecular evolution combines the tools of chemistry and molecular biology with the theoretical constructs of population genetics and systematics. It borrows concepts and methods from many areas of science—including mathematics, statistics, computer science, systematics, molecular biology, genetics, and chemistry—in addressing questions about the evolution of molecules and the evolution of the organisms that possess and transmit those molecules. Molecular evolution has both static and dynamic dimensions, ranging from the study of phylogeny to the experimental investigation of novel catalytic RNA molecules in test-tube environments. Molecular evolution is a comparative science in which inferences are made from the analysis of molecular data sampled from different organisms or from different gene copies within a genome. At its broadest, the science of molecular evolution can be defined as the study of the processes that cause molecular change and the application of that knowledge to our understanding of the history of life on Earth.

The goal of this article is to provide a brief overview of the current state of knowledge of plant molecular evolution. It will also discuss several exemplar problems relevant to crop evolution. A number of excellent books have been published in recent years that provide a detailed treatment of various aspects of molecular evolution, and these should be consulted by readers who wish to study molecular evolution in greater depth.

PLANT GENOMES AND THEIR EVOLUTIONARY PATTERNS

Plants possess three genomes: a chloroplast genome (denoted cpDNA), a mitochondrial genome (denoted mtDNA), and a nuclear genome (denoted nDNA). Each of these genomes has different origins and different evolutionary dynamics. A few of the most important features of the evolution of these genomes will be described briefly in the following sections.

HOW THE ANCESTORS OF PLANTS LEARNED TO CAPTURE ENERGY THROUGH PHOTOSYNTHESIS

A number of convergent lines of evidence provide overwhelming support for the hypothesis that the cpDNA genome originated from an endosymbiotic association between a cyanobacterially like photosynthetic organism (a prokaryote) and an eukaryotic cell. Thus a prokaryote donated the capacity for photosynthesis to the eukaryotic lineage that ultimately evolved into algae and land plants. As the endosymbiotic association evolved it became an obligate relationship, and many genes were transferred from the prokaryotic genome of the endosymbiont to the genome of the eukaryotic host. This transfer process probably occurred over hundreds of millions of years and may still be ongoing.^[3] It represents one of the clearest and most massive cases of horizontal gene transfer in plant evolution. Phylogenetic analysis provides one of the most important lines of evidence for gene transfer, because it reveals that many nuclear-encoded components of photosynthesis are most closely related to cyanobacterial genes with the same (homologous) function.

The cpDNA molecule is conservative in size and in gene content. In land plants and green algae the cpDNA is a reduced molecule that averages about 150,000 base pairs (bp) in size and includes approximately 80 protein coding genes; 30 to 32 tRNA genes; and operons encoding the 16S, 23S, and 4.5S ribosomal RNA genes.^[4] This inventory reveals that the chloroplast has its own protein synthesizing machinery. However, many of the functional components of photosynthesis are nuclear-encoded, owing to the prior history of gene transfer to the nuclear genome, and these polypeptides must be imported into the chloroplast for photosynthetic competence. There is considerable evidence of gene transfer from the cpDNA into both nDNA and mtDNA, but evidence for gene transfer into the cpDNA is essentially absent.

The cpDNA molecule was the first genome to be studied in plant molecular biology and evolution because it was relatively easy to purify and it encoded a limited number of genes, thus facilitating molecular cloning and analysis. An important early discovery was a rate of

evolution for proteins encoded on the cpDNA molecule about five times slower than is typical for plant nuclear protein-coding genes. The significance of the conservative (slower) rate of evolution is that it allows the alignment and analysis of gene sequences that span much greater periods of evolutionary time. This discovery led to a major effort to construct land plant phylogenies based on cpDNA genes. The gene initially selected for this effort was *rbcL*. The *rbcL* gene encodes the large subunit of the enzyme ribulose-1, 5-bisphosphate carboxylase that fixes CO₂ in the carbon cycle. *rbcL* was the first cpDNA protein-coding gene to be cloned and sequenced, and thus it was a natural candidate for these early efforts.^[5] To date more than 2500 *rbcL* sequences are available from land plants, and these data provide an unprecedented picture of land plant phylogeny. An entire field of plant molecular systematics has grown up around the use of cpDNA (and more recently certain nuclear genes) to infer plant phylogenetic history.

ORIGINS OF THE PLANT MITOCHONDRIAL GENOME

The plant mitochondrial genome also owes its origins to an early endosymbiotic association. In this case the enzymatic machinery for oxidative phosphorylation was donated to the eukaryotic lineage by an α -proteo bacterial (prokaryotic) source prior to the separation of plant and animal lineages.^[6] Thus the evolutionary origins of the machinery that permitted the eukaryotic lineage to utilize oxygen and to adapt to an increasing partial pressure of oxygen in the atmosphere were also the result of a prokaryotic association. Many lines of evidence, including phylogenetic analysis, support this conclusion.

The plant mitochondrial genome reveals a strikingly different pattern of evolution when compared to either the chloroplast genome or animal mtDNA. First, the plant mtDNA exhibits a least a tenfold range in total DNA content (from 200,000 bp to 2,000,000 bp). Second, plant mtDNA appears to acquire and integrate DNA fragments from both cpDNA and nDNA sources, and this is thought to account for the large size variations. Third, plant mtDNA shows very high frequencies of genomic rearrangements, in contrast to remarkable stability for cpDNA. Fourth, protein-coding genes on the plant mtDNA are among the slowest-evolving genes characterized to date (roughly ten times slower than nDNA protein-coding genes). Fifth, the frequent loss of certain classes of genes from mtDNA is apparent over flowering plant evolution. And sixth, the mtDNA has repeatedly been invaded by a mobile element (group I intron) that appears to derive from a fungal source, providing clear documentation of

horizontal gene transfer in recent evolutionary time.^[7] So the general picture is one of great plasticity at the genomic level, but remarkable conservation at the gene level.

An important digression: It is remarkable that two of the major biochemical adaptations—photosynthesis and oxidative phosphorylation—that allowed eukaryotes to become dominant life forms on the terrestrial earth were acquired through endosymbiotic associations that each involved massive horizontal gene transfer to the eukaryotic nuclear genome. This history illustrates an important fact about evolution. Evolution is modular and occurs at several hierarchical levels. Molecular evolution is not simply the process of nucleotide substitution or the accumulation of individual amino acid substitutions in proteins over time. It is an open-ended process where genetic change can and does occur at all levels of organismal complexity. The analytical tools for studying the regular processes of nucleotide change allow us to infer time and to reconstruct history, albeit imperfectly. Inferences based on these tools tell us a rich story about the complexity of biological evolution. Perhaps the most important lesson is the hierarchical nature of genetic change.

EVOLUTION OF THE PLANT NUCLEAR GENOME

The eukaryotic nuclear genome is a mosaic of different histories. We have already seen that prokaryotic genes from both cyanobacterial and α -proteobacterial sources have been incorporated into nDNA. Very early in organismic evolution an association between eubacterial and archeobacterial cells appears to have arisen as an adaptation to oxygen poisoning. The eubacterium was motile and could avoid high oxygen concentrations while the archeobacterium provided an energy source in the form of sulfide. Ultimately the two genomes fused, and the nuclear envelope compartmentalized the integrated genome.^[8] So once again we are reminded of the great plasticity of genetic evolution in leading to novel life forms.

We are beginning to acquire a detailed picture of the genetic complexity of the plant nuclear genome as a result of the recent sequencing of the *Arabidopsis* genome.^[9] Moreover, a public version of the rice genome is now available. The ability to compare monocot (rice) and dicot (*Arabidopsis*) genomes should tell us much about the elaboration of gene function in the roughly 150 million years of angiosperm evolution. At the time of this writing our most comprehensive knowledge derives from analyses of the *Arabidopsis* genome sequence. A number of important facts have emerged from this project. First, many plant genes are present in multiple copies as a result of duplication over evolutionary time. Some of these gene

families have diversified and expanded so that they contain in excess of one hundred gene duplicates, as discussed below. Second, gene-rich and gene-poor regions characterize the chromosomes of *Arabidopsis*, so the distribution of coding information appears to be heterogeneous across plant genomes. Third, transposable elements are a ubiquitous feature of plant genomes.

Evolution of Plant Gene Families

Multiple related genes (gene families) encode many important metabolic and regulatory functions. Gene families originate through gene duplication and subsequent divergence in function or in developmental expression. An example of a gene family that encodes an enzyme important in plant secondary metabolism is chalcone synthase (CHS). The CHS enzyme catalyzes a condensation reaction that yields a 15-carbon three-ring structure that is the first committed step in flavonoid metabolism. The CHS gene family exists in multiple copies in most plant genomes studied to date. For example, in plants of the morning glory genus (*Ipomoea*) there are at least six copies. It is possible to study the evolution of these genes using the computational tools of bioinformatics, and these analyses reveal two distinct subfamilies that duplicated and diverged from one another very early in flowering plant evolution. One subfamily (comprising genes *chs D* and *E*) performs the chalcone condensation reaction, but the two genes have diverged in tissue-specific patterns of expression.^[10] The second subfamily (comprising genes *chs A*, *B*, *C* and a pseudogene) appears to have evolved a new catalytic function. This illustrates the fact that duplicate genes can provide a substrate for adaptive divergence by providing new developmental or metabolic capabilities to the plant.

The MYB family of transcriptional activators provides a second example that illustrates the very high levels of redundancy achieved by some plant gene families. MYB proteins are involved in DNA binding by a helix-turn-helix configuration. All known MYB proteins—including those found in plants and animals—have common structural features defined as the R1, R2, and R3 subdomains that are essential for the DNA binding function. The redundancy of MYB genes in plant genomes is much higher than observed in animal genomes. There appears to have been a proliferation of these genes that began early in land plant evolution so that more than 100 duplicate copies of MYB genes are found in the *Arabidopsis* genome. Analyses of the molecular evolution of this gene family reveal at least eight cases where rates of protein evolution accelerated following duplication events, as indicated by excess rates of amino acid change compared to synonymous change, suggesting positive

selection at the protein level. Moreover, it is possible to identify specific nucleotide sites where presumably adaptive amino acid substitutions have occurred. It appears that this family of transcriptional activators has proliferated through duplication and evolved through nucleotide substitution to meet a wide array of regulatory needs within plant genomes. The computational methods of molecular evolution provide a powerful approach to the identification of the precise amino acid changes that are adaptive.

APPLICATIONS IN THE STUDY OF PLANT EVOLUTION AND CROP IMPROVEMENT

Studies of Molecular Diversity

Application of the coalescent framework to samples of nucleotide sequence data are important in

- Screening loci for evidence of past selection
- Determining effective population sizes
- Evaluating general levels of genetic diversity
- Designing germplasm conservation programs
- Tracing the genetic correlates of crop domestication

A second question of importance concerns the structure of molecular diversity. In particular, it is of considerable practical utility to measure the effectiveness of recombination in randomizing different nucleotide sites on a chromosome as a function of physical or genetic distance. Put a different way, it is important to estimate a quantity known as linkage disequilibrium (LD) that measures the correlation in nucleotide state among pairs of nucleotide sites. This follows because correlations within or among genes may act to retard the operation of selection and thereby slow plant breeding progress. To see this, imagine a deleterious gene that is correlated in transmission with a selectively favored gene. The net effect, obviously is, to retard the increase of the favored gene or to slow the elimination of the deleterious gene. Finally, there is substantial contemporary interest in using single nucleotide polymorphisms (SNPs) as a tool for the genetic mapping of useful traits and for marker-assisted selection. This application requires that the marker SNP be correlated in transmission with the actual gene of interest.

There is a small but growing body of data on nucleotide sequence diversity in plants, most of which derives from the model plant *Arabidopsis*, although data increasingly are becoming available from crop plants such as maize and barley. Both *Arabidopsis* and barley are predominantly self-fertilizing plants, and population genetic theory predicts reduced levels of variation in inbreeding

plant species. Moreover, population genetic theory predicts high LD in inbreeding species. Both of these predictions follow from the fact that self-fertilization reduces heterozygosity by a factor of 50% per generation. A population is expected to be composed of a collection of homozygous lines very quickly. Effective recombination occurs only in heterozygotes, so inbreeding greatly reduces the effective rate of recombination—and this should promote higher levels of LD. The effective population size of self-fertilizing populations is half that of comparable random-mating populations, and selection is more effective among homozygous lines. Accordingly, we expect reduced levels of genetic diversity in self-fertilizing species. Current data are equivocal with regard to these two predictions. Levels of LD in *Arabidopsis* are high, but not as high as might be expected relative to, say, human populations.^[11] Preliminary evidence from barley also indicates only modest increases in LD relative to maize.^[12] Levels of genetic diversity are reduced in inbreeding species, and this generalization is well supported by massive isozyme data analyses.^[13] Nevertheless, most self-fertilizing species possess considerable stores of genetic variation and numerous experiments show that self-fertilizing species are able to respond to selection on virtually any phenotypic character.^[14]

Plant Relationships and Crop Origins

Molecular data are providing important insights into crop plant domestication. This topic is dealt with at greater length in other sections of this volume and will only be touched on here. One place where markers are especially helpful is unraveling the complex network of relationships associated with hybridization in plant domestication. To cite a single example, the cultivated avocado is a genetically diverse assemblage comprising three botanical varieties. Microsatellite markers provide a means of identifying the genetic origins of various cultivars, because many loci can be screened to provide an informative average picture of the genomic history of particular lineages. Work of this kind shows clearly that many popular cultivars are the result of intervarietal hybridization. In the longer term this kind of work should also provide clear evidence regarding the geographic origin of useful materials, and it should provide a helpful guide for genetic conservation.

CONCLUSION

Molecular evolutionary analyses have provided a rich picture of the evolution of plant genomes. This picture

begins with the very early endosymbiotic events that presumably led to the eukaryotic cell and continues to the later acquisition of the machinery for photosynthesis and oxidative phosphorylation. Along the way, gene redundancy is seen to have played a major role in the elaboration of biochemical and developmental novelty. An important lesson is thus gleaned: the recognition that molecular evolution has proceeded at several levels, including the level of protein evolution through nucleotide and amino acid substitution, the level of gene duplication, and the level of whole genome transfer events that have taken place several times in the long course of evolution.

INTRODUCTION

The large-scale production of recombinant proteins in plants is known as molecular farming. Plants have many advantages in terms of cost, practicality, and safety over traditional expression systems and are emerging as a significant force in the commercial sector. Providing adequate yields can be obtained, it is estimated that recombinant proteins can be produced in plants at 2–10% of the cost of microbial fermentation systems and at 0.1% of the cost of mammalian cell cultures/transgenic animals. Plants lack the endotoxins often produced by microbial cultures and, unlike animal cells, do not harbor human pathogens or oncogenic DNA sequences. Posttranslational modification occurs in a similar manner in plant and animal cells with only minor differences in glycan chain structure, which makes plants suitable for the production of complex human glycoproteins. Plants also have a number of unique practical advantages such as the high stability of proteins expressed in seeds and the ability to express pharmaceutical proteins in edible organs for oral administration with minimal processing.

PLANT-BASED EXPRESSION SYSTEMS

Transgenic Plants

In the vast majority of cases, molecular farming has been achieved by stable transformation and the regeneration of transgenic plants.^[1] Several crop species have been used as expression hosts, and the best choice for any particular protein must be determined on an empirical basis according to intrinsic properties of the plant (Table 1) and economic factors. This might include the value and intended use of the recombinant protein and the local

availability of labor, storage facilities, processing, and distribution infrastructure.^[2]

Tobacco has the longest history as a successful expression system for molecular farming and is one of the best candidates for the commercial production of recombinant proteins.^[2] The advantages of tobacco include the well-established technology for gene transfer and expression, the high biomass yield (over 100,000 kg per hectare for close-cropped tobacco), and the existence of large-scale infrastructure for processing. However, a major disadvantage of leafy crops is protein instability. The leaf tissue must be frozen or dried for transport or processed at the harvesting site. In contrast, seed-based expression allows long-term storage at ambient temperatures because the proteins accumulate in a stable form.^[2] Several different crops have been investigated for seed-based production, including the cereals rice, maize, and wheat. Prodigene Inc. chose to use maize for the first commercial molecular farming venture due to the combination of high biomass yield and the ease of *in vitro* manipulation; three technical proteins have been marketed successfully.^[3] Recombinant proteins have also been produced in fruit and vegetable crops, which are beneficial because the products can be expressed in edible organs for oral administration.^[4] Clinical trials have been carried out using vaccine candidates, antibodies, and enzymes expressed in leafy crops, seeds, and vegetables, and several companies have plant-derived pharmaceuticals in the late stages of clinical development.^[5]

Transgenic plants are the most cost-effective platform in molecular farming because crops can be established, maintained, harvested, and processed using traditional agricultural practices and existing infrastructure. However, a development phase of 18 months to two years is required to produce the first generation of transformants, and biosafety concerns that transgenes and their

Table 1 Comparison of major transgenic crops used for molecular farming of proteins

Crop	Preferred site of expression	Biomass yield (kg ha ⁻¹)	Storage	Stability	Other comments
<i>Dicots</i>					
Alfalfa	Leaf	14,400	Dried/frozen	Months	Feed
Canola	Seed	1,440	Ambient	>1 year	Dual purpose, oil body targeting
Pea	Seed	2,400	Ambient	>1 year	Food
Potato	Tuber	36,200	Chilled	Weeks	Food
Soybean	Seed	2,640	Ambient	>1 year	Feed
Tobacco	Leaf	>100,000	Dried/frozen	Months	Not food/feed
Tomato	Fruit	67,500	Chilled	Weeks	Palatable raw, requires glasshouse
<i>Monocots</i>					
Maize	Seed	8,880	Ambient	>1 year	Food
Rice	Seed	6,570	Ambient	>1 year	Food
Wheat	Seed	2,870	Ambient	>1 year	Food

products could spread in the environment are limiting public acceptance.^[6] This has prompted research into alternative plant-based technologies for recombinant protein production.

Transplastomic Plants

Chloroplast transformation is a useful alternative to nuclear transformation in molecular farming applications because there are many chloroplasts in the cell, resulting in a high transgene copy number in the transplastomic plants. This, together with the fact that chloroplast transgenes appear not to suffer from position effects or epigenetic transgene silencing, produces unprecedented levels of recombinant protein, in the best cases reaching nearly 50% total soluble protein.^[7] Disulfide bonds are formed correctly in chloroplast-derived recombinant proteins, but there is no glycosylation. In biosafety terms, transplastomic plants are advantageous because there are no plastids in the pollen grains of most crops, thus limiting gene flow by pollen dispersal. Chlorogen, Inc. was established in 2003 to commercialize the chloroplast transgenic system.

Transient Expression Systems

Transient expression assays are often used to evaluate the activity of expression constructs or test the functionality of recombinant proteins, but they can also be used as a routine molecular farming platform if moderate amounts of protein can be produced.^[8] This is possible using the agroinfiltration method, where recombinant *Agrobacterium tumefaciens* are infiltrated into tobacco leaf tissue and milligrams of protein can be produced within a few

weeks.^[9] The advantages of agroinfiltration include the minimal set-up costs and the rapid onset of protein expression, but scaling up is neither as economical nor as convenient as is the case with stably transformed plants.

Virus-Infected Plants

In addition to *Agrobacterium*-mediated transformation and direct DNA transfer, plant viruses can also be used as vectors to deliver foreign genes into plants.^[10] Although viral gene transfer does not result in stable transformation, the prolific replication and systemic spread of many plant viruses means that the onset of recombinant protein expression is rapid and the total yield is high, two features that are ideal for molecular farming. Thus far, viral vectors have not been widely used for molecular farming, perhaps because there is a limit to the amount of DNA that can be incorporated into such constructs. Tobacco mosaic virus (TMV) and potato virus X (PVX) vectors have both been used for the production of recombinant antibodies in tobacco, including scFv fragments and a full-sized IgG. In the latter case, two different TMV vectors containing the heavy and light immunoglobulin chain genes, respectively, were used to coinfect the plant, and correct assembly of the protein occurred in planta.

Plant Cell Suspension Cultures

The production of recombinant proteins in plant cell suspension cultures is an alternative approach that may be beneficial where defined and sterile production conditions and high-level containment are required, e.g., for the production of pharmaceuticals.^[11] Plant cell suspensions are normally derived from callus tissue that has been

cultivated on solid medium and then broken up by agitation on rotary shakers or in fermenters. Transformation may be achieved prior to the formation of cultures, in which case the cells already contain the transgene at the callus stage, or the cells can be transformed in culture. The latter procedure is advantageous because it is rapid and avoids the need to regenerate and characterize transgenic plants, so productive cell lines can be generated within a few months. Suspension cell cultures can be maintained in conventional microbial fermentation equipment with only minor technical modifications, and various different culture modes can be applied, including batch, fed-batch, perfusion, and continuous fermentation.^[12]

OPTIMIZING PRODUCTION OF ACTIVE RECOMBINANT PROTEINS

Maximizing the Rate of Transcription and Translation

The production of active recombinant proteins in plants can be optimized at each stage of gene expression.^[13] Generally, it is useful to use a strong and constitutive promoter to maximize the rate of transcription. The cauliflower mosaic virus 35S RNA promoter (CaMV 35S) is widely used in dicots, while the maize ubiquitin-1 promoter (*ubi-1*) is preferred in monocots. However, there are also advantages to the use of tissue-specific and inducible promoters. The use of seed-specific promoters, for example, prevents the accumulation of recombinant proteins in vegetative organs. This limits toxicity effects in the host plant and reduces the likelihood that herbivores and other non-target organisms will be exposed to the protein. Similarly, inducible promoters activated by chemicals such as tetracycline or by mechanical stimuli can be used to initiate protein accumulation prior to or even after harvest.

The rate of protein synthesis can be optimized by eliminating native 5' and 3' untranslated regions from the foreign gene and replacing these with elements that increase mRNA stability and enhance translational efficiency, such as the 5' leader sequence of the tobacco mosaic virus RNA (the omega sequence). It is also useful to change the translational start site of the expression construct to conform to the Kozak consensus for plants. For some transgenes, it may be necessary to modify the coding region to match the codon usage preferences of the expression host.

Protein Targeting and Modification

Subcellular targeting influences protein stability (thus affecting the yield), determines the type of modification

that takes place (thus affecting protein structure and activity), and can be exploited to simplify downstream processing (e.g., by including affinity tags or fusions). Targeting to the secretory pathway is beneficial, especially if the protein is normally glycosylated since this modification takes place in the endoplasmic reticulum (ER) and Golgi apparatus. The environment of the ER also promotes correct protein folding and thus increases stability. This has been demonstrated in the case of recombinant antibodies, which accumulate in the secretory pathway at levels up to 100-fold greater than in the cytosol.^[14] Targeting to the secretory pathway is achieved by incorporating an N-terminal signal sequence into the expression construct that directs the ribosome to signal receptors on the endoplasmic reticulum. The default destination of proteins targeted to the secretory pathway in plants is the apoplastic space under the cell wall, where they may be retained or secreted depending on their size. Still higher protein levels can be achieved by adding a C-terminal H/KDEL sequence, which causes the recombinant protein to be retrieved from the Golgi and returned to the ER lumen, in the manner of a resident ER protein.^[15]

CONCLUSION

Plants have practical and economical advantages over traditional expression systems, making them suitable for the large-scale production of recombinant proteins. Technological issues that remain to be addressed include the optimization of yields, the modification of glycan structures, and improved biosafety. In order to be commercially viable, plants must produce a target protein at a level exceeding 1% total soluble protein. This has been possible for many proteins, but some unstable proteins tend to accumulate at a level of 0.01–0.1%, often reflecting incorrect folding, assembly, or degradation during extraction. Biosafety issues remain at the forefront of current molecular farming research. Such issues include the development of novel ways to prevent transgene spread, to restrict unnecessary exposure of non-target animals and microbes to transgenes and their products, and to prevent transgenic plant material mixing with the food and feed chains.

Molecular Integrated Cytogenetic Mapping

Jiming Jiang

University of Wisconsin-Madison, Madison, Wisconsin, U.S.A.

INTRODUCTION

Traditional cytogenetic mapping relied on aneuploids, which are often difficult to develop and maintain. Common wheat (*Triticum aestivum*, $2n = 6x = 42$) has long been the classical model for cytogenetic mapping mainly because of its amenability to aneuploidy. Another critical component of cytogenetic mapping is the identification of individual chromosomes in a plant species. Unfortunately, identification of individual chromosomes was impossible in the majority, if not all, of plant species before the modern chromosome banding and DNA in situ hybridization techniques became available. Therefore traditional cytogenetic mapping went through a technically difficult stage with slow progress. The development of molecular marker technologies and fluorescence in situ hybridization (FISH) techniques have dramatically enhanced the power and efficiency of cytogenetic mapping. Because of these new techniques, aneuploids and other cytogenetic stocks can also be more effectively used in cytogenetic mapping.

CHROMOSOME IDENTIFICATION USING MOLECULAR CYTOGENETIC DNA MARKERS

Cytogenetic mapping requires reliable and easy-to-use techniques for chromosome identification. Unfortunately, chromosome identification is a major challenge in many plant species, especially those with large numbers of small chromosomes. Meiotic pachytene chromosomes are significantly longer and provide more cytological features than somatic metaphase chromosomes for chromosome identification. Cytogenetic mapping based on pachytene chromosomes was especially successful in maize,^[1] tomato,^[2] and rice.^[3] However, pachytene chromosome preparation can only be applied in species with relatively few and small chromosomes. Chromosome identification based on banding analysis has been reported in many plant species. However, the banding techniques are practically useful and can only be routinely used in cytogenetic mapping of few plant species.

The most versatile and promising new chromosome identification technique is the application of chromosome-specific cytogenetic DNA markers (CSCDMs).^[4] This

methodology identifies chromosomes based on hybridization signals derived from DNA markers that are specific to individual chromosomes in a plant species. CSCDMs can be isolated by screening large-insert genomic DNA libraries with DNA probes that have been mapped to individual linkage groups. CSCDMs were successfully developed in potato and sorghum by screening bacterial artificial chromosome (BAC) libraries.^[4,5] Additionally, repetitive DNA elements that hybridize to one or few chromosomes can also be used as CSCDMs.^[6,7]

The CSCDM-based chromosome identification system has several advantages compared to the traditional pachytene and banding analyses. First, this method is straightforward and each chromosome can be readily distinguished from the rest of the chromosome complement, while it is difficult to distinguish chromosomes with a similar morphology or banding pattern by pachytene or banding analysis. Thus the CSCDM-based approach is particularly effective for analyzing the mitotic and meiotic behavior of a particular chromosome.^[6] Second, the quality of the chromosome preparations is not important for chromosome identification using CSCDMs, while the quality of chromosome spreads is critical to the success of banding and pachytene chromosome analysis. Third, the CSCDM-based approach can be applied in any plant species with small or large chromosomes. Pachytene analysis and chromosome-banding techniques can be used only in certain plant species. Fourth, the chromosome identified by a CSCDM can be correlated directly with a specific linkage group.

CYTOGENETIC MAPPING USING FISH

FISH has become the most popular technique to map DNA sequences directly onto plant chromosomes.^[8,9] Compared to other physical mapping techniques, FISH is a quick and relatively affordable approach. FISH can be applied to a variety of cytological targets. Commonly used cytological targets for FISH mapping include mitotic metaphase chromosomes, meiotic pachytene chromosomes, and extended DNA fibers.

Somatic metaphase chromosomes are the most popular cytological targets for FISH mapping mainly because mitotic tissues are readily available and mitotic

chromosomes are relatively easy to prepare. However, the highly condensed metaphase or prometaphase chromosomes are difficult to distinguish and provide a low resolution for the purposes of mapping. Pedersen and Linde-Laursen^[10] suggested that a minimum of 5–10 Mb would be necessary to resolve DNA clones on barley metaphase chromosomes. Cheng et al.^[11] recently demonstrated that at prometaphase, the majority of the signals derived from two BAC clones separated by less than 1 Mb overlapped completely on the distal euchromatic region on the long arm of rice chromosome 10. It was suggested that the minimum physical distance required to resolve two DNA clones will be substantially larger than 1 Mb in the proximal regions of prometaphase chromosomes and in the more condensed metaphase chromosomes.^[11] Despite its low resolution, the mitotic metaphase chromosome-based FISH mapping is an easy and quick approach to determine the chromosomal location of targeted DNA probes.

The meiotic pachytene chromosomes are usually 10–20 times longer than somatic metaphase chromosomes. Thus the highly extended pachytene chromosomes provide a superior resolution for FISH mapping. The resolution of pachytene FISH depends on early or late stages of individual pachytene cells, as well as the locations of the targeted DNA clones in the heterochromatic or euchromatic regions.^[9,11,12] In rice, even partially overlapped BAC clones can be resolved on early pachytene chromosomes.^[11] Pachytene FISH mapping also allows DNA probes to be mapped to specific euchromatic or heterochromatic regions. Pachytene FISH mapping of BACs anchored by genetically mapped DNA markers has become a powerful method to integrate genetic and cytological maps.^[12,13]

FISH can be applied on extended DNA fibers. The correlation between the microscopic size of the fiber-FISH signals and the physical length of the extended DNA molecules ranged from 2.87 to 3.27 kb/ μm from different reports.^[11,14,15] DNA probes as small as few hundreds of base pairs can be used in fiber-FISH mapping.^[14] Fiber-FISH can be used not only in fine mapping^[11,15] but also in the analysis of repetitive DNA sequence structure^[14] and complex DNA molecules.^[16–18]

MOLECULAR MAPPING USING CYTOGENETIC STOCKS

Development of genetic linkage maps has become routine in plants because of the advances of molecular marker technologies. However, it is a challenge to integrate genetic linkage maps with specific chromosomes. The genetic linkage maps developed in the majority of the plant species are currently not integrated with cytogenetic maps. Aneuploids are valuable tools to integrate genetic

linkage maps with chromosomes. A DNA marker can be assigned to a specific chromosome by comparing its hybridization intensity to a series of monosomic or trisomic lines.^[19,20] The locations of the centromeres in the genetic linkage maps can be determined using telotrisomics or secondary trisomics.^[21]

Mapping of cytogenetic stocks using genetically mapped DNA markers is a powerful approach to develop physical maps in plant species. The physical maps developed using this approach are fully integrated with genetic linkage maps. Weber and Helentjaris^[22] were the first to demonstrate such a physical mapping strategy in maize. Using B–A translocation stocks, Weber and Helentjaris^[22] mapped RFLP markers to specific maize chromosome arms and identified the chromosomal regions containing the centromeres. Using a similar strategy, Künzel et al.^[23] developed physical maps in barley using translocation stocks.

Chromosomal deletion stocks were developed in wheat using the “gametocidal function” of an *Aegilops cylindrica* chromosome.^[24] Most of the wheat deletion stocks lost only a terminal segment in one of the 21 chromosomes. Thus DNA markers located within the lost chromosomal segment can be readily determined using DNA blot hybridization. This “deletion mapping” strategy powerfully revealed the discrepancy between genetic and physical distances in a large complex genome.^[25] Deletion mapping also led to the discoveries of recombination hot spots and chromosomal regions with high density of genes in wheat.^[26,27]

“Radiation hybrid mapping” is another physical mapping strategy based on cytological stocks. Individual maize chromosomes have been transferred into the genetic background of oat.^[28] Irradiation treatment of the oat-maize chromosome addition lines resulted in radiation hybrids, oat lines possessing different fragments of the maize chromosomes including oat-maize translocation chromosomes and modified maize chromosomes with internal or terminal deletions.^[29] Radiation hybrid mapping is strategically similar to deletion mapping and a DNA marker can be located to a specific chromosomal region based on the presence or the absence of this marker in a specific radiation hybrid.

CONCLUSION

Molecular cytogenetic mapping, which integrates molecular techniques into traditional cytogenetic mapping methods, has become an important genetic mapping methodology. With the molecular cytogenetic mapping approach it is now possible to identify and map individual chromosomes in virtually any plant species. More importantly, aneuploids and other cytogenetic stocks can now be more effectively used in genetic mapping.

Molecular Technologies and Their Role in Maintaining and Utilizing Genetic Resources

Amanda J. Garris
Alexandra M. Casa
Stephen Kresovich

Cornell University, Ithaca, New York, U.S.A.

INTRODUCTION

In the broadest sense, the goal of conservation activities is the preservation of diversity at ecosystem, community, and species levels. Conservation of plant genetic resources, with its focus on diversity within crops and their wild relatives, differs in that it is inextricably linked to a mandate for utilization. Perhaps the greatest challenge lies in identification of useful variation not readily assessed at the phenotypic level, due to the complexity of the trait or the masking effects of environment and genetic background. Exploitation of variation in collections has been achieved primarily through phenotypic screens and back-crossing strategies; however, molecular markers may serve to expedite the identification of useful alleles. It is not the scope of this article to provide a detailed description of molecular techniques, but rather to offer some insights on how understanding the structure of diversity allows the generation of data simultaneously useful for both conservation and use, enabling us to dissect gene function and consequently assess the predictive value of diversity for crop improvement.

CLASSES OF MOLECULAR MARKERS

Although morphological and biochemical markers (i.e., isozymes) still play an important role in understanding diversity, their low abundance and unknown selective neutrality have created a need for more specific DNA-based methodologies for characterizing genetic resources. In addition, the growing number of accessions present in germplasm banks has required faster and more cost-effective methodologies for understanding diversity and directing conservation efforts. Among the most widely used classes of molecular markers for germplasm characterization are restriction fragment length polymorphisms (RFLPs), randomly amplified polymorphic DNAs (RAPDs), amplified fragment length polymorphism (AFLPs), simple sequence repeats (SSRs), and more recently DNA sequence polymorphism.^[1] The choice of a

marker technique will depend on several factors, including what is already known about the species (e.g., mating system and life form), the kinds of questions that are being addressed (e.g., levels of genetic diversity and distribution of variation), and infrastructure (i.e., amount of equipment required, start-up cost, and labor).

Molecular markers have been applied to most crop species in order to characterize the diversity present in nature, in farmers' fields as well as in situ and ex situ collections. These data provide a means to quantify the level of diversity and how it is partitioned within a species, enabling conservation strategies that maximize diversity within collections through reduction of redundancy and identification of unique alleles.^[2] Applications include characterization of crop gene pools, identification of parentage, and selection of a representative core collection.^[3] Much emphasis has been given to the characterization of genetic resources; however, retention of diversity in collections requires effective maintenance strategies. Molecular markers provide a quantitative assessment of the level of diversity and can be used to monitor change over time in collections. In addition, they can provide a basis for setting priorities for additions to collections when used in concert with geographical information system (GIS), which could incorporate agroecological characteristics of collection sites and genetic diversity data to target potentially useful populations.^[4]

APPLICATION OF MOLECULAR MARKERS TO UTILIZATION OF GENETIC RESOURCES

Molecular markers, although widespread, have yielded few examples of successful identification of variation that can be exploited in breeding programs. However, population genetics approaches for identifying adaptive variation developed for noncrop species when applied to genetic resources collections may expedite the identification of useful alleles. Generally, these approaches interpret patterns of molecular diversity to evaluate evidence for a causative role in a phenotype, to identify genes for

adaptation, or to predict phenotypic value. The discussion that follows highlights some approaches that use molecular diversity to identify genes of interest that could be utilized in genetic resources collections.

One promising approach is based on association genetics, in which the statistical association of sequence polymorphisms with a phenotype is evaluated. Developed for use in human genetics, association genetics has been successfully applied in maize. For example, a suite of polymorphisms in the *Dwarf8* gene was found to associate with variation in flowering time.^[5] The application of statistical analysis to the pattern of DNA polymorphism forged the link between molecular and phenotypic diversity in the case of this quantitative trait.

Another approach is to use patterns of molecular diversity to identify genes that have been targets of selection. Natural selection is expected to reduce diversity at a locus; this reduction in diversity is detectable in comparisons to an outgroup that has not been subject to the same selective pressure. Reduced diversity at SSR loci in maize relative to its wild relative teosinte has been used to identify candidate genes involved in domestication.^[6] This approach could be modified to find targets of selection for adaptive traits by comparison of adapted germplasm within a crop. A complementary approach is to identify rapidly evolving genes underlying adaptive variation by their molecular diversity. The approach involves the screening of expressed sequence tags (ESTs) to identify those that have diversified compared to homologues in closely related species. In *Drosophila melanogaster*, this method has been used to identify putative targets of adaptive evolution.^[7]

As the structural and active domains of proteins are better understood, it should facilitate *in silico* allele mining in genetic resources collections via analysis of which changes in DNA sequence will effect functional changes in the protein. This is a computational approach akin to reverse genetics, but uses naturally occurring variation in lieu of disruptions to form predictions about gene function. For example, a collection could be screened with primers to amplify the active region in a disease resistance gene to identify as candidates for further study variants that change the protein sequence.

LIMITATIONS

Although the application of molecular markers holds promise for genetic resources conservation and use, a few caveats should be noted. The methods outlined previously require substantial preliminary data on population structure and appropriate sampling. Patterns of diversity can be

influenced not only by selection; the influence of population structure, linkage, and drift must be understood in order to correctly interpret results. Although these approaches can identify interesting candidate genes, functional studies will be required to establish causation. A greater limitation is that some differences that affect phenotype are not coded in DNA, including such phenomena as epigenetics and differential splicing of RNA transcripts. In addition, the importance of regulatory elements in plant evolution has been demonstrated, indicating that not only structural but regulatory genes will be important in conservation and breeding.^[8]

CONCLUSION

Molecular markers have the potential to build the link between DNA sequence and phenotype, facilitating conservation and use as well as the link between them. Increased access to these technologies, in concert with improved computational methods for analysis, will make molecular techniques both more common and more useful in maintaining and utilizing genetic resources. In the future, important and challenging questions will not be restrained by the lack of appropriate tools, and the allelic diversity in crop collections can be implemented in crop improvement.

Mutational Processes

Michael T. Clegg

Peter L. Morrell

University of California, Riverside, California, U.S.A.

INTRODUCTION

Mutation is a permanent heritable change in the DNA of an individual organism. It is the ultimate source of all the biological diversity on earth. Life could not adapt and diversify without the substrate of heritable variation. In agriculture the exploitation of novel heritable variants has been the engine of plant and animal improvement. This article outlines the mechanisms that are responsible for heritable changes in DNA.

NUCLEOTIDE SUBSTITUTION EVENTS

Many different categories of mutation affect DNA molecules. The most regular form of mutational change is when one nucleotide is incorrectly replaced by a different nucleotide during replication (Fig. 1). These nucleotide substitutions are assumed to be stochastically regular in time. (Like radioactive decay, each mutation is assumed to arrive randomly, but with a constant probability in time.) Nucleotide substitution events are also assumed to occur with the same probability at every nucleotide site, independent of the nucleotide state at the mutated site or at neighboring sites. Much of our direct knowledge of the nucleotide substitution processes comes from the study of bacteria or viruses where many generations and very large populations of organisms can be studied in the laboratory. These studies indicate that the DNA replication process has a remarkably high fidelity, with a nucleotide substitution error rate on the order of one error per one billion replications per site (or 10^{-9} errors per site per generation).^[1] These studies have also tended to validate the assumptions of constancy and independence previously mentioned. Estimates for eukaryotic organisms like crop plants and animals cannot be obtained from direct observation and must be calculated indirectly. Indirect calculations are based on comparisons between homologous gene sequences separated for some period of evolutionary time. Statistical models of the substitution process must be invoked, together with various assumptions about the absence of natural selection, to arrive at estimates of mutation rates. Nevertheless, indirect estimates from, for example, large numbers of mammalian genes are consistent

with those from bacteria, indicating an average nucleotide substitution rate of roughly 4×10^{-9} per site per generation.^[1]

INSERTION/DELETION EVENTS

Another major category of mutation is the insertion or deletion of stretches of DNA (indels). Indels are most frequently observed in areas of untranslated DNA (DNA that does not code for a protein). Much of the genome of eukaryotic organisms is made up of untranslated regions, so on a genomic scale, a substantial fraction of mutation events are likely to be indels. Indels arise from a number of causes, including slipped-strand-mispairing in replication, unequal crossover events, or transposable element insertions. In some cases indels have been shown to depend on local nucleotide context, so the assumption of independence over DNA region cannot be invoked.^[2] Moreover, the assumption of stochastic regularity in time is also of questionable validity, at least for some forms of transposable element insertions. Finally, the alignment of indels is difficult when sequences have diverged for a substantial length of time, because overlapping events cannot be distinguished. All of these factors severely limit our ability to use mathematical models and to make statistical calculations based on indel data.

Slipped-Strand Mispairing

Despite the fact that slipped-strand mispairing events are context-dependent and are usually inferred indirectly rather than observed, it is desirable to get some sense of the rate at which these kinds of events accumulate. The effects of replication slippage or slipped-strand mispairing generally cannot be observed directly and must be inferred based on the distribution of repetitive nucleotide sequence or base composition surrounding indels (Fig. 2). Estimates from *Drosophila* nucleotide sequence data suggested approximately 0.16 indels per nucleotide substitution.^[3,4] Estimates based on chloroplast data from grasses suggested that indels and nucleotide substitutions contributed nearly equal proportions of total mutations; however, the authors point out that the relative contribution of indels

```

GACACGCCG
GGCACCCC

```

Fig. 1 An alignment of DNA sequence data. Three nucleotide substitutions are underlined.

appears to diminish among more highly diverged species because of apparent superimposition of indels on previous indels.^[5] Slipped-strand mispairing appears to play a major role in indel generation, and may be particularly important in the proliferation of repetitive sequences, such as the short two- and three-base motifs that make up microsatellites.^[6]

Unequal Crossover Events

At tandemly repeated genes there is potential for out-of-register recombination, which can result in duplication, deletion, or truncation of a chromosomal region. Such events may be especially common in tandemly repeated arrays of genes such as nuclear ribosomal DNA.

The Interaction Between Mutation and Recombination

Genetic recombination is the process that disassociates mutations along a chromosome, typically through cross over—the breaking and reannealing of homologous portions of parental chromosomes during meiosis. A second form of recombinational exchange is commonly observed between different tandemly repeated gene family members. When such an exchange occurs, a mutant site on one repeated gene copy is transmitted to an adjacent gene copy, causing the repeated copies to become more similar in sequence than would otherwise be the case. This process is called concerted evolution. A related form of recombinational exchange that generates new alleles is observed in microsatellite loci where unequal exchange between tandemly arranged di- or trinucleotide repeats (or higher-order repeats) causes an increase or decrease in repeat number. Finally, unequal exchanges between repeated elements at different chromosomal locations can cause duplications and deficiencies of larger DNA regions.

TRANSPOSON-INDUCED MUTATIONS

Mobile elements (transposons) are a ubiquitous feature of plant and animal genomes. There are two broad categories of mobile elements: class I elements that replicate from an RNA intermediate via reverse transcriptase, and

class II or DNA elements that replicate via a cut-and-paste mechanism. Both classes of elements are relatively common in plant and animal genomes. Class II elements tend to be associated with elevated transposition rates, but both categories are clearly implicated as causal agents in many mutations, owing to their ability to insert into or adjacent to genes, and thereby disrupt or alter gene function or gene expression.

One important aspect of transposon-mediated mutation is the ability to alter gene expression patterns. This may occur because the element has inserted into a 5' UTR (untranslated region in the 5' region of a gene) and has thereby disrupted transcription factor-binding sequence motifs, or it may occur because sequence motifs within the insertion act as novel sites for transcription factor binding. This latter capacity has been documented in a number of cases in plants and animals, and illustrates the creative acquisition of new gene expression patterns through the transposition of appropriate sequence features around the genome. The fact that transposable elements can move entire sequence motifs into new genic environments and induce novel patterns of expression tells us transposon mutation is modular and acts at a level beyond the individual nucleotide site.

GENE DUPLICATION

One of the important discoveries of the genomics era is the fact that many genes are redundant in plant and animal

genomes. The processes that lead to the duplication of genes range from polyploidy (the doubling of entire genomes owing to the union of unreduced gametes, discussed next), to unequal crossover, to transposon-mediated transposition of genes. There are very few estimates of rates of gene duplication, but one recent estimate suggests a duplication rate of 0.01 per gene per million years.^[7]

Transposons are also implicated in the movement of genes or fragments of genes around the genome. This may occur as a consequence of reverse transcription of mRNA molecules or because a gene or gene fragment has been acquired within a mobile element. In either case it represents a kind of higher-level mutation that may provide adaptive flexibility by placing genes into new regions, possibly in association with entirely different expression signals.

POLYPLOIDY

In addition to gene duplication, polyploid formation can potentially induce or accelerate many of the mutational processes outlined in the foregoing discussion. Polyploidy is very common in flowering plants. Crop plants with polyploid origins include bananas, cotton, peanut, and wheat. In addition to extant polyploids, evidence of one or more rounds of ancient polyploid formation have been identified in species such as *Arabidopsis*^[8,9] and maize.^[10] Some of the ancient polyploid events appear to have occurred in lineages ancestral to the majority of flowering plants.^[8,9]

Polyploids are frequently the result of hybridization between well differentiated parental species. Thus, there is a potential for recombination, gene-conversion, and concerted evolution to occur between partially homologous chromosomes from the parental species. Transposons from one parental genome may also invade the genome of the other; with gene duplication, there is the potential for loss of duplicate gene function or even the elimination of coding DNA sequence.^[11]

CONCLUSION

Agriculture developed and flourished because humans learned how to exploit and maintain useful hereditary variants in a wide diversity of plant and animal species. Since the rediscovery of Mendelian genetics, a major research goal has been the acquisition of a detailed understanding of the mechanisms that generate hereditary var-

iation. Our knowledge of the mutational process has grown enormously in recent years, revealing that mutation is a complex phenomenon with many mechanisms. One important lesson has been that mutation operates at various levels, ranging from nucleotide changes to transposition to gene duplication to the doubling of entire genomes. This rich variety of biological process has led to the wealth of mutational diversity that we seek to exploit in adapting plants and animals to human needs.

Mutualisms in Plant–Insect Interactions

W. P. Stephen

Oregon State University, Corvallis, Oregon, U.S.A.

INTRODUCTION

Mutualisms are coevolutionary processes between pairs of organisms that impart joint benefits in the form of increased growth, reproduction, and survival. The relationship between the participants has evolved because the benefits gained are greater than the costs expended.

Mutualisms range from those which are “facultative,” in which each member gains a benefit but is not dependent upon the other, to “obligate,” in which one or both members is dependent upon the other for survival.

POLLINATION

Pollination involves the transfer of pollen from the anthers of one flower to the stigma of the same or a different flower. Nowhere is mutualism and coevolution more prevalent than in plant–pollinator interactions, and among pollinators insects reign supreme.

Flowers requiring insect pollination provide an abundance of nectar and/or pollen on a platform both visually and aromatically unique and attractive. Coevolution between flowers and insects—especially the bees—proceeded at a rapid pace, resulting in increased specialization in flowers to emphasize their identity and the concomitant specialization of pollinators to excel in their efficient utilization of that specialized resource. Although there are a number of insect groups other than bees that effect pollination (beetles, wasps, moths, flies, etc.) it is the bees which are most adept and abundant.

There are over 16,000 species and subspecies of bees in over 1200 genera worldwide, of which approximately 10% are social and 80% solitary. The social bees—*Apis mellifera*, *Bombus* spp., and the stingless bees—exist as long-lived colonies that have life spans which may endure for years, rather than weeks. Although workers in each colony utilize a wide array of pollen sources, individual pollen gatherers usually confine their activities to collecting pollen from one plant source during any single foraging trip and remaining faithful to that source as long as supplies exist. This transient specificity has probably arisen because of the mutual benefits it conveys to both plant and pollinator: The plant benefits from cross-pollination by bees bearing conspecific pollens, and the bees

increase their efficiency in host location and pollen/nectar collection through the associative learning.

Few solitary bee species do not exhibit some degree of specificity to a particular genus or genus-group of plants. Relationships between partners, however, can be judged only by the fidelity shown by a specific pollinator in its pollen collection, for it is this behavior which defines the reproductive continuity of its plant host. Unlike social bees, solitary bees provision their cells with nectar-moistened pollen, and none amass nectar surpluses.

Coevolution between bees and their plant hosts has resulted in varying degrees of pollen collection specificity: *polylecty* (pollen is collected from many diverse plant hosts); *oligolecty* (pollen is limited to groups of related plant hosts); and *monolecty* (pollen is from a single plant species). These terms are relative for intermediate conditions are always found in evolutionary processes, yet they provide guidance.

Adaptations to their floral hosts have occurred in many of the oligolectic bees. In the genus *Diadasia* (Anthophoridae) the hairs of the tibial scopa (areas evolved to transport pollen from floral hosts to nests) have undergone considerable modification to accommodate the various-sized pollen grains of their hosts. Most *Diadasia* that forage on Malvaceae have modestly branched scopal hairs, whereas *D. enevata*, an oligolecte on composites, has fine, densely plumose hairs to transport the small pollen grains common to that family. *D. angusticeps* is the only species of this genus found on Onagraceae, and its tibial scopae comprise stiff, nonplumose hairs that carry the cobweb-like pollen masses of the host. Unrelated genera such as *Anthedonia*, *Diandrena*, and *Anthophora* have species which are oligolectic on *Oenothera*, and all possess sparse, simple, scopal hairs to accommodate the large *Oenothera* pollen with its interconnected viscid threads. *Proteriades* has hooked hairs on its mouthparts (maxillae) used to extract pollen grains from the small, slender corolla tubes of *Cryptantha*. Similarly, the foretarsi of *Calliopsis* (*Verbenapis*) have a series of curled bristles on their forelegs which can be inserted into the flowers of *Verbena* to scrape out the pollen and insert it on the regular pollen-carrying apparatus.^[1,2]

A number of obligate plant–bee associations exist. *Duforea versatilis* has been found only on flowers of *Mimulus nanus*, *Anthemurgus passiflorae* on *Passiflora lutea*, and *Diadasia australis* appears to collect both pollen and

nectar from *Opuntia*, rarely visiting other plants—even for nectar.

The foraging period of oligolectic bees is coadapted to the restricted flowering periods of their pollen hosts. Different species of the same bee genus may appear sequentially throughout the summer, utilizing entirely different pollen sources. In northern Utah, *Anthophora pacifica* appears in April and early May on *Astragalus* and stone fruits; *A. bombooides neomexicana* is on *Trifolium*, *Medicago*, and *Vicia* in June; *A. occidentalis* is on *Cirsium* in July; and *A. flexipes* is on late-summer composites in August.

Some species remain dormant for two or more years if the environmental conditions are unfavorable for either plant or insect activity. In 1961 a large nesting population of *Halictus (Evylaeus) aberrans* failed to appear when their obligate host, *Oenothera latifolia*, failed to germinate. In 1962 *Oenothera* bloomed profusely and the bee was again present. It is not uncommon for a small number of diapausing prepupae of megachilid bees (*Osmia*, *Megachile*) to emerge during the second rather than the first year in that stage.

Bees with matinal (collect pollen in early morning prior to or at sunrise), crepuscular (collect pollen at dusk), or nocturnal (fly and forage at night) activities have adapted to meet the pollination requirements of their floral hosts. *Xenoglossa* collect pollen from *Cucurbita* at dawn; *Pepoapis* work the same flowers in the early sunlight hours; and polyleges such as *Apis* and *Agapostemon* collect pollen until the flowers close. *Halictus (Hemihalictus) lustrans* is a matinal oligolectic on *Pyrrhopappus carolinianus*, the flowers of which close shortly after the sun strikes them in early morning.

Halictus (Sphecodogastra) are common crepuscular bees, foraging on *Oenothera* in the early and late evening. The Indo-Maylasiian subgenus *Xylocopa (Nyctometta)* forages much, if not most, of the night on nocturnal blooming plants.

The most remarkable diversity in flower form (paralleled with the obligate pollinators) is found among the orchids.^[3,4] This highly evolved plant group exhibits the most complex and precise adaptations to their pollinator partners of any plant group. Unlike most obligate cross-pollinated plants which rely largely on pollen-collecting females of various bee genera, the pollinating partners of orchids include wasps, beetles, fungus gnats, flies, moths, butterflies, and both males and females of solitary and social bees. The genome flexibility of orchids, especially in the tropical flora, has given rise to the speculation that many of the tight mutualistic associations may be more serendipitous than coevolutionary, or a combination thereof.

The single most complex mutualistic pollination relationship occurs in the fig (*Ficus* spp.) and its pollinator,

the wasp, *Blastophaga* spp. (each species of fig has its own species of wasp).^[4] There are three types of saclike flower clusters in the fig, each consisting of numerous flowers on a fleshy receptacle. In the spring the first small structures develop, with male flowers located near the entrance and short-styled female flowers near the base. Spring females enter the flower and lay eggs in the ovules that develop into gall-like structures containing either females or wingless males. Males chew out of their galls and enter galls containing females. Upon mating the females leave the gall and become laden with pollen as they pass the male flowers at the fruit entrance. Females then move to the second receptacle type (the true fig), enter, and attempt to—but cannot—oviposit in the long-styled flowers characteristic of this stage. In the process the females pollinate enough of the flowers to yield the mature fruit. A third type of fruit cluster (mother fig), which contains only short-style flowers into which the females oviposit, then develops on the tree. These develop into males and females, which enter diapause and emerge the following spring. In this system the wasp is not only the obligate pollinator, but also a parasite.

A unique obligate relationship exists between plants of the genus *Yucca* and *Tegeticula* moths. Adult yucca moths form the sticky pollen into a small pellet carried in modified mouthparts to the stigma of another yucca flower. Upon deposition of the pellet, the female deposits one to several eggs on the ovary. These hatch and the larvae burrow into the ovary to feed on the developing seeds. The plant tolerates the seed loss in return for pollination services from the adults. The moth consistently limits the number of deposited eggs per ovary and in so doing avoids exploiting its partner and throwing the system into imbalance. Early fruit abortion is a principal cause of yucca moth larval mortality, and it has been suggested that the quality and quantity of pollen provided by the moth are below that necessary for high fruit retention, also helping to promote evolutionary stability in the system.^[5]

PROTECTION

A landmark study on the obligate mutualistic relationship between the ant, *Pseudomyrmex ferruginea*, and the bull's-horn acacia, *Acacia cornigera*, was described from Central America.^[6] The ant provides protection to the plant and the plant, in turn, offers food and nesting sites. Queens of *Pseudomyrmex* bore holes through the hard covers at the thorn bases, excavate some of the pith, and establish their colonies. The colonies grow, occupying increasing numbers of thorns and often reaching populations of several thousand per tree. The ants provide defense against insect defoliators and clip off the vegetative

Fig. 1 Thorns of *Acacia hindsii*, which are excavated for ant nests (left); nectaries at leaf base (middle); and leaves of *Acacia collinsii* with protein-rich Beltian bodies at tips of leaflets (right). (From Ref. 6.)

shoots that invade the acacia canopy. The acacia provides food in the form of high-protein Beltian bodies at the tips of some of its pinnate leaves, as well as sugar-rich nectaries at the leaf bases (Fig. 1). Both ant and plant have evolved traits to cement this association: Ants forage 24 hours a day rather than diurnally, and the plant retains its leaves even through the arid portions of the season. Neither ant nor plant can survive without the other in this ant–acacia relationship, although many other facultative ant–acacia associations occur.

Clear evidence of the antiherbivore defense in ant–plant mutualisms is provided in studies on three species of *Macaranga* which have either obligate or facultative relationships with a common ant. Plants, or parts of plants, that were kept ant-free for about one year lost 70–80% of their total leaf area, confirming the requirement of their ant partners for survival.^[7]

There is normally a prompt response to the site of herbivore damage by the ant partner. In the obligate *Azteca* ant–*Cecropia* tree relationship there was a five-fold increase in the number of ants on damaged versus undamaged leaves, with activity peaking in 8–12 minutes after damage was inflicted.^[8] Rapid recruitment was correlated with the number of ants patrolling the leaves, and the number of ants responding doubled when artificial damage was inflicted on the leaves. Damaged leaves on one tree prompted ant recruitment to leaves in adjacent *Cecropia*, suggesting interplant communication.

There is only one reported example of ants providing protection for an economically important plant. Ants live in close association with the cashew nut tree, *Anacardium occidentale*, which has nectaries on each leaf, the flower stalks, the base of each flower, and on the young nuts.

Local ants living in the area ascend the tree to collect nectar, and in the process of foraging they will capture insect herbivore as they are encountered. Commercial crops of cashew nuts in Malaysia and Sri Lanka, solely protected by local ants, have been produced for as long as 20 years without the use of any pesticide.^[9]

Most ants with obligate mutualistic associations require in situ nesting sites on their partners. These may be structures such as the greatly enlarged thorns of the bull’s horn acacia, or more commonly domatia (or caulinary domatia), expanded hollow stems. It is suggested that ants originally may have colonized later in plant development, when the diameters of the twigs were sufficient to accommodate small colonies. The advantages conferred by the presence of ants resulted in selective pressure for an earlier expression of the domatiale trait.

DISPERSAL

Many ant species carry plant materials, especially seeds, over relatively long distances from the plant source to their nests. Although many of these seeds may ultimately germinate, the habits of these voracious generalist foragers do not fall within the framework of coevolution. However, in South Africa an intimate association has developed between ants and plants in the family Proteaceae that often results in seed dispersal. Many species in this family produce seed with a fleshy, edible appendage termed an elaiosome. Seeds are gathered by the ants and transported to their nests, where the elaiosomes are eaten. The inedible seed is either stored in the underground nest

or discarded on the soil surface, where it may ultimately germinate and establish. The chaparral-like habitat of the fynbos is frequently swept by fires, after which only the seed in the underground nests will germinate.

Mycorrhizal Evolution

David M. Wilkinson

Liverpool John Moores University, Liverpool, U.K.

INTRODUCTION

The predominately mutualistic relationships between mycorrhizal fungi and vascular plants are very common; indeed, textbooks often cite figures suggesting that 80–90% of all vascular plant species are mycorrhizal. While such figures are approximate and based on extrapolation from a limited number of well studied examples, it is clear that mycorrhizae are widely distributed in modern plants, a fact that hints at a long evolutionary history for the relationship.

FOSSIL EVIDENCE

The fungal fossil record is relatively poor. While some spores are readily preserved, it requires unusual conditions to preserve hyphae (which are usually lacking in morphological features to aid identification even when preserved). However, there is now fossil evidence for arbuscular mycorrhizae contemporaneous with the origin of land plants. Important early fossils come from the Rhynie chert of the Lower Devonian age (approximately 400 million years b.p.), which contains well preserved terrestrial plant fossils. An example is *Aglaophyton major*, an enigmatic plant with features found in both vascular plants and bryophytes. Arbuscules (the sites of exchange of material between plant and fungus) are preserved in the fossilized tissues of this plant.^[1]

Recently fossil evidence of fungal hyphae and spores similar to arbuscular mycorrhizae have been found from the mid-Ordovician.^[2] These date from between 460 and 455 million years b.p. and were deposited in shallow marine conditions, presumably having washed in from nearby land. The Ordovician apparently occurred before the evolution of vascular plants and the terrestrial vegetation is poorly known, although it appears to have been dominated by plants similar to modern mosses and liverworts. However, the extent of terrestrial vegetation at the time is still controversial.^[3] The fossilized fungal remains strongly resemble the modern genus *Glomus*. They suggest that such fungi predate the first vascular plants and may have been either free living or formed mycorrhizal-like relationships with the bryophytes. This second suggestion is supported by the facts that modern

arbuscular mycorrhizae are known to form such relationships and that all modern Glomales fungi form mycorrhizae.^[2] Other types of mycorrhizae appear to have developed much later,^[4] although there is currently a shortage of fossil evidence.

IMPORTANCE FOR THE EARTH SYSTEM

Plants attempting to colonize the land would have faced the twin problems of desiccation and low nutrient substrates. Several authors have suggested that mycorrhizal relationships would have been crucial in surmounting these problems,^[4,5] a hypothesis that has acquired the status of textbook orthodoxy. Particular emphasis has been placed on the role of mycorrhizae in acquiring phosphorus.^[4]

If the mycorrhizal symbiosis was crucial in the development of widespread terrestrial vegetation, then it indirectly led to major global changes. Terrestrial plants caused the development of soils that retain water and, by maintaining a high surface area of damp mineral grains, greatly enhance chemical weathering. These reactions reduce atmospheric carbon dioxide and thus have important climatic implications.^[3,6] As well as contributing to this process indirectly by supporting terrestrial vegetation, mycorrhizae directly contribute to weathering rates by producing organic acids and other chemicals that break down mineral material.^[6]

EVOLUTIONARY MECHANISMS

The classic evolutionary problem with any mutualism is the question, why doesn't one of the partners "cheat"? That is, why doesn't one of them become parasitic, extracting resources from its partner without reciprocating by providing resources in return? There is a well established body of theory that can explain why mutualisms should be evolutionarily stable given certain assumptions such as vertical transmission of symbionts. However, these assumptions are not met by any of the various types of mycorrhizal symbioses. For example mycorrhizal fungi

are always acquired by horizontal transmission (from the environment) rather than by vertical transmission (directly from the parent, e.g., in the seed).^[7]

There are a number of mechanisms that could lead to mutualisms based on horizontal transmission being stable;^[7] one possibility is retaliation against cheating symbionts (e.g., by expulsion of fungi from the roots). Another is that local dispersal of plants (many seeds are only dispersed small distances) can lead to pseudovertical transmission. Here the plant acquires fungal partners from the soil that are genetically identical to those that infected the parent and so are equivalent to vertical transmission from an evolutionary perspective. It is also possible to view the acquisition of fungal symbionts by a plant as a biological market where the plant forms relationships with fungi that best suit current local soil conditions.^[8] The potential importance of this latter mechanism is increased by the recent demonstration of very high levels of genetic diversity in arbuscular mycorrhizae at small spatial scales in some soils;^[9] this could mean that the plant has a wide choice of potential fungal partners.

It is becoming increasingly likely that the evolution of mycorrhizae is a dynamic process with repeated gains and losses of the mycorrhizal condition over geological time. This position is supported by a recent molecular phylogeny^[10] of ectomycorrhizal fungi. The evolutionary history of this phylum was reconstructed using 161 species (29% were mycorrhizal, the rest free living). This produced a large number of equally parsimonious trees; however, all of these showed repeated transitions between mycorrhizal and free living forms. This analysis strongly suggests that the relationship has arisen many times.

An additional complication in considering mycorrhizal evolution is the presence of genetically distinct nuclei coexisting in the spores of individual arbuscular mycorrhizal fungi.^[11] This raises intriguing theoretical questions about what prevents competition between these different genomes. Consider the inheritance of organelles in eucaryotes: These are nearly always inherited from just one parent. The conventional explanation for this is that it removes the potential for conflicts of interest, which could arise if two genetically distinct lines of organelles were found within the same cell. Clearly, arbuscular mycorrhizae don't use this strategy to eliminate the possibility of genetic competition. How they deal with this problem is currently an open question.

MYCORRHIZAL NETWORKS

It has become common for people to suggest that ecologically significant amounts of carbon may be moved from plant to plant through mycorrhizal networks,

although the extent to which this happens is still controversial.^[12] If such behavior is real this clearly raises a number of interesting evolutionary questions. Why should a fungus give away important resources to the plants and how can it be evolutionarily stable for a plant to give away resources to competitor plants? These questions have received little theoretical attention; however, Wilkinson^[13] suggests some tentative answers. It may be to the advantage of the fungi to "invest" surplus carbon in plants that may become a future carbon source for the fungi. It is also possible to see a kin selection advantage in plants passing resources through mycorrhizal networks to nearby plants. Because many seeds only disperse short distances, many of these plants could be related to the donor. However, more complex explanations will be required if the mycorrhizal movement of carbon between different plant species is found to be common.^[13]

CONCLUSION

The fossil record suggests that some forms of mycorrhizae have been important since the first terrestrial plants evolved. Indeed, they may have been crucial in this process, which laid the foundation for the complex terrestrial ecosystems we see today and had important implications for weathering rates and through these, for the Earth's climate. One way of viewing the mycorrhizal symbiosis^[8] is that it allows plants to adjust their root systems (which are often a complex of root and hyphae) to temporal and spatial changes in the soil. This allows them to adapt to local conditions with much more flexibility than would be possible by relying on their roots alone.

Mycorrhizal Symbioses

Roger T. Koide

Pennsylvania State University, University Park, Pennsylvania, U.S.A.

INTRODUCTION

Mycorrhizas (or mycorrhizae) are symbioses involving plants that become colonized by mycorrhizal fungi. There are several recognized types of mycorrhizas including arbuscular, ecto-, ectendo-, arbutoid, monotropoid, ericoid, and orchid.^[1] Each type consists of a unique combination of plant and fungal taxa. As has been well documented for the arbuscular, ecto-, and ericoid mycorrhizas, the symbioses may be mutually beneficial. For these mycorrhizas, the plant's nutrient status may be improved as the fungus absorbs nutrients from the soil and transfers them to the plant. The fungus may also derive a significant amount of carbohydrate from the photosynthetic plant. From a human economic standpoint, the arbuscular and ectomycorrhiza are probably the most important mycorrhizal symbioses because these involve the majority of important food, fiber, and timber plant species, as well as many of the important edible fungi. These symbioses are also very important ecologically because most of the earth's land surface is dominated by vegetation that is largely arbuscular mycorrhizal or ectomycorrhizal.

ARBUSCULAR MYCORRHIZA

Arbuscular mycorrhizas are formed when plants are colonized by members of the fungal phylum Glomeromycota^[2], of which there are currently approximately 150 described species. The plants forming arbuscular mycorrhizas include many mosses, ferns, gymnosperms, and angiosperms. The arbuscular mycorrhiza is named for the arbuscule, a highly branched fungal organ usually produced within cortical cells of colonized plant roots. This is the organ across which the fungus absorbs carbohydrate from the plant, and the plant absorbs various nutrients from the fungus including Cu and Zn, possibly N, and especially P. In some cases, P uptake by roots may be downregulated as a consequence of the symbiosis, and the fungus may be the most important organ of phosphate absorption. In P-deficient soils, arbuscular mycorrhizal colonization can significantly improve plant growth and yield.^[3] The main reason for this is that phosphate usually occurs in low concentrations in the soil and diffuses

slowly. The hyphae of the mycorrhizal fungi extending from colonized roots (Fig. 1) compensate for this by exploring a greater volume of soil than can the roots themselves and by presenting a greater surface area for phosphate uptake. Some, but certainly not all, arbuscular mycorrhizal fungi may produce other structures within the roots of colonized plants including vesicles, which are capable of storing high concentrations of lipid. Thus, some of the arbuscular mycorrhizal fungi are vesicular-arbuscular, or VA.

Common agricultural practices may strongly influence the efficacy of mycorrhizal colonization. For example, vigorous disturbance of the soil such as by tilling can disrupt the fragile fungal mycelium, and this can lead to a significant reduction in phosphorus uptake.^[4] Fallow periods can also lead to a reduction in viable mycorrhizal hyphae in the soil. Thus, the planting of mycorrhizal cover crops during normally fallow periods can lead to increased colonization of subsequent crops and to increased yield.^[5] Variation in root anatomy and root system architecture result in variation in the extent to which plants benefit from mycorrhizal colonization.^[3] Plant species that possess few root hairs, for example, are expected to benefit more from mycorrhizal colonization than do those whose roots are densely covered with long root hairs. Moreover, variation in the way different mycorrhizal fungi explore the soil and thus capture P may lead to variation in their effects on plant growth.^[3] In container plant production utilizing soilless media, the effectiveness of arbuscular mycorrhizal fungi may be much lower than in soil. In such production systems fertilizer may supply phosphate in high concentrations and the applied phosphate is often freely available because soilless media typically do not adsorb phosphate as do many natural soils.^[6]

ECTOMYCORRHIZA

Unlike the case with arbuscular mycorrhiza, the ability to associate with roots to form an ectomycorrhiza has developed independently in more than one fungal lineage. The several thousands of fungal species that form ectomycorrhizas include members of the Basidiomycota, Ascomycota, and Zygomycota.^[7] The plants forming

Fig. 1 In vitro carrot/*Glomus intraradices* arbuscular mycorrhiza. (Photograph by Roger Koide.) (View this art in color at www.dekker.com.)

ectomycorrhizas are mostly angiosperm and gymnosperm shrubs and trees including members of the economically important and ecologically dominant Pinaceae, Fagaceae, and Myrtaceae. No fungal structures are produced within the root cells, but the fungus grows between the outer cortical and epidermal cells, and may form a dense mantle external to the epidermis. As it does so the root may cease to grow, giving rise to characteristic short mycorrhizal roots (Fig. 2). Hyphae extending from the surface of the mantle into the soil provide surface area for nutrient absorption. Thus, just as in the arbuscular mycorrhiza, this additional surface area can significantly increase the P status of the plant. N absorption may also be enhanced. The fungi also collectively possess a range of hydrolytic abilities that allows them to access some nutrient sources unavailable to uncolonized roots, including the ability to utilize some proteins, amino acids, amino sugars, and organic phosphates.^[1] Thus, the ectomycorrhizal fungi may be of particular significance in high latitude or high altitude biomes in which litter decomposition rates are relatively low and thus in which large fractions of the nutrients are bound up in organic forms. Ectomycorrhizal colonization may also be particularly important for developing seedlings that typically have poorly developed root systems. Some fungal species are capable of transporting significant amounts of water to the plant,^[8] the lack of which is responsible for a large fraction of seedling mortality.

It is widely recognized that a single tree in a natural ecosystem will be colonized by many ectomycorrhizal fungal species. A single-species plantation may support dozens of ectomycorrhizal fungal species. The causes of this diversity are only now being investigated, but the consequences to ecosystem function are already obvious. Variation among ectomycorrhizal fungi in their physiolo-

gies and morphologies give rise to variation in their functions. Whereas some are better at transporting N to the plant, others may be better at transporting P. Still others may be superior at water transport. Thus, nature may select for plants that support a variety of ectomycorrhizal fungal species. Most ectomycorrhizal fungal species produce macroscopic fruiting bodies such as mushrooms, puffballs, and truffles. Many are of great economic importance because of their edibility. These fruiting structures are also of great ecological importance because many serve as major food sources for a number of animal species.

CONCLUSION

Currently the arbuscular mycorrhizal fungi cannot be grown in pure culture. They are cultured on intact plants or on root organ cultures. Consequently, it is very costly to produce arbuscular mycorrhizal fungi for large-scale inoculation such as in field trials. Inoculation may only prove to be economically viable for crops of high value. For other crops, efforts to manipulate field practices to stimulate indigenous mycorrhizal fungi may be more practical. In temperate climates, for example, minimizing fallow periods and reducing soil disturbance are both effective ways to promote colonization by arbuscular mycorrhizal fungi of subsequent crops. In soilless media, such as in the floriculture industry, arbuscular mycorrhizal fungi may not prove to enhance P absorption, but it may influence other economically important traits such as disease resistance.^[9]

Nurseries of potentially ectomycorrhizal tree seedlings grown for reforestation or ornamental use may lack the

Fig. 2 Ectomycorrhizas of *Pinus resinosa*. (Photograph by Roger Koide.) (View this art in color at www.dekker.com.)

most effective fungi following outplanting. A number of studies have shown that inoculation with appropriate ectomycorrhizal fungi improves survival and growth of tree seedlings.^[10] Thus, the view that inoculation of trees with ectomycorrhizal fungi can be helpful and economically viable is widely held. Indeed, there has been some effort to devise methods to artificially inoculate nursery beds and small seedling pots. Often spores or bits of sporocarp material are used as sources of inoculum. In some cases it is possible to grow ectomycorrhizal fungi in pure culture, allowing one to use vegetative mycelium as an inoculum source. Thus far, however, standard inoculum types, and the quantities and qualities of inocula have not been established for many specific tree species. The appropriate species of fungus must also be carefully selected because there is a wide range of specificity among ectomycorrhizal fungi for plant species.^[10] Other production methods including rate, form, and placement of fertilizer need to be established to encourage ectomycorrhizal colonization. Moreover, the economic benefit from inoculation needs to be established in more large-scale trials. Until then, inoculation may not become the standard silvicultural practice it probably should be.

Mycotoxins Produced by Plant Pathogenic Fungi

K. Thirumala-Devi

Nancy Keller

University of Wisconsin, Madison, Wisconsin, U.S.A.

INTRODUCTION

Mycotoxins are natural, chemically diverse, fungal products that are defined by their harmful effects on humans and animals. Their existence came into the limelight in 1960 when more than 100,000 turkeys died in the UK as a result of consuming aflatoxin-contaminated peanut meal. Mycotoxins are introduced into the diet through consumption of contaminated produce and are toxic to human beings and livestock by exerting specific effects on a given organ system. Detrimental properties exhibited by mycotoxins include carcinogenesis, mutagenesis, teratogenesis, oestrogenesis and/or immunosuppression. Data suggest that exposure to two or more mycotoxins or an interaction between a mycotoxin and a pathogen exacerbates disease symptoms.

The majority of economically important mycotoxins are produced by *Aspergillus*, *Penicillium*, and *Fusarium* species, although other genera such as *Claviceps* also produce potent toxins. These genera are ubiquitous, and according to the Food and Agriculture Organization of the United Nations (FAO) over 25% of the agricultural commodities worldwide are significantly contaminated by mycotoxins. Although they are a postharvest problem, these fungi also cause significant preharvest contamination. In particular, contamination occurs in countries where climate and poor storage conditions favor the growth of mycotoxin-producing fungi. This article gives an account of a selected group of economically important mycotoxins and refers the reader to recent reviews and the Council for Agricultural Science and Technology (CAST) report published in 2003 for greater detail.

MYCOTOXINS PRODUCED BY *Aspergillus* AND *Penicillium*

Aspergillus and *Penicillium* species are closely related and can produce the same mycotoxins. These molds grow on a wide variety of food- and feedstuffs worldwide, especially cereals and oilseeds (Table 1, Fig. 1).

Aflatoxins

Aflatoxins are a group of polyketides produced by *Aspergillus flavus* and *A. parasiticus* on a variety of crops. The highest levels of contamination have been recorded in peanuts, maize, Brazil nuts, pistachio nuts, cottonseed, and copra. Lower levels are recorded in almonds, pecans, walnuts, raisins, spices, and figs. The four aflatoxins (AF)—AFB1 > AFG1 > AFB2 > AFG2 (ranking based on toxicity)—are the most common, and of these AFB1 and AFG1 are most frequently found in foods. AFM1 (derived from AFB1) contaminates dairy products. Aflatoxins target the liver and immune system, causing hepatocellular carcinoma especially in humans who are infected with the hepatitis B virus.^[6] Aflatoxins can also cause several pathological effects on various other organs and tissues.

Sterigmatocystin is the penultimate precursor of AFB1 and is produced most commonly by *A. nidulans* and *A. versicolor*.^[7] It contaminates cereal crops and milk products, including cheese.^[8] Sterigmatocystin is hepatotoxic and carcinogenic;^[9] nevertheless its toxicity is one-tenth that of AFB1.

Ochratoxins

Ochratoxins are a group of dihydroisocoumarins produced by *A. ochraceous* and *Penicillium verruculosum* on a diverse group of crops including barley, oats, rye, maize, wheat, coffee, nuts, olives, and grapes. Ochratoxins bind tightly to serum albumin and are carried in animal tissues and body fluids. Consequently, they can be detected in sausage derived from contaminated meats. Ochratoxin A, the most toxic member of this group of mycotoxins, has been shown to be nephrotoxic, hepatotoxic, teratogenic, carcinogenic, mutagenic, and immunosuppressive.^[10] Of greatest concern for human health is its implicated role in an irreversible and fatal kidney disease referred to as Balkan Endemic Nephropathy. Ochratoxin A has also been shown to contaminate human milk, and thus can cause kidney disorders in breast-fed infants.

Table 1 Selected mycotoxins produced by plant pathogenic fungi, and their biological effects

Fungi	Commodities	Mycotoxins	Biological effects
<i>Aspergillus/Penicillium</i>			
<i>A. flavus</i>	peanuts, maize, cottonseed, tree nuts, milk	aflatoxins	hepatotoxic carcinogenic mutagenic teratogenic
<i>A. parasiticus</i>			
<i>A. flavus</i>	maize, wheat, barley	sterigmatocystin	hepatotoxic carcinogenic
<i>A. parasiticus</i>			
<i>A. nidulans</i>	barley, maize, wheat, sorghum, coffee beans, milk	ochratoxin	nephrotoxic teratogenic
<i>A. ochraceous</i>			
<i>P. verruculosum</i>	maize, peanuts	cyclopiazonic acid	nephrotoxic cardiovascular lesions
<i>A. flavus</i>			
<i>P. cyclopium</i>			
<i>Fusarium</i>			
<i>F. verticillioides</i>	maize, sorghum	fumonisin	neurotoxic hepatotoxic
<i>F. proliferatum</i>	barley, maize	trichothecenes (T2, DON)	apoptosis neurotoxic
<i>F. sporotrichioides</i>			
<i>F. graminearum</i>	maize, cereals	zearalenone	genitotoxic
<i>Claviceps</i>			
<i>C. purpurea</i>	rye	ergot alkaloids	neurotrophic

Cyclopiazonic Acid

Cyclopiazonic acid is an indole tetramic acid produced by several *Penicillium* species, including *P. cyclopium*, *P. aurantiogriseum*, *P. crustosum*, *P. griseofulvum*, and *P. camemberti*, as well as the *Aspergillus* species *A. flavus*, *A. tamari*, and *A. versicolor* on maize and peanuts.^[11] Cyclopiazonic acid often co-occurs with aflatoxins and causes necrosis of the liver, spleen, pancreas, kidney, and salivary glands.

MYCOTOXINS PRODUCED BY *Fusarium*

Fusarium species are pathogens on a wide variety of crop plants throughout the world. They cause mainly stem and root rots and frequently infect the grain of cereal crops. Several species of *Fusarium* produce mycotoxins on a range of cereal crops, which include wheat, maize, rice, barley, and oats.

Fumonisin

Fumonisin are pentahydroxyicosanes produced by *F. verticillioides* and *F. proliferatum* on maize and sorghum. Fumonisin B1, the most toxic fumonisin, promotes cancer and causes equine leukoencephalomalacia^[12] and porcine pulmonary edema.^[13] A high incidence of human esophageal cancer in South Africa and China has been

correlated with the presence of fumonisins in foods. Fumonisin exert their toxic effects by altering sphingolipid metabolism. In laboratory tests fumonisins induced cancer of the kidney and liver in rodents.

Trichothecenes

T2 toxin and deoxynivalenol (DON) belong to a large group of structurally related sesquiterpenes known as trichothecenes.

T2 toxin is produced by *F. sporotrichioides* on barley, maize, oats, and wheat. It can severely damage the entire digestive tract and cause rapid death due to internal hemorrhage. It is also implicated in pulmonary hemosiderosis. Damage caused by T-2 toxin is irreversible.

DON is probably the most widely occurring *Fusarium* mycotoxin, contaminating a variety of cereals, especially maize and wheat. It is most frequently produced by *F. graminearum*. The outbreak of emetic syndromes in livestock due to the presence of DON in feeds has resulted in coining the name "vomitoxin." It is implicated in outbreaks of acute human mycotoxicosis in India, China, and rural Japan. However, DON is much less toxic than T2 toxin.

Zearalenone

Zearalenone is a β -resorcylic lactone produced by *F. graminearum* on maize, wheat, and other cereal grains. It

Fig. 1 Chemical structures of selected mycotoxins.

is produced along with DON and has been implicated in the outbreaks of acute human mycotoxicosis. Exposure to zearalenone-contaminated maize elicits estrogenic effects in the mammalian reproductive system and has specifically been associated with hyperoestrogenism in livestock (especially pigs), characterized by vulvar and mammary swelling, infertility, and abortions.

MYCOTOXINS PRODUCED BY *Claviceps purpurea*

Ergot is the common name of the disease caused by *Claviceps purpurea*, a fungus that occurs on rye and other small grains, where it replaces the kernel with a fungal body called a sclerotium.^[14] The sclerotium contains ergot alkaloids that when ingested cause toxic reactions, including convulsions, hallucinations, and dry gangrene, that lead to loss of limbs. Epidemics of ergotism have been recorded throughout history. This often fatal condition has since been traced to the presence of alkaloids, derivatives of the four-ring-structure ergoline, in the sclerotium.

GENETIC AND MOLECULAR BIOLOGY OF MYCOTOXIN BIOSYNTHESIS

Aflatoxin and sterigmatocystin biosynthesis is the most thoroughly characterized of any mycotoxin. Molecular genetic analyses of three species of *Aspergillus* have resulted in the cloning of an aflatoxin/sterigmatocystin gene cluster containing all of the enzymatic genes and at least two regulatory genes required for aflatoxin/sterigmatocystin biosynthesis.^[15] In general, it appears that genes for fungal secondary metabolism are found in clusters; the trichothecene,^[16–18] fumonisin,^[19] and ergot alkaloid^[20] gene clusters have also been described. Furthermore, additional studies of aflatoxin/sterigmatocystin biosynthesis have shown that mycotoxin formation is genetically linked to asexual spore production through a G protein/cAMP/protein kinase A signaling pathway.^[15] Gene cluster expression is also subject to regulation by environmental parameters including nitrogen and carbon source and external pH mediated through the global regulators AreA, CreA, and PacC, respectively.^[21]

CONTROL

Regulation of the moisture content of crops is the most effective postharvest management control of mycotoxin

formation and is successfully used in developed, but not developing, countries. Preharvest contamination remains a problem worldwide, although some recent success has been documented by using atoxigenic *Aspergillus flavus* strains as biocontrol agents.^[22,23] Crop plants which can suppress mycotoxin biosynthesis or resist fungal entry may offer a long-term viable option for reducing mycotoxin contamination. Several research groups are focusing both on traditional plant breeding and on development of engineered plants to reduce mycotoxin contamination.

Once contamination occurs it is not economically feasible to reduce the mycotoxin content of foods. However, potent adsorbents such as activated clays have successfully been used by the feed industry in developed countries to minimize the influence of aflatoxins on livestock.

CONCLUSION

Mycotoxin contamination of foods and feeds has assumed economic importance globally because of its influence on the health of human beings and livestock. This article has given a brief account of the chemical nature of mycotoxins; the deleterious effects caused by economically important mycotoxins; progress in the molecular genetics of mycotoxin biosynthesis; and existing control strategies. Clearly, given the importance of this disease problem, additional controls are needed. Current research focused on identification and characterization of fungal and/or plant genes and gene products important in the production of mycotoxins should yield insight toward the development of additional control strategies.

Natural Rubber

Dennis T. Ray

University of Arizona, Tucson, Arizona, U.S.A.

INTRODUCTION

Natural rubber is an essential part of society used in the manufacture of over 40,000 products, more than 400 of which are medical devices.^[1] Over 2000 rubber-producing plant species have been described; however, historically only two—the Brazilian rubber tree (*Hevea brasiliensis*) and guayule (*Parthenium argentatum*)—have been exploited commercially.^[2] The Brazilian rubber tree at present is the only commercial source of this essential natural plant product.^[3]

Natural rubber is a renewable resource accounting for approximately 40% of the world's total rubber consumption,^[4] the remainder coming from synthetic rubber, a nonrenewable resource derived from petroleum. Synthetic rubber cannot substitute for natural rubber in applications that require high elasticity, resilience, and/or minimum heat buildup (e.g., high-performance tires and medical latex products).^[5] Because of these characteristics, the global demand for natural rubber continues to increase,^[1] but in the future, because synthetic rubber is a nonrenewable petroleum product, even more natural rubber will be required to replace synthetic rubber's market share.

Having more than one source (biodiversity) of natural rubber is desirable, especially to meet the anticipated need of this essential natural product. At this time guayule has the greatest potential of the over 2000 rubber-producing plants to become an additional commercial source of natural rubber, mainly because of the extensive research and development that have already taken place. Commercialization of guayule would not replace the production of rubber from the Brazilian rubber tree, but would increase total global rubber production.

NEED FOR INCREASE IN BIODIVERSITY OF RUBBER PRODUCTION

Growing guayule as a commercial source of natural rubber would lead biodiversity as well as help stabilize global rubber production. The Brazilian rubber tree is grown exclusively in tropical climates;^[5] today commercial production is centered almost exclusively in Asia.^[1] Guayule is a xerophytic shrub native to the Chihuahuan desert of north-central Mexico and southwestern Texas;^[2]

commercial production would be in arid and semiarid environments. The Brazilian rubber tree is grown almost exclusively from clones, which are extremely narrow genetically. This makes the crop particularly susceptible to crop failure due to disease, as in the case of the South American industry's decline due to leaf blight.^[3,5] Guayule populations contain a great amount of genetic diversity, making them ideal for selecting plants best suited for cultivation in different areas and environments. Guayule also has a very complicated reproductive system that continually generates genetic diversity among progeny of a single plant.^[5,6]

It appears the demand for natural rubber will continue to grow at a rate greater than can be met by new plantings of the Brazilian rubber tree; changing political climates in production areas can also jeopardize the continuity of the natural rubber supply. Growers in developing countries are moving away from plantation farming of the Brazilian rubber tree to higher-value agricultural crops.^[3] Guayule, on the other hand, has the potential to add jobs in rural areas with arid and semiarid environments where traditional agriculture is becoming less economical because of water and salt problems. The commercialization of guayule will enhance the sustainability of agriculture in these rural areas, and will benefit more than growers through the concurrent development of local processing facilities and manufacturing plants. Because guayule would be grown in other environments and areas of the world, its production would ensure the continued flow of this essential natural product.

NATURAL RUBBER/LATEX

Natural rubber is an isoprenoid molecule, related to plant compounds essential for plant growth and development.^[7] Its desirable qualities are due to its molecular structure and high molecular weight.^[5] In the Brazilian rubber tree, natural rubber in the latex form is produced within subcellular rubber particles in a pipelike system of laticifers, from which the latex can be harvested by tapping.^[8] Natural rubber latex in guayule is produced within rubber particles found within the cytoplasm of intact bark parenchyma cells, and does not flow from continuous ducts as in the Brazilian rubber tree.^[5] Grinding the stem tissues

and using solvents in order to free the rubber molecules affect extraction of rubber latex in guayule.

Many commercial, medical, transportation, and defense industries are dependent on natural rubber in the production of their products. Although the development of synthetic rubber by the chemical industry after World War II was a great breakthrough, synthetic materials have not been able to achieve the same properties as natural rubber for many high-performance applications.^[1]

GUAYULE AS A POTENTIAL RUBBER-PRODUCING CROP

Guayule has been known as a source of natural rubber since pre-Columbian times, its first use dating to the production of rubber balls for indigenous people's games in present-day Mexico.^[2] In the early 1900s, guayule was considered an alternative source of natural rubber in the United States due to the high price of rubber imported from the Amazon region.^[9] This initial interest resulted in the first of three major efforts to domesticate and commercialize guayule.

This initial attempt started with the harvesting of wild guayule stands in Mexico, and accounted for up to 24% of the total rubber imported to the United States by 1910.^[9] At this time, up to 20 extraction plants were either operational or under construction in Mexico, when production came to a halt in 1912 because of the Mexican Revolution.^[2] Production then moved across the border to the United States, with efforts centered in Arizona and California. This first effort to commercialize guayule came to a halt in 1929 as a result of the Great Depression.^[2]

The second major effort to utilize guayule as a source of natural rubber was the Emergency Rubber Project of World War II. Natural rubber production had moved almost exclusively to large plantations of the Brazilian rubber tree grown in Southeast Asia, and these sources were cut off at the beginning of the war.^[2] The Emergency Rubber Project was very successful. It generated the bulk of our knowledge about the basic biology of the guayule plant and developed the germplasm on which current breeding programs are based. The effort ended with the end of the war and the development of synthetic rubber.

Guayule was seriously investigated a third time in the early 1970s, when crude oil prices quadrupled. The fear was that if the oil supply could be manipulated, there might again be a shortage of natural rubber due to either natural disaster or political unrest in Southeast Asia. This led in the United States to the enactment of the Native Latex Commercialization and Economic Development Act of 1978. A tremendous amount of work was again

accomplished, resulting in significant yield increases and the refinement of cultural practices to fit modern mechanized agriculture.^[2,10] This third effort again showed that guayule could be planted, cultivated, harvested, and processed as a source of natural rubber. However, as the political climate changed, this effort was also terminated, and guayule was again considered a source of natural rubber only in times of emergency.

This appeared to be the end of guayule's commercialization efforts. To be considered a commodity in direct competition with the Brazilian rubber tree, guayule rubber would have to either perform the same functions at lower cost or perform better at the same costs. Although guayule rubber is equivalent in quality to the Brazilian rubber tree latex, it was not competitive economically.^[2] However, guayule is once again being considered for commercialization because of the occurrence of latex allergy in the general population.^[11]

PRESENT POTENTIAL FOR GUAYULE COMMERCIALIZATION

Allergic reactions are a result of protein contaminants in rubber products, and range from contact dermatitis to anaphylactic shock when susceptible individuals come in contact with these proteins. With over 400 medical devices containing natural rubber, this is potentially a very serious problem. Guayule latex contains low levels of proteins, none of which elicit an allergic response in subjects who are sensitized to Brazilian rubber tree latex proteins.^[12] Therefore, guayule affords a potential new product—hypoallergenic latex—to be used as an alternative in the manufacture of products for individuals with latex allergy. A method to extract natural rubber in latex form from guayule has been developed,^[13] and the goal of producing hypoallergenic guayule latex products is moving toward becoming a reality.^[14]

CONCLUSION

Natural rubber is an essential part of life in today's society. The demand for natural rubber will continue to increase because of both increased consumption and the eventual need to replace synthetic rubber. At this time the Brazilian rubber tree is the only source of commercial natural rubber. Thus there is a need for additional sources to expand the growing range and worldwide production. At this time guayule is the most promising plant to fill this niche. Guayule makes a natural rubber of at least the quality required for high-end uses, such as high-performance tires and medical products, but it is not directly economically competitive with the Brazilian rubber tree in

these markets. However, guayule makes natural rubber latex that is nonreactive to individuals sensitized to proteins found in Brazilian rubber tree latex products. Thus, guayule has the potential to become a commercial crop for the production of hypoallergenic latex products.

INTRODUCTION

Nematodes are an extremely successful group of thread-like, worm-shaped animals that are found in many ecological niches, including extreme environments. They may be the most abundant multicellular animals, occurring as parasites of plants and animals and as free-living nematodes feeding on bacteria, fungi, and protozoa. This article presents a description of nematode history and anatomy, including size relationships, life cycle, general external and internal anatomy, survival, and feeding habits.

DISCUSSION

Nematodes are a remarkably successful group of thread-like, worm-shaped invertebrate animals adapted to survival in most ecological niches. Because they require water for locomotion, they occur in marine and freshwater environments, in the film of water between soil particles, and in plant and animal tissues. Nematodes also are found in extreme environments such as desert and polar regions. They may be the most abundant multicellular animals, and the more than 20,000 described species occur as parasites of plants and animals—including humans—and as free-living nematodes feeding on bacteria, fungi, and protozoa. They are inconceivably abundant and can be found in the most unexpected places, forming a recognizable world with all plant and animal life and geographical landmarks visible, even if all the matter on the earth except nematodes were somehow swept away.^[1]

A rich history of nematodes derives from early writings on symptoms, signs, and treatment of large human parasitic nematodes, especially *Ascaris*, a large intestinal roundworm. The oldest writings describing these maladies are from the Chinese culture and date back to about 4700 years ago. References to nematodes were also recorded during the dominant civilizations of the Middle East and Mediterranean areas over 2000 years ago. The advent of

the microscope in the 17th century resulted in many contributions to the science of nematology. The 18th and early 19th centuries were a time of historic discoveries in nematode anatomy, embryology, taxonomy, and life cycle studies of animal and human nematode diseases, including elucidation of the principles of alteration of generations, intermediate hosts, and vectors. During this time, the study of nematode parasites of livestock and other domestic animals flourished, and the seriousness of the many human diseases caused by nematodes was established.^[2]

The study of plant-parasitic nematodes has a relatively recent history dating back only to 1743, when John Turbevill Needham, a clergyman interested in science, observed nematodes emerging from distorted grains of wheat. This seed gall nematode, *Anguina tritici*, had seriously affected wheat yield in the great Middle Eastern civilizations. Over 100 years elapsed until the plant pathologist Julius Kühn described an eelworm disease that caused stunting of teasel, a plant whose spiny fruit were used to raise the nap on wool. Only two years later, a serious disease of sugar beet in Europe was determined to be caused by the nematode later named *Heterodera schachtii*. Discovery of another European nematode-induced disease on potato soon followed. Investigations on controlling these and other nematode pathogens dominated nematological research in Europe for about 40 years. The basic principles of disease management tactics such as soil fumigation and crop rotation were established during this period are still applicable today.^[3]

The word nematode means “threadlike” in Greek and amply describes the appearance of these animals, especially the smaller forms when dispersed in a vial of water. Nematodes are nonsegmented, unlike earthworms for example, and are spindle-shaped, tapering slightly at both ends. Plant-parasitic species vary from about 0.3 μm long in the genus *Paratylenchus* to about 5 mm in the genus *Longidorus*. The longest mammalian parasite occurs in whale placenta and reaches 8 meters in length. Females in

some plant-parasitic genera are kidney-shaped, lemon-shaped, pear-shaped, or otherwise swollen as adults, whereas the males remain vermiform (worm-shaped).

Plant-parasitic nematodes exhibit a simple, direct life cycle that usually includes egg, four juvenile, and adult stages. Nematodes are usually bisexual, existing as distinct males and females. Some nematodes, however, are hermaphroditic, and the female sex organs produce both sperm and eggs that combine during fertilization. In another variation, called parthenogenesis, males (and spermatozoa) are not required for reproduction, although males may be present in the population.

The nematode oral aperture is surrounded by six lips, or fewer if they have become partly combined as in more derived genera. There is typically a single papilla on the inner edge of each lip adjacent to the mouth, and two on the outer side of each lip in some ancestral forms. Certain marine nematodes, which are thought to be ancestral, have the inner row of papillae on the lips surrounding the mouth, an adjacent row of setae, and an outer row of larger setae. Plant-parasitic nematodes have few papillae, no setae, and combined lips that have taken on new forms.

The nematode head skeleton supports the lip region and is composed of radial blades and basal ring, which appear light or dark depending on the degree of hardening. The mouth is the beginning of the alimentary canal and it is followed by the buccal cavity or stoma. In plant-parasitic nematodes the buccal cavity is armed with a hollow, protrusible stylet or mouth spear (<http://www.barc.usda.gov/psi/nem/what-nem.htm>). The stylet is the most distinctive structure in the head; its shape varies among the genera of plant-parasitic nematodes and can often be used to determine the nematode genus (<http://nematode.unl.edu/key/nemakey.htm>). The stylet is hollow for part of its length and is used to withdraw nutrients from plant cells. It also can serve as a conduit for digestive gland secretions into the plant cell. The stylet has protractor muscles attached at the base and forward at the anterior wall of the esophagus. Contraction of these muscles thrusts the stylet out of the mouth and into the host plant cell.

The stoma, or mouth cavity, is followed posteriorly by the esophagus, composed of the corpus, the isthmus, and a basal glandular region. The corpus can be further subdivided into the anterior procorpus, followed by the metacarpus, which may or may not contain a distinctive valve. A very narrow (<1 μm) food channel, called the lumen, passes through the esophagus and connects it with the intestine. The metacarpus in plant-parasitic nematodes is often furnished with radial muscles, making it a pump chamber that can pulsate up to several times per second. This pump chamber with its valve withdraws nutrients from cells in the active feeding phase and passes the nutrients through the valve into the intestine. Depending

on the nematode, there may be an initial passive-feeding phase that does not require the pumping of the metacarpus to feed the nematode. The esophageal lumen is tri-radiate as it passes through the metacarpus and has one ventral and two subdorsal rays when relaxed. When the radial muscles contract, the lumen becomes more circular and food passes posteriorly. The isthmus that follows the metacarpus is a narrowing of the esophagus before the basal glandular portion of the esophagus. The morphology of the esophagus is one way in which nematodes are identified and is especially important for plant-parasitic genera. The plant virus vectors *Xiphinema*, *Longidorus*, *Trichodorus*, and closely related genera have a two-part esophagus, consisting of a narrow anterior portion and an expanded basal glandular portion.

The excretory system of more ancestral nematode forms may contain an H-shaped system of lateral ducts ending in a cuticularized duct and anterior ventromedian pore. Plant-parasitic genera in the class Secernentea (containing most of the plant parasites) may have a duct or a portion of a duct on one side leading to a ventral excretory cell, or the more advanced forms may have only the ventral cell, excretory duct, and pore. Adenophorean nematodes have only the single ventral cell, without collecting tubules (ducts), and a noncuticularized excretory duct leading to the outside pore. There is some debate on whether this system is solely for the function of excretion or possibly also for osmoregulation or secretion of materials other than wastes.^[4,5]

The female reproductive system is divided into ovary, oviduct, and uterus. There are one or two ovaries composed of an anterior germinal zone where eggs are produced and an ovum growth zone. If a globular spermatheca for the storage of sperm is present, it is part of the uterus.^[6] The tubular reproductive system opens through the ventral vagina and vulva. The tubular male testis joins posteriorly with the digestive system to create a common duct called a cloaca that opens ventromedially through the anus. Males have one or two testes and an external pair of hooklike spicules used to pry open the vulva during copulation. There may be a spicular guide piece called a gubernaculum and another accessory piece called a telamon (capitulum) adjacent to the spicules on the anterior side.

Nerve cells in the nematode are grouped into ganglia that in turn are grouped into a circumesophageal commissure (nerve ring), a collection of coordinated nerve cell bodies that become the primitive nematode "brain." Nerves extend anteriorly toward the mouth and provide chemosensory and tactile information to the nematode. Nerves also extend posteriorly in the dorsal and ventral hypodermal cords and provide chemosensory and tactile sensation. The main nerve is the ganglionated ventral nerve.

Nematodes have an external covering called a cuticle, a nonliving, proteinaceous, multilayered covering secreted by an underlying living, cellular hypodermis (“tissue below the skin”). In order to accommodate growth-necessitated expansion, the passage of a nematode from one juvenile stage to another (or to the adult stage) is accompanied by molting, a process during which the new cuticle is synthesized and the old cuticle is shed. The physiological and biochemical control of nematode molting has not yet been elucidated, unlike the molting process in insects. In many plant parasites, the old cuticle substantially dissolves and is probably absorbed by the hypodermis. The hypodermis invaginates in four sectors and forms cords that contain a limited number of hypodermal cells, separating the bands of muscle fibers into quadrants of two subdorsal and two subventral bands. Nematodes are unique in that the muscle cells send out innervation processes to the nerve cell body, rather than the more typical arrangement of nerve cell axons providing transmission of electrical impulses to the muscles. For most nematodes, muscles of the body are limited to longitudinally oriented fibers.

The ability of nematodes to thrive in a variety of habitats results from their anatomy and physiology. The selective permeability of the nematode cuticle often facilitates the entry of nutrients or the export of wastes, yet impedes the entry of detrimental compounds. Many nematodes can survive extended periods of drought or temperature stress via morphological and biochemical adaptations, such as the accumulation of the sugar trehalose and other specific molecules. The eggs of some plant-parasitic nematodes can survive for years in soil; eggs often hatch when stimulated by exudates from host plants. Identification of these so-called hatching factors is an active research area; only one such chemical has been identified to date.

Although some plant-parasitic nematode species climb on and penetrate the aerial parts of plants, most plant-feeding nematodes are root pathogens. Some of these move through plant tissues and feed on different roots, whereas others become established in a permanent feeding site. These sedentary root parasites greatly alter the physiology of host roots. Their esophageal glands secrete proteins and possibly other factors that cause structural and physiological modification of the host cells the nematodes feed upon.

The free-living nematode species *Caenorhabditis elegans* was the first multicellular animal to have its genome completely sequenced. This nematode contains more than 19,000 genes, although their functions are as

yet largely uncharacterized. Analyses comparing the sequences of genes from *C. elegans* to those of plant- and animal-parasitic nematodes are yielding insight about the function of genes important in parasite development and pathogenesis (<http://elegans.swmed.edu/genome.shtml>).

Nematodes possess the same biochemical pathways present in most animals. Unlike their mammalian and plant hosts, nematodes cannot biosynthesize heme or steroids; unlike all other animals, nematodes possess a glyoxylate cycle that enables them to biosynthesize carbohydrates from their storage lipids. Although many nematode parasites of mammals extensively catabolize organic molecules anaerobically and produce short-chain fatty acids as waste products, carbohydrate catabolism in plant-pathogenic species is primarily aerobic, via typical tricarboxylic acid and electron transport pathways.

Nematode Feeding Strategies

Richard S. Hussey

University of Georgia, Athens, Georgia, U.S.A.

INTRODUCTION

Plant-parasitic nematodes have evolved diverse parasitic strategies and feeding relationships with their host plants to obtain nutrients that are necessary for development and reproduction. Depending on species, these biotrophic parasites feed from the cytoplasm of unmodified living plant cells or have evolved to modify root cells into elaborate, discrete feeding cells. These parasitic nematodes use a hollow, protrusible feeding structure called a stylet to penetrate the wall of a plant cell, inject esophageal gland secretions into the cell, and withdraw nutrients from the cytoplasm of the parasitized cell. Certain species take up cytosol from the parasitized cell directly through a minute perforation created in the plasma membrane at the stylet orifice, while others ingest nutrients through a feeding tube.

NEMATODE FEEDING STRATEGIES

Plant-parasitic nematodes have evolved diverse parasitic strategies and feeding relationships with their host plants to obtain nutrients that are necessary for development and reproduction. Depending on species, these biotrophic parasites feed from the cytoplasm of unmodified living plant cells or have evolved to modify root cells into elaborate, discrete feeding cells.^[1] These parasitic nematodes use a hollow, protrusible feeding structure called a stylet to penetrate the wall of a plant cell, inject esophageal gland secretions into the cell, and withdraw nutrients from the cytoplasm of the parasitized cell. Plant-parasitic nematodes can be separated into four general groups according to the evolution of their mode of parasitism: migratory ectoparasites, sedentary ectoparasites, migratory endoparasites, and sedentary endoparasites (Fig. 1). The migratory ectoparasites have the most primitive mode of parasitism, directly feeding from unmodified root cells. In contrast, the more evolutionarily advanced sedentary endoparasites have evolved a very specialized mode of parasitism, dramatically modifying root cells of susceptible hosts into elaborate, unique feeding cells, including modulating complex changes in cell morphology, function, and gene expression. The

amount of tissue destruction and the degree of plant response are often related to the type of feeding relationship between the nematode and its host. The migratory ectoparasites remain outside the root and insert their protrusible stylet to feed either on epidermal cells or cells deeper within the root. As a rule, species that possess a short stylet (e.g., *Tylenchorhynchus* spp.) feed on epidermal cells, while species with a long stylet (e.g., *Belonolaimus* spp.) are able to exploit tissues deeper in the root. With the exception of species of a few genera (e.g., *Belonolaimus*) that feed on root tips, nematodes with this type of feeding strategy generally cause little obvious tissue damage. Sedentary ectoparasites feed from a single site or root cell for a prolonged period of time while remaining outside the root. Feeding by *Criconemella xenoplax* causes little tissue damage, but other species, such as *Hemicycliophora arenaria*, induce terminal galls when feeding at root tips.

Another group of nematodes, the endoparasites, invades root tissue with part or all of their body. Although some endoparasites feed as soon as they enter the root, other species feed only after migrating to a preferred feeding site. Migratory endoparasites (e.g., *Pratylenchus* and *Radopholus* spp.) enter roots and feed on cells as they migrate intracellularly through the root tissue. These endoparasites inhabit primarily the cortical tissue of roots. Migratory endoparasites possess a small but robust stylet which is first used to pierce the walls of root cells and then to withdraw food from the cytoplasm. This feeding behavior causes extensive destruction of root tissue along the path of the migrating nematode. Sedentary endoparasites (e.g., *Meloidogyne*, *Globodera*, and *Heterodera* spp.) have evolved very specialized and complex feeding relationships with their host plants, feeding from a single cell or a group of cells for prolonged periods of time. These nematodes invade roots as vermiform second-stage juveniles. Those of the *Meloidogyne* species move within the intercellular space in the cortex and those of the *Globodera* and *Heterodera* species migrate intracellularly within the root cortex. Further nematode development depends upon the elaborate modification of the phenotype of vascular cylinder cells to form specialized feeding cells that become the sole source of nutrients for the parasites.^[1,2] The association of feeding sites with the root vascular cylinder supports a more concentrated and

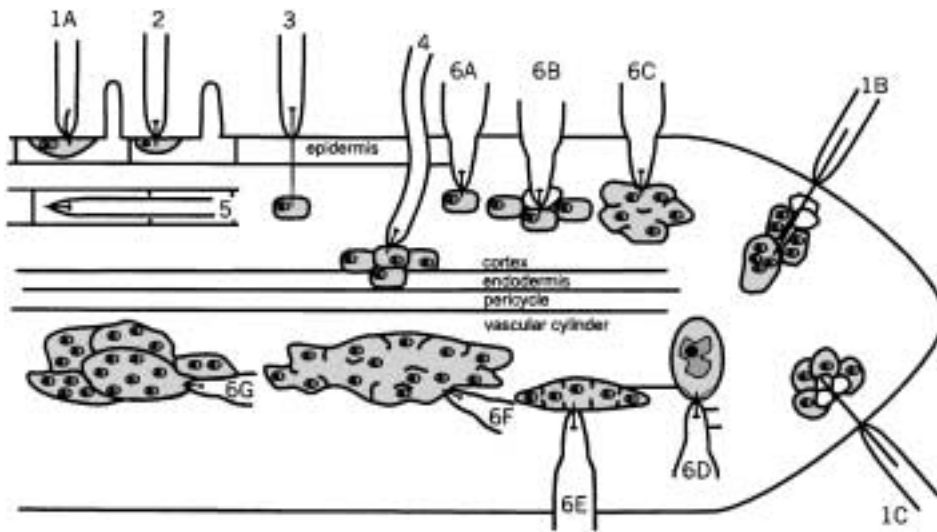

Fig. 1 Schematic representation of feeding sites of selected root-parasitic nematodes. 1: Dorylaimid migratory ectoparasites: 1A, *Trichodorus* spp.; 1B, *Xiphinema index*; 1C, *Longidorus elongatus*. 2–6: Tylenchid nematodes: 2: Migratory ectoparasite: *Tylenchorhynchus dubius*; 3: Sedentary ectoparasites: *Criconebella xenoplax*. 4: Migratory ecto-endoparasites: *Helicotylenchus* spp. 5: Migratory endoparasites: *Pratylenchus* spp. 6: Sedentary endoparasites: 6A, *Trophotylenchulus obscurus*; 6B, *Tylenchulus semipenetrans*; 6C, *Verutus volvingentis*; 6D, *Cryphodera utahensis*; 6E, *Rotylenchulus reniformis*; 6F, *Heterodera* spp.; 6G, *Meloidogyne* spp. (From Ref. 7.)

sustainable supply of nutrients. When feeding commences, the second-stage juvenile grows and becomes saccate and immobile. In this feeding strategy, destruction of root tissue is usually limited to cells around the feeding site and the endoparasitic nematode.

In addition to the protrusible stylet, plant-parasitic nematodes have a well-developed esophagus for feeding on plants. In tylenchid nematodes, which are the most important plant parasite group, the esophagus has a muscular metacarpus containing a triradiate pump chamber

Fig. 2 Fine structure of the *Criconebella xenoplax*–feeding cell relationship. A. Cross-section of a feeding cell (FC) in the cortex of a tomato root. The nematode stylet (S) penetrated between two epidermal cells (EC) and was inserted into the feeding cell without penetrating the plasma membrane (arrowhead). A zone of the cytoplasm of the feeding cell is modified around the stylet tip. A profile of the cell’s nucleus (N) is visible. B. Detailed view of the opening created in the plasma membrane (PM), which was invaginated around the stylet (S) tip when the membrane (arrow) became tightly appressed (arrowhead) to the wall of the stylet orifice. (From Ref. 8).

and three large and complex secretory gland cells.^[3] The transcriptionally active gland cells, one dorsal and two subventral, are the principal sources of the secretions involved in plant parasitism. During secretion, the gland cells release secretory proteins stored in granules into the lumen of the esophagus to be injected through the stylet into host tissue. Changes in the esophageal gland cells during the parasitic cycle indicate various roles for the gland's secretory proteins during different stages of parasitism. The nature of nematode esophageal gland secretory proteins and their function in parasitism is now beginning to emerge.^[4]

Nematode feeding from root cells is a very deliberate process and can be divided into distinct phases that include stylet insertion, injection of esophageal gland cell secretions, ingestion of nutrients, and stylet retraction.^[1] The feeding phases of migratory and sedentary parasites are similar, but each phase—and particularly nutrient uptake—is considerably longer for the sedentary than for the migratory feeders. When a potential feeding site is selected by the nematode, the wall of the root cell is penetrated by the stylet, which remains protruded and in contact with the cell cytoplasm during the secretion and ingestion phases. During the secretion phase, secretory proteins synthesized in the esophageal gland cells pass through the stylet into the parasitized cell. After cessation of the secretion activity, rapid maximum dilation of the metacorporeal pump chamber creates the suction necessary for the nematode to withdraw nutrients from the cytoplasm of the feeding cell through the stylet lumen. When the metacarpus ceases pumping to terminate the ingestion phase, the stylet is retracted from the plant cell to end the feeding cycle. However, the sedentary ectoparasitic and endoparasitic nematodes establish a prolonged biotrophic feeding association with the elaborate feeding cells they induce.^[1,2] During feeding, the sedentary nematode inserts its stylet through the wall of the parasitized cell without piercing the plasma membrane, which becomes invaginated around the stylet tip. Initially in the feeding cycle, esophageal gland cell secretions that may modify the cell are injected through the stylet. Certain species (e.g., *Criconemella xenoplax* (Fig. 2)) take up cytosol of the parasitized cell directly through a minute perforation created in the plasma membrane at the stylet orifice, while others (e.g., root-knot or cyst nematodes (Fig. 3)^[8]) ingest nutrients through a feeding tube.^[5,9]

Feeding tubes are formed within the cytoplasm of parasitized root cells from stylet secretions injected by sedentary endoparasitic nematodes (*Globodera*, *Meloidogyne*, *Heterodera*, *Rotylenchulus* spp.). These unique structures are used by the nematode to efficiently withdraw nutrients from the feeding cell. Feeding tubes formed by *M. incognita* females are 1 μm wide and up to 110 μm long with a uniform lumen of approximately 450 nm diameter (Fig. 3).^[5] The distal ends of feeding tubes are

Fig. 3 Feeding tubes formed by *Meloidogyne incognita*. A. Nomarski light micrograph of a cryosection of a giant-cell (GC) from the root of a tomato plant infected by root-knot nematode. One long feeding tube (FT) and sections (arrowheads) of other feeding tubes are visible in the cytoplasm. A section of the head of the adult female nematode (N) that was feeding from the giant-cell is visible. Bar at A = 20 μm . B. Longitudinal section through a feeding tube (FT) with its proximal end attached to a wall ingrowth (WI) where the nematode's stylet penetrated the cell wall (CW) of a giant-cell in a tomato root. Bar at C = 0.5 μm . (From Ref. 5.)

closed. The sedentary endoparasitic nematodes feed in cycles from the modified cells and a new feeding tube is formed each time the nematode reinserts its stylet into the parasitized cell to initiate a new feeding cycle. Feeding tubes are formed from dorsal gland cell secretions injected into the cytoplasm of the parasitized cell through a pore in the plasma membrane. Feeding tubes function in facilitating the transport of soluble nutrients from the cytosol of the feeding cells to the stylet orifice. For *M. incognita*, which inserts its stylet only 2 to 3 μm through the wall of the feeding cell without piercing the plasma membrane, the long feeding tube provides the nematode access to more of the cytoplasm of the feeding cell than would be accessible if the nematode used only its stylet to

withdraw nutrients. The sealed distal end of the feeding tube and the lack of noticeable wall perforations suggest that the wall of the feeding tube is permeable to soluble assimilates. Microinjection studies, in fact, show that feeding tubes function as a molecular sieve during ingestion of nutrients from the feeding cell by the nematode.^[6]

K. Dong

California Department of Food and Agriculture, Sacramento, California, U.S.A.

INTRODUCTION

There is in general an inverse relationship between initial nematode population densities and annual plant growth and crop yield. This relationship results in nematode population assessment being crucial for their management. Assessing nematode populations often involves an initial diagnosis and quantification of diverse kinds and numbers present, after which specific taxa within the nematode community may be monitored. The diversity of nematode species with different morphology, modes of reproduction, survival mechanisms, and feeding habitats increases the challenges of this endeavor.

DISCUSSION

Nematodes that attack higher plants are obligate parasites, and a number of important species within certain genera may vector plant viruses. Ectoparasitic nematodes feed from the outside of plants by inserting stylet into root tissue. Some of these nematodes may become sedentary and may feed on a specific group of cells for an extended period of time, whereas others are browsers and move frequently about the root surfaces as they feed. The latter nematodes are migratory ectoparasites. In contrast, other nematodes invade plant tissues where they feed internally. Nematodes that move throughout cortical or other tissues are called migratory endoparasites, whereas the sedentary endoparasites induce elaborate modifications of certain cells, giving rise to highly specialized feeding sites that are essential for nematodes' life cycles (Fig. 1).

Nematode infestation of soil and infection of plants may be assessed by sampling associated soil and/or plant tissue and extraction of the nematodes from those samples. Infected plant tissue also may be stained to render endoparasitic nematodes readily visible via microscopy. An effective nematode assessment should be accurate, rapid, simple, sensitive, and quantitative at the species/subspecies level. Light microscopic examination of extracted specimens is still the primary means of species identification and quantification. Nematode spe-

cies identification generally is based on rather specific morphological structures.^[1,2] However, differential plant-host responses and biochemical and molecular characteristics are becoming increasingly important for nematode diagnosis; the integration of these techniques with traditional morphological data is ongoing.^[3-7]

SIGNS AND SYMPTOMS

The facts that most plant-parasitic nematodes are microscopic, inhabit the soil, and induce relatively nonspecific plant symptoms add to the challenges encountered in assessing their infestation. Assessment of nematode pathogens that attack stem or foliage tissues is less difficult but requires awareness of the potential for this type of disease agent. Thus, associated symptoms and signs of nematode infection are often helpful in initial phases of assessing related maladies. Foliage-infecting nematodes induce specific aboveground symptoms. For example, *Aphelenchoides besseyi* incites the development of pale yellow or white leaf tips on rice, whereas *Ditylenchus dipsaci* causes extensive distortions and swellings of infected tissues on alfalfa and other crops. The key general symptom of nematode infestation is irregular growth patterns within a field and/or a general decline and dieback. The latter often occurs on perennial crops such as fruit trees or ornamentals, e.g., *Radopholus similis* on banana or citrus trees.

Belowground symptoms of nematode infection range from large root galls induced by *Meloidogyne* spp. to root-surface necrosis caused by the migratory endoparasite *Pratylenchus* spp. Surface lesions are also caused by ectoparasites such as *Xiphinema* spp. and *Belonolaimus longicaudatus*. Some of the ectoparasitic nematodes, including *Paratrichodorus minor*, induce characteristic modifications of root size and shape, such as stubby roots. Signs of nematode may include structures such as cysts of *Heterodera* and *Globodera* and egg masses of *Meloidogyne* and *Rotylenchulus*, both of which can be observed on plant roots without a microscope. Thus, an initial assessment might include foliage or root signs and

(From Ref. 2.)

symptoms. Sample collection, extraction, and identification of key nematode species, however, should follow this type of preliminary assessment.

SAMPLING

A representative sample is crucial for qualitative and quantitative assessment of nematode infestation, whether soil or plant tissue.^[3,8] An excellent sample also is essential for molecular-based as well as traditional nematode-assessment procedures. Generally, a pre-determined number of subsamples of soil is collected with a cylindrical sampling tube and bulked before extraction. The exact number of subunits (cores) is determined for a given area by the purpose of the assessment. For example, soil samples composed of 20 to 30 subunits from 2 hectares (ha) may provide assessments that fall within

50% of the mean of the population levels. However, much greater sample numbers and volume of soil are needed for highly precise assessments.^[9] The timing of sample collection is even more critical for securing meaningful data. In temperate and tropical regions, populations of nematodes, especially *Meloidogyne* spp., decline sharply in the absence of a host. Thus, detection failures may be encountered for certain nematodes unless sampling is performed within the root zone at mid to late summer, at harvest, or within a few weeks after harvest. The timing of sampling is less critical for cooler regions where population decline is less severe and with cyst nematodes.

EXTRACTIONS AND BIOASSAYS

The biology and life cycle must be considered in selecting the specific extraction procedures (Fig. 1). Assessments of

infestation of ectoparasitic nematodes are limited to soil extractions, whereas most affected soil and/or plant tissue may be assayed for endoparasites. Life stages that occur in soil and/or in plant tissue range from mobile to quiescent forms and include juveniles, adults, cysts, individual eggs, egg masses, and various combinations. Numerous methods for extracting nematodes are available.^[1,3,8,10] For most extraction procedures, nematodes are separated from soil by a combination of flotation and sieving, or they are encouraged to emerge from plant tissues by being placed in a wet environment. Specialized extraction procedures are also available for assessing nematode eggs (especially in those highly damaging species, *Meloidogyne*, *Globodera*, and *Heterodera*^[8,10]).

An appropriate host plant can be used in performing a bioassay for assessing low-level infestations, genetic variants, or related host resistance, and for assessing nematicide efficacy for highly aggressive nematodes, including species of *Meloidogyne*, *Globodera*, and *Heterodera*.^[8] Bioassays are invaluable in assessment of nematode races/pathotypes that may attack given sources of host resistance. For an immediate assessment of potential tissue infection by these parasites, a tissue stain such as acid fuchsin-glycerin or cotton blue-glycerin greatly enhances the visibility of endoparasites via microscopy. The gelatinous egg matrix or egg mass produced by *Meloidogyne* spp. may be stained with phloxine B to facilitate the quantification of these structures on plant roots.^[8]

NEMATODE IDENTIFICATION

For a detailed treatment on species identification, the reader is referred to the earlier article by J. G. Baldwin that addresses classification and identification of nematodes. Currently, identification of these parasites is based largely on morphology and in some instances on cytology, host response, biochemistry, and molecular diagnostics. As discussed earlier, symptoms and signs on plants may be characteristic of certain nematode species, but identifications should be confirmed by more precise criteria. In addition to nematode morphology, differential host tests are important for assessing infestation of certain nematode species. For many root-knot nematode populations, the North Carolina differential host test has been used widely to differentiate the common species *M. arenaria*, *M. hapla*, *M. incognita*, and *M. javanica*, as well as related host races. This system is especially useful for cropping systems that include peanut, cotton, corn, soybean, and tobacco. In another widely used host-nematode system, 16 host races of *Heterodera glycines*, based on four soybean-

genotype differentials, are central to characterizing genetic variants in given fields and facilitating the development of new breeding lines/cultivars with resistance to this pathogen. The subspecies designation system for *H. glycines* was recently revised to include seven host differentials with field populations placed in "HG Types."^[11]

APPLICATION OF BIOTECHNOLOGY IN NEMATODE ASSESSMENT

After more than a century of taxonomic research on nematodes, only an estimated 10% of all nematode biodiversity has been characterized, primarily morphospecies.^[4] Although morphology continues as the primary focus in nematode identification, protein and nucleic acid analyses offer much for the future. These emerging approaches to assessment and characterization of nematode species and populations offer much for advancing our understanding of nematode biodiversity, general ecology, and population assessment for management and regulatory purposes. Molecular methods for nematode identification could be more objective and reliable than traditional systems. Also, molecular probes may be suitable for any life stage present in a sample.

Electrophoretic enzyme phenotypes have proven to be a practical means for identifying species and/or subspecies of *Anguina*, *Meloidogyne*, *Globodera*, *Heterodera*, and *Radopholus*.^[3,5] The utility of identification of the common *Meloidogyne* species using isozyme phenotypes has been particularly effective in the root-knot nematode research projects. For example, *M. arenaria*, *M. incognita*, *M. javanica*, *M. mayaguensis*, and *M. naasi* can be distinguished via esterase phenotypes. Differential esterase alleles also have proven useful for demonstrating multiple matings among inbred lines of *H. glycines* as well as tracking crosses of certain inbred lines of that species. In addition to the isozyme phenotypes, differences in 2-D protein patterns have proven useful for separating species and infraspecies or variants of *Globodera*, *Heterodera*, and *Meloidogyne*. Unique proteins are available that could be used to develop serological kits for detection.^[7] Monoclonal and/or polyclonal antibodies have been developed for *Bursaphelenchus*, *Ditylenchus*, *Globodera*, *Heterodera*, and *Meloidogyne*. For example, species-specific proteins were used to develop monoclonal antibodies for distinguishing *Globodera rostochiensis* and *G. pallida* in immunoassays.^[6] These monoclonal antibodies, in addition to separating the two species when used in an ELISA, have potential for the quantitative determination of potato cyst nematodes in soil samples. This technology

has great potential for use in regulatory as well as diagnostic and management programs.

The range of techniques now available for studying DNA has resulted in much progress in characterizing genomic, mitochondrial, and ribosomal DNA of nematodes. In addition to advancing our understanding of nematode phylogenetic relationships, this rapidly expanding information also provides useful tools for nematode diagnostics (Fig. 2). For molecular diagnostic assess-

Fig. 2 Electrophoretic patterns from Meloidogyne species. A) RAPD patterns from primer AAAACCGGGC showing variation among nematode species and populations. The 26 tested isolates from left to right were three *M. hapla* (Mh) (VA, NC, WI); seven *M. arenaria* (Ma) (Canada race 2, GA race 1, SC race 2-Florence, NC race 2-EM, SC race 2-Govan, SC race 2-83, SC race 2-Rawl); five *M. javanica* (Mj) (NC, FL, AZ1, AZ2, GA); and 11 *M. incognita* (MI) (NC race 1, NC, race 2, NC race 3, NC race 4, TN, NC-cotton IA, GA, SC-Cotton, SC-Edisto, NC3-99); B) Specific-specific PCR patterns from *M. arenaria* primer pair (Ma-f TCGAGGGCATCTAATAAAGG and Ma-r GGGCTGAATATTCAAAGGAA). The same 26 nematode populations tested in Fig. 2-A were utilized in this test. (From Ref. 12.)

ments, the objective is to obtain low-cost, user-friendly, reliable molecular data that distinguish nematode species or subspecies levels.^[3,5,6,12] The DNA techniques developed and utilized in the diagnostic purposes include amplified fragment length polymorphisms (AFLP); specific oligonucleotide probe; microsatellite and repetitive DNA; polymerase chain reaction (PCR) and multiplexed PCR; randomly amplified polymorphic DNA (RAPD); restriction fragment-length polymorphisms (RFLP); ribosomal DNA (rDNA) intergenic (IGS) and internally transcribed (ITS) spacer region PCR-RFLP and sequence; sequence-characterized amplified region (SCAR); sequence tag site (STS); and variable number tandem repeat (VNTR). In addition to assaying the sedentary endoparasite nematodes *Globodera*, *Heterodera*, *Meloidogyne*, *Nacobbus*, and *Cactodera*, specific DNA diagnostic methods have also been applied to migratory ecto- and endoparasites such as *Anguina*, *Belonolaimus*, *Bursaphelenchus*, *Criconebella*, *Ditylenchus*, *Hoplolaimus*, *Helicotylenchus*, *Pratylenchus*, *Radopholus*, and to the virus vector nematodes *Longidorus*, *Trichodorus*, and *Xiphinema*.^[3,5,12]

CONCLUSION

Based on the ongoing molecular characterization of nematode-plant interactions, the above approaches should prove fruitful for species and population-level assessment of these important crop pathogens.

Nematodes: Parasitism Genes

Eric L. Davis

North Carolina State University, Raleigh, North Carolina, U.S.A.

INTRODUCTION

Secretions from the stylet (hollow mouth spear) of phytonematodes mediate the process of plant parasitism, including nematode penetration and migration within host plant roots, and dramatic transformations of plant cells into permanent feeding sites for the nutrition of sedentary nematode life stages. The stylet secretions are produced in three elaborate esophageal gland cells that have evolved to enable plant parasitism by tylenchid nematodes. The genes expressed within the gland cells that encode the stylet secretions are termed parasitism genes. The nature and number of parasitism genes in phytonematodes identified to date has been somewhat surprising, and includes significant evidence that phytonematodes may have acquired some of their parasitism genes from other organisms.

PARASITISM GENES

The primary morphological adaptations of nematodes for parasitism of plants include a protrusible stylet (hollow feeding spear) connected to three elaborate esophageal secretory gland cells (Fig. 1). These adaptations allow nematodes to feed on plant cells directly from outside plant roots (as ectoparasites) in soil or to penetrate plant roots (as endoparasites) to modify and feed from internal plant tissues (see R. S. Hussey, this volume). Although the genes that control the formation of the stylet have evolved to promote plant parasitism, it is the genes that encode the secretions synthesized in the esophageal gland cells that control the dynamic interaction of the nematode with its plant host.^[1,2] Changes occur within sedentary nematodes during plant parasitism—including atrophy of the two subventral esophageal gland cells shortly after feeding site formation—and the concomitant increase in the size and activity of the single dorsal esophageal gland cell (Fig. 1). Products from the nematode gland cells may be secreted through the stylet (Fig. 2) into plant tissues for relatively simple feeding processes such as the predigestion of plant cell contents by some ectoparasitic nematodes, or for the complex processes of plant tissue penetration and feeding site formation by some sedentary endoparasitic nematodes. The potential range of functions of nematode

secretions and their regulated expression during plant parasitism make the genes that encode nematode esophageal gland secretions the primary parasitism genes of plant-parasitic nematodes.^[1]

The isolation of nematode stylet secretions to analyze their components has been difficult because the nematodes are microscopic in size and they are obligate parasites. Monoclonal antibodies have been generated that bind to specific secretory proteins within the esophageal gland cells of both cyst and root knot nematodes (Fig. 2), and the antibodies have demonstrated that the proteins can be secreted through the nematode stylet and that the gland cell secretions change during the course of plant parasitism.^[1] One gland-specific monoclonal antibody was used to immunoaffinity-purify a protein produced in the subventral esophageal gland cells of both the soybean cyst nematode (*Heterodera glycines*) and the potato cyst nematode (*Globodera rostochiensis*). The amino acid sequence of the purified gland protein was used to design degenerate oligonucleotides to obtain cyst nematode complementary DNA (cDNA) clones from the cyst nematodes that encode the subventral gland protein. Database searches indicated that the cDNA clones encoded β -1,4-endoglucanases (cellulases)—the first endogenous cellulases to be isolated from animals.^[3] It was further demonstrated that the cellulases could degrade a carboxymethylcellulose substrate,^[3] that the cellulases are secreted into plant tissues (Fig. 3) by cyst nematodes,^[4] and that the cellulases are expressed exclusively within the cyst nematode subventral gland cells only during the motile life stages.^[5] Interestingly, β -1,4-endoglucanases (and likely other cell wall-modifying enzymes) of plant origin are upregulated in nematode feeding sites when the nematodes become sedentary.^[6] The data strongly supported a role for cellulase secretion by cyst nematodes to facilitate their penetration and intracellular migration in plant roots but not for feeding site formation. One striking feature of nematode cellulase genes was their strong similarity to bacterial cellulase genes and relatively weak similarity to cellulases of eukaryotic origin or to any genes identified in the model nematode *Caenorhabditis elegans*.^[7] Because the nematode origin of the cellulases was confirmed by both in situ localization studies and analyses of nematode cellulase genomic clones, microbial contamination was ruled out. It has been postulated that one

potential origin of the cellulase genes in plant-parasitic nematodes was ancient horizontal gene transfer from prokaryotes.^[1,3]

Cloning of several other genes encoding secretions from the esophageal gland cells of plant-parasitic nematodes supports the hypothesis that some nematode parasitism genes—particularly those expressed in the

subventral gland cells—may have been derived via horizontal gene transfer. Subtractive hybridization procedures were used to enrich a pool of cDNA clones from the root knot nematode, *Meloidogyne javanica*, for genes expressed in the esophageal gland cell region.^[8] One gene that was demonstrated to be exclusively expressed in the esophageal gland cells of *M. javanica* during plant parasitism was homologous to bacterial chorismate mutase.^[8] The nematode chorismate mutase gene was able to complement function in a bacterial chorismate mutase-deficient mutant. A cDNA clone derived from the parasitic stages of *Meloidogyne incognita* by RNA

fingerprinting encoded a predicted cellulose-binding protein with homology to bacterial cellulose binding domains, and its expression was localized within the nematode's subventral esophageal gland cells.^[9] Genes from cyst nematodes that encode the cell wall-degrading enzyme pectate lyase are also expressed in the subventral gland cells of infective stages, and the nematode pectate lyases have their greatest similarity to pectate lyases of bacteria and fungi.^[10]

Although the examples of potential horizontal acquisition of some nematode parasitism genes have been unexpected, the likelihood that some endogenous nematode genes have evolved roles in plant parasitism is great.^[1] It is also clear that large-scale isolation and identification of genes expressed in parasitic nematodes is a more efficient and comprehensive way to isolate parasitism genes than to isolate and purify secreted nematode proteins. Expressed sequence tags (ESTs) provide partial sequence of random cDNA clones from a given library, which can be used for homology searches and genome-mapping efforts. cDNA libraries can be generated from whole nematodes of any chosen life stage for direct EST analysis, but the identification of potential parasitism genes (i.e., gland genes) becomes difficult unless the random sequences provide an obvious database homologue (i.e., cellulase, pectinase, etc.). One strategy to narrow the search for parasitism genes is to differentially compare genes expressed in whole nematodes between preparasitic and parasitic life stages—to see what genes are turned on in the nematode during parasitism. This was the basis of the RNA fingerprinting strategy that isolated the cellulose-binding gene expressed in the subventral gland cells of *M. incognita*.^[9] It also has been observed that the activity and contents of the esophageal gland cells of *G. rostochiensis* change in preparation for plant parasitism when infective juveniles are incubated in potato root diffusate (PRD). A cDNA-AFLP method was used to compare genes expressed in juveniles that were incubated in water and juveniles that were incubated in PRD, and a number of genes specifically upregulated in *G. rostochiensis* from PRD treatment were isolated and confirmed to be expressed specifically within the nematode's esophageal gland cells.^[11]

A tissue-specific way to isolate nematode parasitism genes is to directly target the genes expressed within the nematode esophageal gland cells. The chorismate mutase gene (mentioned earlier) expressed in the gland cells of *M. javanica* was isolated by differentially screening cDNA from sections of nematode esophageal gland regions and (glandless) tail regions that were manually dissected.^[8] However, the most direct method has been to exclusively microaspirate the contents of nematode esophageal gland cells and use the gland cell mRNA in RT-PCR to create gland cell cDNA libraries.^[12,13] Contents of the esopha-

geal gland cells microaspirated from mixed parasitic stages of *H. glycines* were used to generate a cDNA library that profiled gene expression in the gland cells during the entire parasitic process. Gland cell cDNA clones that contained a secretion signal peptide were selected using a specialized vector in yeast, and 14 unique secretory *H. glycines* gland cell cDNA clones were identified.^[12] mRNA in situ hybridization was used to demonstrate that a number of the clones were specifically upregulated within the dorsal gland cell of parasitic stages of *H. glycines* (Fig. 3), but not within preparasitic stages. Another gland-cell cDNA library prepared similarly from mixed parasitic stages of *H. glycines* was used in suppression subtractive hybridization (SSH) against cDNA from the tail region to yield 23 unique clones from the gland cell library.^[13] A LD-PCR cDNA library prepared from the same *H. glycines* gland cell cytoplasm was used to obtain full-length clones of the gland cell cDNAs. Sequences of the full-length clones indicated that 10 unique cDNA clones contained a predicted signal peptide, and mRNA in situ hybridizations demonstrated that four of the clones with signal peptides were expressed specifically within the esophageal gland cells of *H. glycines*.^[13]

The initial attempts (discussed earlier) to select genes from the *H. glycines* esophageal gland-cell cDNA libraries suggest that the libraries are an enormous source of potential nematode parasitism genes—worthy of extensive EST analysis without prior selection. Bioinformatics development and analysis will be a key component to deduce potential nematode parasitism genes among the many clones, and a scheme to prioritize candidate parasitism genes has been developed. Database homology searches using the Basic Local Alignment Search Tool (BLAST) algorithm may immediately suggest candidate genes with potential function in parasitism. cDNA clones that contain complete 5'-end sequence can be analyzed by the SignalP and PSORT II algorithms for the presence of signal peptides and predicted subcellular (i.e., extracellular) localization, respectively. These analyses provide a manageable number of cDNA clones for high-throughput mRNA in situ hybridization to confirm the expression of secretion genes within the nematode esophageal gland cells.^[12,13] For example, one *H. glycines* gland-cell library cDNA clone that had homology to a hypothetical *C. elegans* protein in BLAST analysis, and a second cDNA clone that had homology to a salivary proline-rich glycoprotein of *Rattus norvegicus*, both had predicted extracellular (secreted) localization by PSORT II and were confirmed to be expressed in *H. glycines* esophageal gland cells by in situ hybridization.^[13] In other cases, however, sequence of *H. glycines* gland-cell library cDNA clones provided no database homologues (i.e., pioneers) using BLAST analysis, yet the encoded peptides were

predicted to be secreted and were expressed exclusively within the dorsal esophageal gland cell of only parasitic stages of *H. glycines*.^[12]

CONCLUSION

As bioinformatic analyses are improved and functional assays for candidate nematode parasitism genes are developed in the near future,^[1] our understanding of the molecular basis of nematode parasitism of plants will accelerate. Knowledge of the function of nematode parasitism genes will present multiple targets for intervention in the parasitic process and lay the foundation for the development of novel strategies to reduce nematode damage to crops.

Nematode Population Dynamics

Robert McSorley

University of Florida, Gainesville, Florida, U.S.A.

INTRODUCTION

Population dynamics focuses on the rise and fall of nematode population numbers over time. Nematode population changes are somewhat predictable, although patterns vary depending on whether crops are annual or perennial. The host status of the crop to plant-parasitic nematodes is critical in determining rates of nematode buildup or decline. Many other biological, physical, and chemical factors affect nematode population dynamics. Knowledge of population dynamics is important in planning crop rotations and sequences with minimal nematode damage. However, much additional biological information may be needed to understand population dynamics in specific sites and situations.

IMPORTANCE OF NEMATODE POPULATION DYNAMICS

Plant-parasitic nematodes cause serious losses on many different crops, and in many instances, thresholds for damage to crops by nematodes have been estimated.^[1,2] Above the threshold population density—tolerance limit—the severity of nematode damage increases as population density increases.^[3] Properly collected soil samples can reveal the kind and number of nematodes present and indicate whether the threshold for damage has been exceeded. Although nematodes can be moved from place to place in soil or on equipment, they cannot migrate easily on their own. Therefore, the nematode population density in a site is unlikely to be changed much by immigration or emigration, and population growth or decline within the site determines most future trends in nematode population levels.

NEMATODE POPULATION GROWTH OVER TIME

If population density of a plant-parasitic nematode on a favorable host crop is plotted over time, population growth may follow a logistic growth curve (Fig. 1). Individual points typically show deviation from the theoretical logistic curve due to sampling error. Popula-

tion growth from low initial densities may be quite rapid, approaching exponential growth.^[4,5] Ultimately, population growth slows and population density levels off as a carrying capacity—or equilibrium density (E)—is reached.^[5] Fluctuations in population growth may be particularly severe as E is first approached, with population density stabilizing over time.

Annual Crops

On an annual crop, the population growth curve (Fig. 1) may correspond with the life cycle of the crop. Once the crop is removed or the roots deteriorate, population levels may fall due to lack of a host or may increase to even greater levels if the next crop planted is a better host and has a greater E value. Over a long period of time, nematode population densities will appear as a sequence of peaks and valleys, increasing to the equilibrium densities appropriate for favorable crops and conditions, and decreasing if poor hosts are grown or during winter or fallow periods.

Perennial Crops

Long-term fluctuations in nematode population levels occur on perennial crops as well. Seasonal growth flushes of active feeder roots provide feeding sources for nematodes and opportunities for population growth. Populations may decline as older roots senesce or as plants approach winter dormancy. Because a root food source may be present most of the time, it is difficult to determine whether nematode population fluctuations are influenced directly by key environmental factors such as temperature and moisture or indirectly by the effect of these factors on root growth.

NEMATODE HOST STATUS

An impression of the host status of a crop cultivar relative to a particular nematode species can be obtained by examining the relationship between the initial population density (P_i) and the final population density (P_f) reached after a constant time interval. The life span of an annual crop is often used as a convenient time interval. If $P_f > P_i$, then the nematode population has increased on that crop,

Fig. 1 Typical relationship between nematode population density and time for a series of points, showing smooth logistic growth curve. E =equilibrium density (dashed line).

and the crop could be considered a host of the nematode. A comparison of P_f/P_i for a group of different crop cultivars could be used to provide a comparison of which cultivars were good hosts or poor hosts. However, the relationship between P_f and P_i may be too complex to make such straightforward comparisons.^[5] If the natural logarithm of P_f is plotted against the natural logarithm of P_i across a range of different P_i , a curved relationship typically results, leveling off at E (Fig. 2). At a very low P_i , a cultivar may appear to be a good host ($P_f > P_i$), but at a very high P_i , the same cultivar may appear to be a poor host ($P_f < P_i$). The potential for population increase is much greater if P_i is low than if P_i is near E . Therefore, relative comparisons of host status must be made at constant P_i and over a constant time interval. The designation of cultivars as good host, intermediate host, or poor host is relative, and depends on the shape of the relationship between P_f and P_i .^[5]

FACTORS AFFECTING POPULATION DYNAMICS

A variety of biological factors affect nematode population dynamics. The genetics, degree of resistance, and resistance mechanisms available are essential features of the crop cultivar that affect its host status to nematodes. The responses of the same nematode species on the same crop cultivar may differ from place to place due to genetic and physiological variation among nematode populations. Recognized biotypes, races, or pathotypes are known in a number of important nematode genera including *Heterodera*, *Globodera*, and *Meloidogyne*.^[6] But even when biotypes are not recognized, isolates (populations from different sources) of the same species may respond differently in their virulence and population growth.

Predators, parasites, and competitors all have the potential to affect nematode population dynamics and change the equilibrium density for a particular situation. When fungal parasites or other nematode antagonists are present, population densities of plant-parasitic nematodes stabilize to lower levels than those present in soils without antagonists or in soils from which antagonists have been removed.^[7]

A number of physical and chemical soil properties affect nematode dynamics to varying degrees. These include texture, pH, organic matter, salinity, aeration, bulk density, nutrient status, as well as moisture and temperature.^[4] Rainfall and soil type interact to determine soil moisture, which greatly affects nematode activity. Activity and population growth may cease or decline as soil conditions become too dry or too cool. Nematode population growth is directly related to temperature as well as time. Therefore, the use of heat units or degree days often provides a forecast of population growth more accurate than the use of time alone.^[4]

POPULATION DYNAMICS AND NEMATODE MANAGEMENT

Many agricultural practices are used to suppress nematode population levels.^[2] The use of crop rotation and cover crops for nematode management is based on the disruption of nematode population cycles. By understanding the relative degree of buildup or decline on various crops, an optimum crop sequence can be planned for minimizing nematode impact. The P_f at the end of one crop becomes the P_i for the next crop planted in the site, and so forth. Winter or fallow periods must be included as well,

Fig. 2 Typical relationship between the natural logarithm of final nematode population density (P_f) and logarithm of initial population density (P_i) for a series of points, showing smooth curve. E =equilibrium density (dashed line).

because they result in population decline ($P_f < P_i$). Using this approach, simple models of crop sequences and nematode dynamics over time can be constructed.^[4] Models forecasting population dynamics are available for a number of plant-nematode systems.^[4]

With perennial crops, methods may be directed toward minimizing equilibrium densities of plant-parasitic nematode over time. This may be accomplished by use of resistant rootstocks, if available. The task is more difficult with susceptible perennials, but plant-parasitic nematode numbers in orchards of various fruit crops were suppressed or stabilized at relatively low levels when natural enemies were present.^[7] Efforts to conserve and enhance the naturally occurring antagonists that are common in agricultural soils have focused primarily on the use of appropriate organic amendments, tillage practices, and cover crops, but much remains to be learned in this area.^[2,7]

CHALLENGES

Measuring changes in nematode population levels and forecasting population growth over time requires sampling to determine P_i and other critical population estimates. The difficulty and variability involved in nematode sampling is well-known, and so estimates of P_i may be associated with substantial error. If P_i values measured with error are used in population dynamics equations and models, the error of the estimate may be magnified over time. Therefore, periodic sampling of nematode population densities in future crops and sequences is useful to be sure that forecast estimates are not drifting far from reality. Alternatively, a more complex and stochastic approach could be used, providing model output as probability distributions or ranges rather than mean population densities.^[4]

The greater limitation in applying population dynamics in nematode management is the relative lack of specific information on the dynamics of particular nematode species and isolates on specific crop cultivars. Furthermore, the nematode-host relationship varies with local agricultural practices and environmental conditions. This type of highly specific information is required to better anticipate nematode population changes and design appropriate management strategies.

CONCLUSION

Although deficiencies exist in our current knowledge of nematode population dynamics, new information is con-

tinually becoming available on nematode population response and host status on existing crop cultivars, new crop cultivars, and on potential and currently used rotation crops and cover crops. As concern over local variation in nematode isolates and dynamics increases, small on-site tests of host status and nematode buildup on candidate crop cultivars should become more frequent. As chemical nematicides become more limited, demand should increase for alternative practices such as resistant cultivars, rotation crops, cover crops, or allowing land to lie fallow. All of these alternative methods require a detailed understanding of nematode population dynamics to be used effectively.

Nematode Problems: Most Prevalent

Larry Duncan

University of Florida—IFAS, Lake Alfred, Florida, U.S.A.

INTRODUCTION

The phylum Nematoda (Nemata) comprises aquatic roundworms that occupy virtually all habitats on earth. Nematodes are the most numerous metazoans on earth and the phylum is one of the most species-diverse. It has been estimated that only 3% of a half-million species have been described. Nematodes are adapted to numerous life strategies with major trophic groups consisting of primary (plant parasites) and secondary consumers (bacterivores, fungivores, omnivores, predators, and animal parasites). They play a critical role in the fertility of agricultural soils as major contributors to nutrient decomposition in soil food webs, and their ubiquity makes them ideal organisms to study as biological indicators of soil processes. In contrast to the beneficial roles played by nematodes, all plant and animal species have nematode parasites. Parasitism of crop plants by some nematode species is of little economic significance, whereas others are among the most serious agricultural pests.

ECONOMIC IMPORTANCE

Crop losses due to nematodes vary by crop and region. Losses are difficult to estimate because plant-parasitic nematodes are microscopic soilborne organisms and damage frequently goes undetected. Most crop plants in a field are parasitized by several species of nematode, yet spatial patterns and population densities of damaging species are often poorly understood within fields and across regions.^[3] Average losses in the major food and forage crops worldwide have been estimated in the range of 11–14%.^[4] As for most pests, nematode damage to crops is greater in tropical than in temperate regions due to greater diversity and abundance of nematodes in the tropics. Average estimated losses to nematodes are also higher in less developed countries (13–17%) than in industrial countries (7–11%) due to a lack of management resources. For example, citrus yield loss to nematodes in Florida and California, where resistant rootstocks and nursery certification programs are used, do not exceed 5%,^[5] whereas average yield losses of 14% are reported from other regions of the tropics and subtropics.

SELECTED NEMATODE-CROP ASSOCIATIONS

Two classes, Secernentea and Adenophorea, are generally recognized in the Nematoda. The orders Tylenchida and Aphelenchida (Secernentea) contain plant-parasitic nematodes, as does the order Dorylaimida in the Adenophorea (Table 1). The mouthparts of all plant-parasitic nematodes are modified sclerotized structures known as stylets. The stylet functions much as a hypodermic needle, puncturing cells to secrete digestive enzymes and other chemicals into plant cells, and thereafter withdrawing cell contents (Fig. 1A). The generalized life cycle of these parasites is also similar, consisting of the egg, four juvenile stages, and the adult. However, feeding habits of plant-parasitic nematodes differ and are a means to categorize species based on general behavior.

Ectoparasites and Semi-Endoparasites

Genera such as *Criconomella*, *Helicotylenchus*, *Rotylenchus*, *Hoplolaimus*, and *Tylenchorhynchus* are found frequently in the rhizospheres of many types of plants. These nematodes remain in the soil or penetrate only partially into the root cortex as they feed on root epidermal or cortical cells. Frequently they produce no measurable effect on their plant hosts. However, species in these and other ectoparasitic genera are major pests of some crops. *Mesocriconema curvatum* (part of a group known as ring nematodes) is the most frequently encountered plant-parasitic nematode in Florida citrus orchards where it is of no economic significance. The closely related *Criconomella xenoplax* causes severe root pruning of peach trees, increases susceptibility of trees to bacterial canker by *Pseudomonas syringae*, and results in the disease complex peach-tree short life.^[6] More than 1.5 million peach trees were killed by the disease in South Carolina in the decade 1990–99, and the nematode affects orchards throughout the southeastern United States and to a lesser extent in California. *Hoplolaimus* spp. (lance nematodes) parasitize a wide range of plants with little effect; however, *Hoplolaimus galeatus* damages turfgrass, corn, and cotton in the eastern United States, and *Hoplolaimus columbus* is an even more serious pathogen

of cotton and soybean. *Scutellonema bradys* causes dry rot in stored yam tubers and causes major losses of this food staple in Africa, Asia, the Caribbean, and South America. *Helicotylenchus* spp. are among the most commonly encountered ectoparasitic nematodes worldwide, often in high numbers. There are few reports of significant damage by these nematodes with the exception of *Helicotylenchus multicinctus* on banana. The nematode is widespread throughout tropical America, Africa, the Middle East, and Asia, where it causes stunting, delayed fruit maturation, reduction of yield, plant toppling, and shortening of the productive life of the plant. Stinging nematodes, *Belonolaimus longicaudatus*, are widespread in the southeastern United States and occur also in parts of the U.S. Midwest

and California. In sandy soil, the nematode is highly pathogenic to a large number of agronomic and horticultural crops including cotton, potato, sweet potato, corn, turfgrass, strawberry, and citrus. The nematode can break resistance to Fusarium wilt in crops such as cotton. In addition to lesions in the root epidermis and cortex typical of feeding by ectoparasitic nematodes, stinging nematodes frequently feed at the root meristem where they may cause cessation of root growth (stubby root symptoms) and cell hypertrophy, resulting in swelling or small galls at the tips of roots (Fig. 1B).

The economic importance of ectoparasites in the Dorylaimida derives not only from direct damage to the plant root, but also from their ability to vector nepoviruses and tobaviruses responsible for numerous crop diseases (Table 2).^[7] Species of *Longidorus* (needle nematodes) also cause direct damage and yield loss in crops such as corn, strawberry, tobacco, sugarbeet, lettuce, and celery. *Xiphinema* spp. (dagger nematodes) are widespread and cause serious damage to citrus, stone and pome fruit trees, forest tree seedlings, strawberry, and numerous other crops. Stubby root nematodes (*Trichodorus* spp. and *Paratrichodorus* spp.) are widespread in many crops including sugarbeet, in which they cause Docking disorder, and potato, where they increase the incidence of corky ringspot (tobacco rattle tobavirus). All dorylaimid plant-parasitic nematodes have feeding habits and cause symptoms similar to those of stinging nematodes. Effective nematode management can be more difficult to

Table 2 Examples of virus diseases of crop plants and their nematode vectors

Vectors of nepoviruses	Virus	Partial list of susceptible crops
<i>Xiphinema americanum</i>	Cherry rasp leaf virus (CRLV)	Apple, peach, plantain, raspberry, cherry
	Tomato ringspot virus (ToRSV)	Raspberry, peach, cherry, almond, apple, blueberry, tobacco
	Peach rosette mosaic virus (PRMV)	Peach, grapevine, blueberry
	Tobacco ringspot virus (TRSV)	Tobacco, soybean, blueberry, cucurbits
<i>Xiphinema diversicaudatum</i>	Strawberry latent ringspot virus (SLRSV)	Strawberry, raspberry, celery, rose
	Arabidopsis mosaic virus (ArMV)	Raspberry, strawberry, cucumber, sugar beet, clover, hop, rose
	Grapevine fanleaf virus (GFLV)	Grapevine
<i>Xiphinema index</i>	Artichoke Italian latent virus (AILV)	Artichoke, chicory
<i>Longidorus apulus</i>	Cherry rosette virus (CRV)	Cherry
<i>Longidorus arthensis</i>	Tomato black ring virus (TBRV)	Artichoke, bean, cabbage, grapevine, lettuce, peach, potato, raspberry, tomato
<i>Longidorus elongatus</i>	Raspberry ringspot virus (RRSV)	Raspberry, artichoke, red currant, strawberry, gooseberry, grapevine, narcissus
<i>Longidorus macrosoma</i>	Mulberry ringspot virus (MRSV)	Mulberry
<i>Longidorus martini</i>		
Vectors of tobraviruses		
<i>Paratrichodorus</i> spp. and	Pea early browning virus (PEBV)	Bean, clover, pea
<i>Trichodorus</i> spp.	Tobacco rattle tobravirus (TRV)	Potato, gladiolus, pepper, narcissus, hyacinth, tulip

achieve for the dorylaimid species because reducing population numbers below levels that cause direct damage is often insufficient to prevent virus transmission.

Migratory Endoparasites

The most important groups of migratory endoparasitic nematodes are lesion nematodes (*Pratylenchus* spp.), burrowing nematodes (*Radopholus* spp.), and rice root nematodes (*Hirshmaniella* spp.). All life stages of the species in these groups are found within the roots of host plants where the nematodes migrate intercellularly (Fig. 1C). Secondary bacterial and fungal pathogens are important components of the damage resulting from lesions caused by migration of these nematodes. More than half of the world's rice fields have been estimated to be infested by the tropical *Hirshmaniella* spp., with up to 25% yield losses. *Radopholus similis* is another tropical species with more than 250 known plant hosts. With the exception of Sigatoka disease, it is the most important pest of banana worldwide.^[8] The nematode is also a serious pest of coconut, tea, and spices such as black pepper, ginger, and turmeric. The citrus race of the nematode causes spreading decline disease of citrus in Florida, where yield reductions >50% are common in the absence of nematode management. The many *Pratylenchus* spp. also often have wide host ranges, with species adapted to both temperate and tropical climates. Species such as *Pratylenchus penetrans*, *Pratylenchus scribneri*, and

Pratylenchus neglectus can damage a large number of tree fruit, vegetable, and field crops in temperate regions. An important interaction between *Verticillium dahliae* and *P. penetrans*, *P. scribneri*, or *Pratylenchus thornei* results in the potato early dying disease. *Pratylenchus coffeae* and closely related species are major parasites of coffeae, tea, yam, banana, and numerous other major crops throughout the tropics.

Sedentary Endoparasites and Semi-Endoparasites

All of these forms require complex physiological responses by the host plant to initiate and maintain permanent feeding sites.^[9] Juvenile nematodes penetrate roots and transform vascular or cortical cells into permanent nutrient transfer cells. Most of the juveniles then develop into sessile adult females that assume a variety of nonvermiform shapes. Frequently, masses of eggs are produced in a gelatinous matrix, usually on the root surface.

The root knot nematodes (*Meloidogyne* spp.) are the most economically important nematodes, worldwide. With over 2000 known host species, relatively few crops are not susceptible to serious damage by one or more species of *Meloidogyne*. Infested plants are easily recognized by galls caused by hyperplasia and hypertrophy of cells adjacent to the feeding cells (Fig. 1D). Widely distributed species such as *Meloidogyne incognita*, *Meloidogyne javanica*, *Meloidogyne hapla*, *Meloidogyne*

arenaria, and many others have broad host ranges on weeds and many field, vegetable, tuber, and ornamental crops. Fewer species (i.e., *Meloidogyne coffeicola* on coffee) are more limited in distribution and have few known hosts among crop species. In many crops (i.e., cotton and tomato), the incidence of Fusarium wilt and other soilborne diseases increase dramatically in association with root knot nematodes.

Host ranges of cyst nematodes (*Globodera* spp. and *Heterodera* spp.) tend to be narrow. An important adaptation by these nematodes is an ability of eggs to persist for long periods in the absence of hosts, protected within the body of the female, which forms a resistant cyst. Eggs hatch over a period of several years, and chemical cues from host plants stimulate eclosion of some species. The cyst also provides a very effective means of long-range dispersal by wind, through the alimentary process of birds, and on plant debris. Management of *Globodera rostochiensis* and *Globodera palida* on potato in Europe and elsewhere has been an ongoing research goal for more than half a century. *Heterodera glycines* is well recognized for the remarkable speed with which it spreads to become a limiting factor in soybean growing regions where it has inadvertently been introduced. *Heterodera trifolii* (clover), *Heterodera avenae* (cereal), and *Heterodera goettingiana* (pea) are examples of other important species, as is *Heterodera shachtii*, which has an unusually wide host range (sugarbeet and other Chenopodiaceae as well as many Cruciferae).

Nacobbus aberrans (false root knot nematode) is endemic in the Americas where it has a wide host range and is an important pest of potato in South America, tomato in Central America, and sugarbeet in North America. *Rotylenchulus reniformis* (reniform nematode) is a warm/temperate climate nematode with worldwide distribution. It has a semi-endoparasitic habit; the anterior of the female is embedded deeply in the root while the posterior end and egg mass remain visible on the root surface. It can survive long periods and be transported by wind in a dehydrated condition (anhydrobiosis). It has more than 300 known host plants and is an economic problem on many vegetables, legumes, and cotton.^[10] In contrast, the host range of the semi-endoparasite *Tylenchulus semipenetrans* (citrus nematode) is limited to a few species of woody plants. It is ubiquitous in citrus industries throughout the world where it causes the disease slow decline.

Parasites of Aboveground Plant Parts

Ditylenchus dipsaci is a parasite of stems, leaves, or bulbs of onion, garlic, alfalfa, clover, and oat. Stems of infected plants are short and swollen, oat stems tiller prolifically, and infected bulbs of onion and garlic often rot in storage. *Anguina tritici* is known as the seed gall nematode. It

transforms wheat and rye ovules into galls containing infective juveniles. Juveniles of *A. tritici* and *D. dipsaci* survive long periods (sometimes many years) between crops in an anhydrobiotic condition.

Aphelenchoides fragariae and *Aphelenchoides besseyi* cause serious losses in strawberry, in which they parasitize leaves and stems causing the disease spring crimp. When combined with the bacterium *Rhodococcus fasciens*, *A. fragariae* causes cauliflower disease on strawberry. *Aphelenchoides ritzemabosi* induces interveinal necrotic lesions in chrysanthemum and other ornamental plants. *Bursaphelenchus xylophilus* causes the devastating pine wilt disease and *Bursaphelenchus cocophilus* causes red ring disease of coconut. Both of these nematodes are transported to new hosts by insect vectors.^[11]

MANAGEMENT: CURRENT PROBLEMS AND PROSPECTS

As with all plant pests, some characteristics of nematodes pose special challenges for devising effective management systems.^[12] Growers must make management decisions before planting, because there are no remedial options for many nematode problems. However, soil or plant samples must be processed by trained personnel to identify and quantify nematode infestations. As a result, nematodes are monitored less frequently than pests that are readily recognized in the field, and monitoring is beyond the means of farmers in developing countries. The effectiveness of crop rotation to reduce nematode numbers can be compromised by nematodes with wide ranges of crop hosts, or by communities of multiple species with different host ranges, or by nematodes adapted to survive for many years in the absence of a host. Host plant resistance is commercially available for some sedentary endoparasitic nematodes, but not for most other species. Resistance-breaking race development within genera such as *Heterodera* and species shifts in genera such as *Globodera* and *Meloidogyne* commonly occur. A trend toward discontinuation of pesticide-based management tactics due to environmental concerns will likely increase nematode-induced losses in some crops until appropriate alternatives are developed.

Ongoing research is focused on development of new sources of resistance, farming systems that employ cultural practices to reduce nematode numbers and help crops tolerate nematode parasitism, and biochemical/genetic approaches to a variety of management needs.^[12] Since 1997, a few genes responsible for host resistance to nematodes have been cloned and sequenced.^[13] Genes and gene products involved in nematode parasitism are being discovered that will provide new means to disrupt the nematode life cycle. Numerous nematode species have

been characterized using DNA-based methods that will eventually provide growers rapid and simple diagnostic tools to better manage these serious pests.

Nematodes and Host Resistance

Philip A. Roberts

University of California, Riverside, California, U.S.A.

INTRODUCTION

Host resistance to nematodes can be classified in several ways. First, it is important to recognize that parasitic nematodes have finite host ranges. Host plants are susceptible to nematode infection and allow the nematode to feed, develop, and reproduce, using the plant cells and tissues as a substrate. Some nematode species have broad host ranges that include hosts from many diverse plant taxa. Other nematode species, often the more specialized types, have narrow host ranges limited to one or a few plant families. Thus, nematodes do not parasitize all plants. The nonhost plants of a nematode are ones typically immune or resistant in the broadest sense, such that many attributes of the morphology, physiology, and biochemistry of the plant render it unsuitable as a host and prevent the nematode from feeding, developing, and reproducing.

Host resistance is more narrowly defined by its characteristic of being a heritable trait conferred by one or more genes that renders a host plant resistant. That is, the nematode is unable to feed, develop, and reproduce on the resistant plant to some measurable extent compared to a susceptible host plant. The importance of host resistance lies in its ability to protect the plant from full-scale infection, and in preventing the nematode from multiplying its populations. In agriculture and horticulture, resistance is considered a highly valuable character that, through plant breeding, can be transferred into elite crop and horticultural cultivars, varieties, or rootstocks. Significant research effort is invested to identify and quantify nematode-resistance and -tolerance phenotypes in breeding materials, including wild relatives of crops, for use in plant breeding. Genetic and molecular characterization of resistance traits and the matching determinants of pathogenicity and virulence in nematode populations are an important part of the overall advancement of host resistance as a component of genetic improvement of crops and nematode pest management.

TERMS AND DEFINITIONS

Definitions of some important terms used in host resistance to nematodes are given here, and these have been

described in detail in several reviews.^[1–4] Broader discussions of terminology for use in general plant pathology are also available.^[5] Fig. 1 provides a pictorial representation of some common terms. Most plants are immune or nonhost to most nematodes, blocking root invasion, nematode development and reproduction, and plant injury. For example, root-knot nematodes (*Meloidogyne* spp.) avoid roots of Royal Blenheim apricot, rendering the tree immune. “Resistance” refers to the ability of a host plant to suppress development or reproduction of the nematode, and it can range from low to moderate (partial or intermediate) resistance, to high resistance. The term “resistance” is also used to describe the capacity to suppress the disease, especially root-knot. Partially or moderately resistant plants allow some intermediate levels of nematode reproduction. “Susceptibility” is used as the opposite of resistance. A susceptible plant allows normal nematode development to take place, as well as the expression of any associated disease (Fig. 1).

“Tolerance” and its opposite, “intolerance,” are used to describe the ability of the plant to withstand the damage resulting from nematode infection. Tolerant plants grow well despite the presence of heavy infection, whereas intolerant plants are injured and grow less well or even die when infected (Fig. 1). Typically, resistant plants are also tolerant and most susceptible plants are injured to some extent by most nematodes. However, resistance and tolerance are not always linked, being under separate genetic control in some plant-nematode interactions.^[4] A useful discussion of concepts of tolerance is given by Wallace.^[6]

Resistance defined by mode of inheritance can be monogenic (single gene), oligogenic (a few genes), or polygenic (many genes). These genes may be major genes (large effects) or minor genes (small effects) for phenotypic expression. Other descriptions of resistance follow Vanderplank’s^[7] classification of vertical resistance (race-specific or qualitative, differentiating intra-specific variants—races, pathotypes, or biotypes—of the pathogen) and horizontal resistance (race-nonspecific or quantitative, effective against all variants of the pathogen). Vertical resistance is usually simply inherited and conforms to a gene-for-gene type of plant-pathogen interaction.^[8] Horizontal resistance usually involves several genes with additive effects that express a quantitative

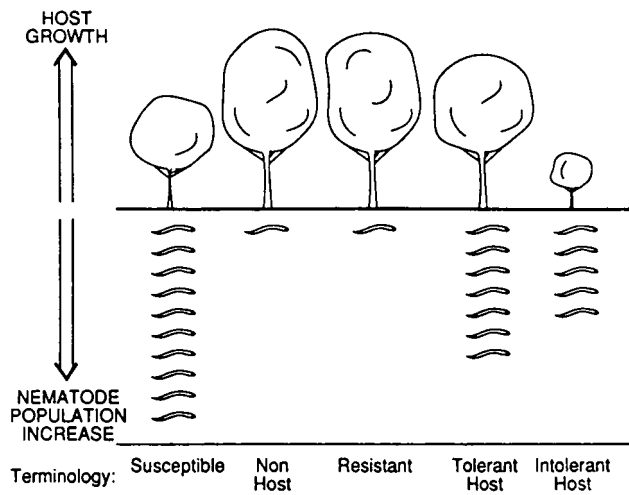

Fig. 1 Diagrammatic representation of terms describing plant growth response to nematodes and nematode reproduction on plants. (From Ref. 18.)

level of resistance. In general, quantitative resistance tends to be less likely to “break down” due to selection pressure operating on the nematode parasite population.^[9]

Genes for virulence in the nematode match resistance genes in the host plant. Virulent nematodes are able to reproduce, whereas avirulent nematodes are unable to reproduce on a host carrying a specific resistance gene(s).^[9] The frequency of virulent individuals in nematode populations will determine the potential for selection of virulence in the presence of resistant host plants. In plant pathology, the genes encoding this trait are typically called avirulence or Avr genes. Nematologists sometimes refer to avirulence genes as genes for parasitism or parasitism genes, but these terms also have broader meanings.^[2]

Several terms have been used to categorize the variation within a nematode species based on differential responses to a host or resistance trait. Their use is somewhat confusing because of the indiscriminate use of them for different nematode groups. For example “race” or “host-race” has been used for categorizing variations within soybean cyst nematode (*Heterodera glycines*); “pathotype” has been used for potato cyst nematodes (*Globodera pallida* and *Globodera rostochiensis*) and for cereal cyst nematode (*Heterodera avenae*); and “biotype” for variations within the stem and bulb nematode (*Ditylenchus dipsaci*). Triantaphyllou^[10] offered the term “biotype” as a biological unit consisting of “a group of genetically closely related individuals sharing a common biological feature or phenotypic trait,” in this case parasitic ability on given differential hosts. Field populations may consist of individuals of different biotypes, and combinations of biotypes comprising field populations could be designated as races. An individual nematode may be assigned to more

than one biotype, depending on the array of genes for avirulence that it possesses in relation to the genetic constitution of the host differentials used to classify the biotypes.^[10] Roberts^[11] adapted this biotype concept for categorizing variants within species of root-knot nematodes (*Meloidogyne* spp.) defined by reaction to resistance genes in different host plants.

AVAILABILITY OF RESISTANCE

The current availability and use of resistant cultivars and rootstocks for nematode management is well documented.^[1,4,9,12–14] Success has been achieved in a significant range of crops for identification of resistance, followed by incorporation into commercially acceptable crop varieties and rootstocks and implementation in management programs. Even so, a large genetic resource of nematode resistance remains to be developed in many crops. Examples of highly successful developments in nematode resistance include the use of the *Mi* gene in tomato and the use of the Nemaguard rootstock for *Prunus* crops (plums, peaches, nectarines, and almonds), both used against root-knot nematodes, and the *H1* gene in potato, used against potato cyst nematodes. These resistance traits are used widely, but they do not protect against all populations and species of the target nematodes. Thus, there continues to be a concerted effort to find additional resistance traits in these crops.^[9,14] Technical advances in marker-assisted breeding, resistance-gene cloning, and plant transformation, and in bioengineering novel types of resistance to nematodes will undoubtedly expedite development of nematode resistant crops.^[3]

Plant resistance has been developed mainly to the highly specialized parasitic nematodes such as *Globodera*, *Heterodera*, *Meloidogyne*, *Rotylenchulus*, *Tylenchulus*, and *Ditylenchus*, which (except *Ditylenchus*) have a sedentary endoparasitic relationship with their host. The resistance may be effective against nematode species of different genera, against more than one species from the same genus, against a single species, or against certain populations of a species.^[13] Resistance to less specialized parasitic groups such as the migratory endoparasitic genera *Aphelenchoides* and *Pratylenchus* has been developed only in a few cases, and also to a few ectoparasitic nematodes, for example, to *Xiphinema* in grapevines.^[15] This pattern of resistance reflects the co-evolutionary forces between host and parasite, the more highly specialized relationships having resulted in specific genes for resistance and parasitism.^[12] The root-browsing ectoparasitic nematodes, with less specific feeding requirements, apparently have not been a strong selection force for resistance in plant hosts in most interactions, although useful differences in resistance do occur.^[16] Recently, the

potential for bioengineering novel forms of resistance based on molecular approaches has gained considerable attention and holds much promise, particularly as technologies advance to enable a more streamlined approach, and some progress has been made in developing novel root-knot nematode resistance.^[17]

EFFECTS OF RESISTANCE

Resistance has two major attributes that contribute to its success in nematode management programs. These are the tolerance of most resistant plants to nematode infection, which imparts a “self-protection” characteristic to enhance growth and yield, and the suppression of nematode multiplication, which results in fewer nematodes in soil that could damage a following susceptible or intolerant crop planted in rotation.

Protection of Yield Potential

The impact of resistance and tolerance traits on crop yield can be quantified, and such knowledge can be used for predictive management approaches based on preplant sampling of nematode population densities in soil. The general relationship of relative yield to initial nematode density, called a damage function, has been defined according to the relative levels of resistance and tolerance and is depicted in Fig. 2^[12] For susceptible, intolerant crops, this relationship is linear except at very low or very

Fig. 2 Hypothetical damage functions (relationship between yield and initial nematode density) for crop cultivars possessing different nematode resistance and tolerance traits. RT = resistant, tolerant; RI = resistant, intolerant; ST = susceptible, tolerant; SI = susceptible, intolerant. (From Ref. 12.)

high population densities. Both the position and the slope of the curve will be governed by the relative tolerance of the particular cultivar. The ideal genotype is one that combines high tolerance with high resistance. The main advantage of this yield protection is that in many cases, the resistant crop can be grown successfully without additional inputs of nematode control. For many crops, resistance and the associated tolerance eases or eliminates the reliance on chemical controls with soil-applied nematicides. In perennial vine, tree fruit, and nut crops, the primary objectives of incorporating nematode resistance into acceptable cultivars and rootstocks are improved yield and longevity, and the majority of forms of resistance in these crops also confer the required tolerance to infection to meet these objectives.^[14]

Suppression of Nematode Populations

In annual cropping systems where from one to several crops per year may be grown on the same ground, nematode problems can be managed by including crops with different levels of resistance. Susceptible crops allow large increases in nematode populations, even from low initial population densities. The large population densities remaining after the susceptible crop often will be highly damaging to a following susceptible crop. Resistance, on the other hand, will suppress nematode multiplication to an extent determined by the level of resistance expressed in the plant. Resistance may be expressed at low, moderate, or high levels, and these expression levels will largely determine the nematode multiplication rate. Therefore, a susceptible crop planted after a highly resistant crop will be protected from nematode infection to a level that reduces or eliminates the need for additional nematode management inputs. These rotation benefits of nematode resistance have been demonstrated in several nematode-plant interactions in annual cropping systems, most notably for root-knot and cyst nematodes and their host crops.^[3] In practice, the use of host plant resistance in combination with other control tactics is encouraged, because field research has shown that resistance can break down through selection of virulent nematode populations. An integrated management approach will tend to lower the selection pressure for virulence that may occur when resistance is used alone, thereby promoting the durability of the resistance.^[3,9]

Nematodes: Ecology

Howard Ferris

University of California, Davis, California, U.S.A.

INTRODUCTION

Nematodes are among the most successful of multicellular organisms. They inhabit every environment imaginable. Although less diverse in number of species than some other phyla, they are incredibly abundant in number of individuals. An estimated four out of every five multicellular organisms on the planet are nematodes,^[1] surely a testament to their success and their ability to adapt physiologically and behaviorally to diverse habitats and niches. Cobb^[2] asserted that if all matter other than nematodes were removed, the outlines of geographic features, vegetation, and centers of habitation would be recognizable by the abundance and characteristics of nematode communities. That understanding has grown, and nematode community structure is now recognized as a powerful tool in the biomonitoring of soil history and condition.^[3] The ecology of plant and soil nematodes can be considered at several levels of resolution, for example, the physiological and behavioral response of individuals to environmental conditions; the reaction of life history traits to environmental resources, and the resulting consequences to abundance and spatial patterns; and the structural positions and functional roles of the organisms in the ecosystems that they inhabit.

PHYSIOLOGICAL ECOLOGY OF PLANT AND SOIL NEMATODES

Like all nematodes, those in plants and soil respond both physiologically and behaviorally to environmental conditions and cues. As poikilotherms, their metabolic activity is modified by temperature; the efficiency of energy release for cellular and organismal function approaches a maximum when they are exposed to favorable temperature ranges. Nematodes are aquatic organisms. In soil, they inhabit water surrounding soil particles, and their permeable cuticle provides direct contact with their microenvironment. They do not rapidly migrate from stressful conditions, and many species survive dehydration, freezing, or oxygen stress; others are more sensitive. Metabolic activity becomes constrained by limiting factors, including availability of moisture in the soil or plant material in which the nematodes live, or the availability of

oxygen to drive metabolic processes. They are also affected physiologically by the osmotic condition and pH of the milieu. Such factors vary considerably as concentrations of the soil solution are affected by rainfall, percolation, and evapotranspiration. The amplitude of tolerance to such varying conditions determines the habitats occupied by different species.^[4]

It seems reasonable to assert that population levels or aggregations of nematodes in soil or plant material will be greatest where the integral affect of environmental conditions is optimal for their metabolism. In such locations they should feed more effectively, move most efficiently, reproduce most rapidly, and survive longest. Aggregations of nematodes are also enhanced by kinetic effects (movement). Movement is most rapid in favorable zones and less rapid, or even prevented, in unfavorable zones. Of course, the overriding determinant of population aggregates is the presence of food and the ability of nematodes to detect and access it while potentially constrained by the top-down effects of density-dependent predation by natural enemies.

BEHAVIORAL ECOLOGY OF PLANT AND SOIL NEMATODES

Nematodes respond to environmental (and other organismal) cues through taxes and kineses. Kineses are alterations in rate of activity; taxes are directional responses to stimuli. Chemosensory signals are detected by the amphids, which may be relatively small in environments where signal strength changes slowly (e.g., soil), or elaborate where signal strength is more dilute or changes rapidly (e.g., freshwater or marine environments). Even where amphids are small, as in most soil nematodes, expansions of the neuronal endings and the presence of mucoidal material may enhance their sensitivity. In those nematodes (e.g., *Caenorhabditis elegans*) where the nervous system has been studied intensively, cell bodies of amphidial neurons are aggregated in the nerve ring, which may allow some integration of signal strength from the amphids on either side of the head—or between amphids and the posterior phasmids—and allow generation of a signal for muscular responses.^[5,6]

Chemosensory communication between individuals is evident in taxis responses of males to females in sexually reproducing species and in the apparently tactile determination of the location of reproductive structures during mating. Response to host signals is generally strongest in plant-feeding nematodes that have a narrow host range and less obvious in those species with wide host ranges. Nevertheless, coordination of life history events with host availability is very important in species that have evolved sophisticated host–parasite relationships, for example, the root-knot nematodes, *Meloidogyne* spp.^[7] In those cases, the food reserves packaged into the egg by the female nematode must be sufficient to drive the embryo through several hundred cell divisions, a molting event from the first to the second juvenile stage, hatch from the egg, detection and migration to a host root, penetration of the root tissues through a complex migration pathway, and induction of a feeding site. All of those energy-intensive activities are necessary before the nematode is able to independently obtain new resources. Clearly, there are many opportunities for disaster, including inability to find a root, a nonhost response by the root, and insufficient residual energy to complete the penetration process.

POPULATION ECOLOGY OF PLANT AND SOIL NEMATODES

Population processes are, of course, regulated by physiological responses to the environment. The dynamics of increase and decrease in nematode populations are the integral of birth and death rates as constrained by environmental conditions, resource availability, and community regulatory pressures. Birth rates are affected by the intrinsic capacity of female nematodes to produce eggs and the duration of the life course over which those eggs are produced. Birth rates may be influenced by availability of males where fertilization is necessary, but not where parthenogenesis occurs.^[8] Hermaphroditism occurs in some bacterial-feeding nematodes (e.g., *C. elegans*). In those cases, the number of viable eggs produced is greater when cross- rather than self-fertilization occurs, apparently because the hermaphrodite does not produce and store enough sperm to fertilize all the eggs it is capable of producing.^[9]

Most plant and soil nematodes seem to produce eggs for the duration of their adult life course. Induced mutants of *C. elegans* may have extended survival beyond the reproductive period, with possible competitive consequences for food. The occurrence of such variants in nature is unknown and, arguably, there would be strong selection pressure against them, as there does not appear to be any social contribution to the population on the part of elderly nematodes.

The life course of plant and soil nematodes may be as short as a week in opportunistic bacterial-feeding species; is often in the 4–8 week range in plant-feeding species; but may be as long as several years in long-lived, large-bodied plant-feeders, predators, and omnivores inhabiting undisturbed and stable environments.^[3] The distribution of death expectancy around the mean life duration is generally not known except in some model systems.^[10]

Resource availability in an environment determines its carrying capacity for a nematode population. In closed systems, that carrying capacity may be fixed by the total amount of carbon available. But in dynamic systems, such as those generated by a growing plant that is continually fixing carbon, producing roots, and depositing and leaking materials into the rhizosphere, the carrying capacity changes with time. For a plant-feeding nematode species, there is a delicate balance between the amount of damage or pressure a successful parasite applies to the growth of its host plant and the rate and amount of food that the host can make available to the parasite. At higher starting population levels, the damage to the host may be so great that growth and development of the plant is impaired, total photosynthetic input is compromised, and the nematode population is limited to a lower level than it might have been if initial population pressure were lower.^[11,12]

COMMUNITY ECOLOGY OF PLANT AND SOIL NEMATODES

Nematodes in any environment are components of communities of organisms and, depending on their feeding habits and life history attributes, fit into their communities in various functional roles. The essential feature of a community is that the participating organisms are interdependent as food resources or interact in some way in the acquisition of resources.

The community of interacting soil organisms is sometimes known as the soil food web. The primary sources of carbon and energy from soil organisms stem from the photosynthetic activity of plants. The flow of carbon from plant material into the soil food web is influenced by nematodes in various ways. Some nematodes are herbivores that channel carbon and energy into the soil food web by direct herbivory on the plant. Others feed on fungi and bacteria and so constitute important bridges between primary decomposers of organic material and detritus and the balance of the food web. Still others are predators and omnivores consuming a range of higher soil organisms. These exert pressure on the abundance of their prey and potentially regulate or even suppress prey populations. Structure of the community is maintained as the integral of the population ecology of various taxa and the regulatory effects of predation across and within

Fig. 1 A management goal in sustainable agricultural production: to maximize the flow of carbon (C) into the soil food web through detritivore rather than herbivore channels.

trophic levels, but ultimately the size and activity of the food web must depend on the amount of carbon entering the soil. A major goal of sustainable production systems that are reliant on the functional roles of soil food webs is to increase carbon flow into the system through detrital channels while minimizing carbon flow resulting from herbivory (Fig. 1).

Besides predation, mechanisms of interaction at the community level include interspecies competition and mutualism. Certainly, nematodes with the same feeding habits compete for resources, but in some situations, competition is mitigated by adaptation of the nematodes to different environmental conditions. Predominance of species in the communities varies with their thermal adaptation; competition is reduced by spatial and seasonal variations in temperature and its diurnal amplitude.^[13] One interesting example of mutualism in soil nematodes is exhibited by the so-called entomopathogenic nematodes. These bacterial-feeding nematodes transport mutualistic bacteria into the intestinal tract of insects. There the bacteria are released, which kills the insect and provides an abundance of food for the nematode.^[14]

Communities of organisms tend to be centered on sources of food. In the soil, such foci may occur at the interface of organic litter layers and the mineral layers of the soil. They also occur at the metabolically active parts of the root system, the root tips. Because of the multiplicity and dispersion of the various organic matter sources that drive the soil food web (Fig. 1), coupled with the physical heterogeneity of the soil environment, the soil community tends to exist in patches. It might be considered a metacommunity, a series of borderless communities with opportunities for migration of organisms among the patches, depending on their motility and sensory capabilities.

Both resource availability and predation pressure affect soil nematodes, and the interplay between these forces affects the dynamics of the participating populations. Bacterial-feeding nematodes may enter inactive “dauer” states, which allows them to conserve resources and, perhaps, renders them less accessible or attractive to predators. Nevertheless, the predators require food, and both they and the prey nematode populations must decline in the absence of resources entering the system.

SUCCESS OF NEMATODE ECOLOGICAL STRATEGIES

Nematodes are found in every habitat, from frozen tundra to hot springs, and from marine sediments to alpine peaks. They obtain sustenance from every form of fixed carbon imaginable, from algae and bacteria to humans. Recent classification systems recognize around 19 orders that constitute the phylum Nematoda. Plant-feeding species occur in three of those orders and are most prevalent in one, the Tylenchida. This relatively small sector of the phylum has developed strategies for feeding on perhaps every species of higher plant and for coexisting with other species on the same plant. Most species feed on root tissues and so avoid the dry conditions of the aboveground habitat, but some species have become behaviorally and physiologically adapted to feeding in stem, leaf, and seed tissues. Enormous diversity exists among root-feeding strategies, from root tip feeders to root hair piercers, and from migratory ectoparasites that withdraw contents of individual cells to sedentary endoparasites that elicit highly specialized feeding-site responses from the host.

New Industrial Crops in Europe

Jan E. G. van Dam

Wolter Elbersen

Agrotechnological Research Institute, Bornsesteeg, Wageningen, The Netherlands

INTRODUCTION

Crop diversification has been one of the promises for European agriculture in recent decades. As a result of surpluses in production of the major food crops, which have arisen from increased productivity in the 1970s and EU pricing policy in the 1980s,^[1] alternative crops for nonfood markets have received substantial interest. Overproduction of traditional food crops (sugar beet, grain, and potatoes) in Europe resulted in increased competition and a decline in profitability. Reduction of EU subsidies and the threat of cheap imported products from low-wage countries prompted many farmers to abandon their businesses. Farmers would benefit from additional outlets, especially in novel, industrial nonfood applications. Attention has been given to new markets for existing crops as well as to developing novel crops. Research and development activities have been directed toward valorization of agricultural residues and product development for various “industrial” crops to produce specific seed oils, proteins, starches, carbohydrates, or cellulosic fiber.

AGRICULTURAL DIVERSIFICATION AS EU POLICY

In the specific framework RTD programs of the European Commission covering agriculture and fisheries (ECLAIR 1988–1993, 3rd framework 1991–1994 AIR, 4th framework 1994–1998 FAIR, and 5th framework 1998–2002 Quality of Life) a large number of precompetitive projects have been conducted during the last decade to address the various aspects of agricultural crop diversification. Substantial budgets of millions of euros have been spent to enhance the links of agriculture with industry and to encourage collaboration between the institutions from the various member states. Many of the EC-funded projects (with $\geq 50\%$ EU contribution) have been selected to promote industrial participation in innovation to enhance the chances of success for project implementation.^[2,3] In addition to the EU framework programs, specific developmental work for agricultural diversification also has been carried out on a national level.

The EU policy for sustainable development promotes the use of renewable resources for production of industrial products that currently are derived from petrochemical or mineral resources. The potential for agricultural production of a wide range of industrial feedstocks has been scrutinized as a source for composites, plastics, and polymers; resins and adhesives; building and insulation materials; energy and fuel feedstocks; paints, coatings, and dyestuffs; soaps, detergents, surfactants, lubricants and waxes; and agro-chemicals, pharmaceuticals, and cosmetics.

AGRO-INDUSTRIAL PRODUCTION CHAINS

A large number of new crops for European farming have been studied for the purpose of agro-industrial production, together with some obsolete crops that have long been neglected. Successful (re)introduction of agricultural raw materials for energy, “green” chemicals, and other nonfood uses requires addressing the whole agro-industrial production chain, from primary agricultural production to the perceptions of industrial end-users and consumers.

Generally, research and developmental work is directed at technical bottlenecks in product development. Successful market introduction, however, depends largely on the reliability of supplies and on added value for the consumer. Quality control and product standardization have been considered to overcome problems in the industrial use of renewable raw materials. Crops are a natural product, and intrinsic changes in quality between crops grown under different conditions introduce a certain degree of variability that has to be accounted for.

The production chain for renewable resources can be divided into three main links: agricultural primary production, crop processing, and utilization (see [Table 1](#)). Difficulties in the organization of integrated production chains (including storage and transport, marketing and sales) for innovative agro-industrial products have been identified as major constraints in the successful commercial introduction of novel (ecologically enhanced) products to the market. Despite the interdependency of the different links in the chain, the interests of the various

Table 1 Integrated agro-industrial production chains

<i>Agricultural production</i>	
Breeding	Genetics, crossbreeding, and reproduction
Growth	Agronomy: seed density, soil fertility, climate conditions, irrigation, crop protection, weed and pest control, fertilizers
Harvest/storage	Maturity and handling, mechanization
<i>Postharvest processing and conversion technology</i>	
Product extraction	Cleaning and extraction/residue valorization
Product preparation	Conversion technologies (refining, extrusion, steam explosion, etc.), chemical modification/biochemical treatments, etc.
Product processing	Product compilation, finishing, compounding
<i>Application and use</i>	
Utilization	Product performance/marketing and sales
Disposal	Reuse and recycling, incineration/degradation

players may be divergent and counterproductive. The price and performance ratio of the products prevails in terms of competitiveness on the market, rather than in quality or ecological benefits.

Since ecological arguments are not decisive in getting industries or consumers to choose renewable products, legislative measures on the use of less-sustainable products favor the utilization of new crops.

OILSEED CROPS

A number of crops previously established as minor crops for production of fodder, such as rapeseed, have been considered as feedstock for biofuel (biodiesel) production or plant-oil-based surfactants. The increasing area of oil crops in the EU, e.g., sunflower (*Helianthus annuus*) (with a 1993 maximum of 3.3 million ha) and rapeseed (*Brassica oleracea*) (2.4 million ha in 1990 and over 3.0 million in 2000),^[4] has also initiated a search for outlets for by-products such as lecithin for cosmetics and fermentation substrates.

The reduction of volatile organic solvents in paints, coatings, and adhesives has enhanced the industrial demand for specific plant oils. Legislation restricts the use of those solvents for professional use in the EU, and alternative products are on the market. However, higher costs and reduced practical value still restrict the more common use of ecological products.

Research has been conducted for the breeding and agronomy of new oilseed crops such as meadow foam (*Limnanthes alba*), crambe (*Crambe abyssinica*), castor (*Ricinus communis*), and *Dimorphotheca pluviales*. The oils and their derived products have been evaluated for the production of pharmaceuticals, cosmetics, oleochemicals, lubricants, coatings, resins, and lacquers. The economic

feasibility of primary production and industrial product development has been evaluated, but so far, available varieties have not been able to yield sufficient product to generate larger industrial interest. However, the primary production of crambe has been addressed to enhance its productivity.

Commercial interests in specialty oils containing unusual fatty acids, such as poly-unsaturated fatty acids and hydroxyl- or epoxy fatty acids, has inspired much work on alternative oil crops. Examples are lupin (*Lupinus mutabilis*, *L. albus*), jojoba (*Simmondsia chinensis*), and *Stokesia* sp., investigated for use in cosmetics, pharmaceuticals, and as lubricants; and false flax (*Camelina sativa*), caper spurge (*Euphorbia lathyris*, *E. lagascae*), and marigold (*Calendula officinalis*), studied because of their specialty fatty acids content for medicinal purposes, food, and a variety of nonfood uses as well.

FIBER CROPS

Automotive industries have been the driving force in developing cellulosic fiber production for (thermoplastic) composite car parts. Traditional fiber crops such as flax (*Linum usitatissimum*) and hemp (*Cannabis sativa*), but also crops new to Europe such as kenaf (*Hibiscus cannabinus*) and broom (*Ginestra* sp.), have been studied intensively for nontraditional end uses in compounds and fiber composites with numerous synthetic polymers.^[5]

The breeding and agronomy of new hemp varieties has been studied to produce high-yield fiber and low Tetrahydrocannabinol (THC) content. Experimental fields of fiber hemp have been established in many EU countries and commercial production has been introduced at some locations. New fiber production technologies for specific industrial utilization have been studied. Some products

have entered the market successfully at a modest scale. Production of high quality fiber hemp for textile use so far has not been commercially successful.

One of the identified issues for sustainable developments and ecological building—apart from the energy conservation aspects—is the use of renewable resources as building materials. Fiberboards, panels, and insulation materials for building applications have been developed based on flax, hemp, miscanthus, or fibers derived from agro-residues (wheat straw, reeds, etc.). The production scale (and related costs) of established building materials is hindering extension of the market share for renewable building products.

The use of plant fibers as geotextiles in civil engineering and as horticultural substrates or biodegradable plant pots is increasingly receiving attention. The competing (synthetic or mineral) market products, however, hold a strong position.

Despite substantial research on the pulping of annual fiber crops and agro-residues, the contribution of non-wood pulp as raw material in European paper and board industries remains marginal. Some flax and hemp fiber is processed into specialty paper.^[6] Efforts to upgrade straw pulps for paper and board production have been unsuccessful, and the last straw-pulp mills have been closing in the EU.

Other fiber crops investigated for cultivation in various EU regions are *Hibiscus esculentus*, for making paper and reinforcing fiber, and for its nutritious pods; and domestications of stinging nettle (*Urtica dioica*), with potential as textile fibers.

Profitable EU agricultural production of nonfood crops implies competitiveness with cheaper raw materials produced from other regions. The availability of bulk quantities of fiber products like jute and sisal, and the potential large-scale production in Eastern Europe of flax or hemp is forcing EU agro-industrial production into a specialized niche market. Traditionally, flax fiber production in Western Europe for high-quality linen textiles has been able to cope with competing imported raw materials because of its high quality standard. The concentration of conventional linen promotion on the fashionable textile market in past decades has increased the dependency of the sector on a strongly fluctuating market segment. One way for EU agriculture to compete on the world market in lignocellulosic fibers is to supply high-quality raw materials with added value for the user. Only when the qualitative aspects of each specific end use have been defined in detail can this be achieved.

BIOMASS (ENERGY) CROPS

Promotion of the use of biomass for the production of “green” energy is one of the means to achieve a political

target: to stop global warming and reduce CO₂ emission levels. Agricultural production of biomass crops for generation of bioenergy has received substantial attention in the EU. Elephant grass (*Miscanthus* sp.) especially has been selected for its potential high productivity and has been intensively studied agronomically to find suitable genotypes for different climatic regions. Breeding, propagation, planting, and harvesting technologies for miscanthus crops have been the subject of study. Other perennial C4 grasses such as sweet and fiber sorghum (*Sorghum* sp.) and giant reed (*Arundo donax*), which may be suitable for biomass production in the southern regions of the EU, have been evaluated. A production system for reed canary grass (*Phalaris arundinaceae*) has been investigated in the more northern regions. More exotic species studied for Europe are switchgrass (*Panicum virgatum*) and bamboo (*Phyllostachys* sp.).

Because of the relatively low costs for fossil fuel and the lack of supportive political policy, dedicated agricultural production of new energy crops still remains questionable. Therefore, dual-crop-use options are being evaluated to increase the total added value. For example, the same crop might provide both energy and paper pulp, or composites, or building materials, or horticultural substrates.

Apart from the fast-growing grasses and tree species such as willow, poplar, and eucalypt, that have been promoted for paper pulp or biofuel production, another high-yielding perennial, cardoon (*Cynara cardunculus*), has been investigated for growing on marginal and set-aside lands in arid areas of southern Europe.

The work on biofuel utilization has been focusing on thermal conversion by burning, gasification, and pyrolysis of biomass. However, the costs of energy production remain a critical component in the development. For the production of liquid fuel, laboratory-scale hydrolysis/fermentation experiments have been conducted to produce ethanol, ABE (acetone, butanol, ethanol), and hydrogen gas from lignocellulosic feedstock.

CARBOHYDRATE CROPS (CEREALS AND TUBERS)

Innovation and industrial product development for established crops such as cereals, sugar beets, and potatoes would offer the advantage of known agricultural production. Possible uses as feedstock for bioethanol fuel production have remained at the R&D stage due to the economics of production and political factors (bioethanol production would become competitive only when crude oil sells at \$30–40 per barrel). Other biotechnological methods to valorize agricultural waste products, such as sugar beet pulp or wheat and maize bran, have been investigated in detail, for example, for the production of vanillin.

Much research effort by various groups has been directed into the production and processing of biodegradable plastics based on thermoplastic starches from potato, corn, and other cereals. Biodegradable plastics for packaging and single-use items are being produced on industrial scale, but so far no breakthrough has been accomplished to generate a wider market share.

A production area of 15,000 ha of chicory (*Chicorium intybus*) for inulin production has been established, concentrated in Belgium, France, and the Netherlands. Inulin and fructan for nonfood applications are under investigation.

“GREEN” CHEMICALS AND PHYTOPHARMACEUTICALS

Higher-value-added specialty chemicals that can be derived from plant sources have been investigated for use in textiles, cosmetics, flavors, fragrances, and pharmaceuticals. Some examples:

- Reintroduction of traditional dye plants such as woad (*Isatis tinctoria*), madder (*Rubia tinctorum*), weld (*Reseda luteola*), and goldenrod (*Solidago* sp.) has been attempted by improving the harvesting and extraction technologies. On a modest scale, some production has been realized in Germany.
- Caraway (*Carum carvi*) has been introduced as a crop for the production of carvon, which has been demonstrated to have sprout-suppressing properties in potato storing.
- Some research on guayule (*Parthenium argentatum*) as a source for nonallergenic natural rubber production has been conducted.
- Agricultural production of *Stevia rebaudiana* as a promising new crop for southern regions of the EU has been studied, both for its sweetener properties and for nonfood uses.
- Glucomannan from konjac (*Armorhophallus* sp.) has been studied for its use as a texturing agent in food and nonfood applications.
- The tuber and seeds of ahipa (*Pachyrhizus ahipa*) have been evaluated for their specific (glyco)protein content and biocidal action.

WHOLE CROP UTILIZATION

Since it has been concluded that primary production of many crops is not economically feasible to produce only one principal component, valorization of residues from the crop has been considered. Many crops grown for fiber also may yield a useful oil (or the other way around) and produce other biomass residues (stalks, shives) that could tip the overall economic balance.

Bulk quantities of biomass with reduced (or negative) costs are available from many sources. For example, large quantities of verge grasses are being produced annually from roadsides, and many residues from agricultural and horticultural production accumulate without further use. Utilization of these residues for energy production would make a cheaper feedstock, but for a useful fuel preprocessing is a prerequisite.^[7] Green tissues are generally richer in water, protein, and minerals, which could cause more difficulties in thermal conversion.

CONCLUSION

Despite the scope for new outlets and prospects for sustainable production of renewable raw materials, the acceptance of new crops at the farm level, in industry, and in the market has been complicated because of the adapted machinery and investments required at the various production levels. Much has been achieved over the last decade in exploration of the potential markets for different new industrial crops, although a real breakthrough still has to come. As a renewable raw material, crops do present strong marketing arguments as “eco-efficient” products for the development of sustainable consumption and production. Diversification of the market for renewable raw materials in the automotive industry, building and construction materials, paper and pulp, bioenergy, geotextiles, etc., are all in the picture if: 1) quality control of the agro-industrial production chain can be organized according to ISO standards; and 2) supplies of specified products to industrial buyers can be guaranteed.

Concerted action by the whole agro-industrial production chain will be necessary to attain the targets of sustainable consumption and ecologically safe production of the whole range of renewable products.

APPENDIX

Oil Crops

Sunflower	<i>Helianthus annuus</i>
Rapeseed	<i>Brassica oleracea</i>
Meadow foam	<i>Limnanthes alba</i>
Crambe	<i>Crambe abyssinica</i>
Castor	<i>Ricinus communis</i>
	<i>Dimorphotheca pluviales</i>
Lupin	<i>Lupinus mutabilis</i>
	<i>L. albus</i>
Jjoba	<i>Simmondsia chinensis</i>
	<i>Stokesia</i> sp.
False flax	<i>Camelina sativa</i>
Caper spurge	<i>Euphorbia lathyris</i>
	<i>E. lagascae</i>
Marigold	<i>Calendula officinalis</i>

Fiber Crops

Flax	<i>Linum usitatissimum</i>
Hemp	<i>Cannabis sativa</i>
Kenaf	<i>Hibiscus cannabinus</i>

New Secondary Metabolites: Potential Evolution

David R. Gang

University of Arizona, Tucson, Arizona, U.S.A.

INTRODUCTION

When we consider the potential within the plant kingdom to evolve new metabolites, we need to consider two important properties of plants. The first is the diversity of building blocks—of current metabolites—found in plants, and the ability of these building blocks to be put together in new ways to produce new metabolites. The second important property to consider is the biosynthetic machinery within a plant that is responsible for producing metabolites, and the ability of this machinery to be modified so that new metabolite transformations are possible.

PLANT METABOLITE STRUCTURE AND DIVERSITY

Plants produce an amazing array of metabolites with very divergent structures and functions. These metabolites result from the action of several important and diverse biosynthetic pathways. Beyond the primary metabolic pathways—such as glycolysis, gluconeogenesis, and amino acid biosynthesis—the most significant metabolic pathways in plants are the terpenoid pathway (over 30,000 compounds identified), the phenylpropanoid pathway (over 5000 compounds), and the alkaloid pathways (over 12,000 compounds). Over 50,000 such metabolites have been identified in the plant kingdom,^[1] and in the whole of nature there may be several hundred thousand or more of such compounds.^[2]

Examples of this structural and functional difference are shown in Fig. 1. These molecules (eugenol, curcumin, or indole glucosinolate) can have simple structures, or they can be much more complex, (salvianin, vinblastine, or taxol). Plant secondary metabolites (also called specialized metabolites or natural products) may be the best manifestation of biodiversity within the plant kingdom. The features that most readily distinguish plant species—the colors, odors, medicinal value, and levels of toxicity—are caused by these metabolites. These are just a few of the many important and highly variable plant attributes that directly result from the production of specific metabolites. Such compounds can also be the initial cohort in plant defense arsenals. Many (e.g., eugenol, vinblastine, and taxol) are produced constitutively in the

plant to ward off all but the most agile of pests or pathogens. Other metabolites (called phytoalexins) are produced in response to attack, either to kill the potential predator or prevent further damage. Furthermore, many metabolites (e.g., salvianin) are essential for attraction of pollinators and seed dispersers, and thus are vital for sexual reproduction in most angiosperm species. In fact, these latter roles clearly demonstrate that these compounds are not secondary at all, but are requisite parts of a plant's survival strategy.

BIOSYNTHESIS OF PLANT METABOLITES

The majority of plant metabolites are constructed in a manner whereby a basic structural motif is first synthesized and defines a new set or class of compounds. This core molecule is then further modified, often leading to great structural diversity within members of its compound class. This is what happens in the production of the anthocyanins, which are produced by a branch of the flavonoid pathway (Fig. 2). In the flavonoid pathway, a number of structural classes are formed (indicated by parentheses in Fig. 2). These classes serve as core building blocks for production of more elaborate molecules (e.g., salvianin).

The vast majority of chemical reactions involved in the production of plant metabolites are catalyzed by enzymes that are part of specific biosynthetic pathways.^[2] For example, a number of steps are known in the pathway that leads to the formation of salvianin in scarlet sage^[3] (Fig. 2). All of these appear to be catalyzed by enzymes: 1) polyketide synthases; 2) isomerases; 3) hydroxylases (cytochromes P450); 4) NADP⁺-dependent dehydrogenases; 5) dehydratases; 6) glycosyltransferases; and 7) acyl-CoA-dependent acyltransferases. Even though the reaction converting the chalcone to the flavanone can occur spontaneously, this reaction is nevertheless catalyzed by an enzyme. Many other enzyme classes and reaction types are involved in the formation of other plant metabolites, but this example clearly shows that many different classes of enzymes are involved in the formation of any given metabolite that accumulates in a given plant. The genes encoding these enzymes are the genetic material in the plant kingdom that can be modified through evolutionary processes to produce new enzymes that in

Fig. 1 Examples of the structural and functional diversity in plant secondary metabolites.

turn catalyze the formation of new metabolites.^[2,4] The ability to produce new enzymes is the key to the ability of plants to evolve new metabolites.

EVOLUTION OF NEW ENZYMES AND PATHWAYS

Several processes occur in plants that may lead to the formation of new enzymes. These range from polyploidization events and whole genome evolution, to gene duplication and divergence, and allele divergence.

Polyplodization events have been a common phenomenon in plant evolutionary history.^[5] These events lead to the merging of whole genomes from two distinct species. When this latter process occurs, large amounts of DNA can be lost or rearranged. This leads to formation of new chimera chromosomes.^[5] As can be imagined, this can lead to the duplication of some sets of genes. This

sometimes occurs with the concomitant loss of other sets of genes. Only those losses that are not detrimental to the plant's survival will lead to viable progeny. Thus, it is possible that whole groups of biosynthetic enzymes and the resulting pathways and metabolites may be lost, so long as these metabolites are not absolutely required for survival of the plants. In addition to the process of polyploidization, it is possible that segments of chromosomes may be duplicated by other processes. These duplications may be large or small. As a result of all of these processes, the newly duplicated genes become redundant. This sets the stage for the evolution of new functions.

Once duplicate genes are formed, only one copy need retain the original activity for the plant to continue to make the same set of metabolites. The other copy is free to be mutated—to evolve. Many processes may be involved in this evolution. The new gene could simply accumulate random mutations, possibly leading to an altered substrate-binding cavity and new enzyme specificities. The

Fig. 2 Biosynthetic pathway to anthocyanin flavonoids such as salvianin, demonstrating the diversity of structural classes and enzymes involved.

results of this process have been observed in the production of a group of phenylpropanoid compounds in sweet basil.^[6] In this case, two very similar enzymes (90% identical at the amino acid level) have been found that possess different substrate preferences. The difference in activity is the result of mutation of a single nucleotide in the gene sequence, which led to incorporation of a different amino acid in the active site of the enzyme, and thus to altered enzyme function. In this case, the original enzyme was from a secondary metabolic pathway. Another example of divergence of duplicated genes is the evolution of homospermidine synthase, which is found spo-

radically in a number of unrelated plant families.^[7] This enzyme has very high homology to deoxyhypusine synthase, which is involved in activation of eukaryotic initiation factor 5A (eIF5A). eIF5A is required for proper cell growth. Thus, formation of new enzymatic functions in plant secondary metabolism can be derived directly from enzymes duplicated from primary metabolism.

Other examples of divergence after duplication are found in plant glycosyltransferases,^[8] polyketide synthases,^[9] cytochrome P450s,^[2,4,10] terpene synthases,^[2,4] and many other enzyme classes.^[2] In fact, for some of these enzyme types, there are dozens to hundreds of

individual members in a given plant's genome. For example, there are over 250 different cytochromes P450, over 360 glycosyltransferases, over 60 acyltransferases, and over 50 dehydrogenases in *Arabidopsis* alone.^[2] This plant produces only a limited number of secondary metabolites. The function of only a small handful of the genes in these large gene families is known. The diversity in extant enzymes in these classes in the plant kingdom as a whole must be significantly larger.

CONCLUSION

Given the great number of extant metabolites in plants, a great pool of structural building blocks can be modified by future evolution in plants. In addition, a large pool of enzymes in any given plant—many of which are duplicates and redundant—are available for transformation into new enzymes via mutation and other evolutionary processes. Thus, because of the existing complex matrix of metabolites and enzymes in the plant kingdom, there is great potential for the evolution of new enzymes, new pathways, and new metabolites. Advances in genomics, proteomics, and metabolomics allow this area to be investigated in a manner not previously possible.

Nitrogen

Peter J. Lea

Lancaster University, Lancaster, U.K.

INTRODUCTION

The availability of water and nitrogen are considered to be the two major factors controlling plant growth and crop yield. In the past, the application of large amounts of nitrogen fertilizer by farmers has been a common practice. However, concern has been raised over the leaching of nitrogen from the soil, which can contaminate drinking water, cause toxic algal blooms, and thus affect human health, commerce, and tourism. There is now a strong move to adjust nitrogen input according to the nitrogen requirement of the plant and corresponding to the target yield.

USING NITROGEN TO OBTAIN HIGH CROP YIELDS

The yield of a high-quality wheat crop grown in Western Europe can reach 10 metric ton hectares (ha^{-1}). In addition, an equivalent amount of straw is produced, with an average 1.5% N in the dry matter, representing a nitrogen (N) requirement of 300 kg ha^{-1} . A grass crop used for animal fodder may produce 20 ton ha^{-1} but will contain 4% N, thus representing a N requirement of 800 kg ha^{-1} .^[1] It therefore follows that in order to obtain these high yields, farmers need to apply large amounts of N fertilizers. The global use of N fertilizers has increased dramatically in the last 50 years and has now stabilized in the region of 80 million tons per annum. Nitrogen may be applied to crops in the form of ammonium (NH_4^+) or nitrate (NO_3^-) ions (often both together), urea, or as organic fertilizers derived from farmyard manure. In addition, legume crops are able to fix N_2 directly from the atmosphere through the utilization of symbiotic bacterial species in the root nodules. In well aerated neutral soils, the majority of the N is converted to nitrate. However, in acidic and/or anaerobic soils (e.g., in forests or for rice), ammonium ions are the major form of available N. The use of N fertilizers and the subsequent metabolism of the nitrogen-containing compounds within the plant are covered in two recent books edited by Bacon^[2] and Lea and Morot-Gaudry^[3] and in a special issue of the *Journal of Experimental Botany*.^[4]

Unfortunately, the uptake of N by the crop plant seldom exceeds 60% of that applied. This loss of fertilized

N can be due to leaching, erosion, runoff, or by gaseous emissions. The leaching of $20\text{--}30 \text{ kg N ha}^{-1}$ can increase the nitrate concentration in the groundwater to above the threshold stipulated by the European Union (EU) for drinking water of 50 mg l^{-1} . Nitrogen may be lost to the atmosphere as NH_3 or following denitrification as N_2 or intermediate oxides, e.g., N_2O , NO , and NO_2 . In addition, N may be sequestered by soil microorganisms in an organic form, which may then be available for subsequent crops.^[5]

BIOMASS AND NITROGEN

The relationship between biomass production and the amount of N applied to the soil has been determined in a large number of field trials for most economically important crop plants. The generalized response curve shown in Fig. 1 clearly demonstrates that when there is a shortage of available N, productivity is very low. However, biomass production increases linearly with the supply of N until the asymptote is reached, at which point additional nitrogen does not increase productivity, and productivity is then limited by genetic potential. If growth is related to the N accumulated by the crop, then the initial slope, which is the true or intrinsic efficiency of nitrogen use by the plant, is steeper (more biomass per unit of N) than if related to the amount of N applied. The difference is a measure of the efficiency with which nitrogen is used, as is the difference between the point at which the plateau for biomass production is reached, when expressed per unit of absorbed and applied N.^[6]

An abundant nitrogen supply increases the number of meristems produced by plants, thus encouraging branch and tiller formation and hence growth in most plants. In cereals and grasses the increased production of tillers gives rise to increased biomass and increased numbers of ears in grain-producing plants. As a consequence of the increased N supply, the leaf area index (leaf area/ground area, LAI) increases considerably. In a well watered winter wheat crop receiving $300 \text{ kg ha}^{-1}\text{N}$ grown in Europe, the LAI can reach 6 by June. However, in a crop receiving only $75 \text{ kg ha}^{-1}\text{N}$, the LAI may only reach 2, with values below 1 reported in crops receiving no nitrogen at all.^[1] The light energy received by the crop is

Fig. 1 A generalized response curve relating the production of biomass to the uptake and supply of nitrogen. The differences between the curves is due to losses of N in the soil and limitations of uptake by the plant. (From Ref. 6.)

used by the leaves to assimilate CO_2 in photosynthesis and also to carry out a range of other synthetic reactions. In fact it has been calculated that 20% of the N in the leaf of a C_3 plant is contained in light-harvesting pigments and proteins, 35% of the N is in the enzymes of the Calvin cycle including RuBP carboxylase/oxygenase (which is the major single component), and a further 20% is in other biosynthetic enzymes.^[1] Thus the addition of nitrogen not only stimulates the formation of new leaves to intercept all the light available (a LAI of >4 is required), but also raises the amount of enzyme protein available to carry out photosynthesis. Ultimately during leaf senescence, N is mobilized from the enzyme proteins and transported to the seed for incorporation into storage protein.^[7]

A range of models of crop growth is currently available based on the concentration of N within a plant. These models utilize the terms $\%N_{max}$, which is the maximum concentration of nitrogen that can be accumulated by the plant, and $\%N_{min}$, which is the minimum concentration of nitrogen below which the plant cannot survive. These values can be obtained from field trials with increasing applications of N fertilizer. The critical value for N concentration $\%N_{crit}$ lies between $\%N_{max}$ and $\%N_{min}$ and corresponds to the concentration of nitrogen, which permits maximal crop growth. Thus crops that are grown in conditions below $\%N_{crit}$ suffer N deficiency and reduced growth, whereas plants that are grown above $\%N_{crit}$ are able to store N. A discussion of the value of the various

models available to establish $\%N_{crit}$ has been recently provided by Jeuffroy et al.^[18]

VARIABILITY IN NITROGEN UPTAKE

The nitrogen uptake by field crops is highly variable within a single year, between years, between sites, and with different crops even when the N supply is plentiful. This is partly due to the fact that the increase in crop N content with crop mass is not linear. Additional N uptake per unit of additional biomass declines as the crop gets bigger. A plot of $\%N_{crit}$ against biomass provides a gentle downward curve and has been carried out for a range of plant species. C_4 species (e.g., maize and sorghum) were found to have a lower $\%N_{crit}$ -biomass curve than C_3 species (e.g., wheat, rape, and pea), presumably due to the lower content of photosynthetic proteins within the leaf. The curves of a wide range of C_3 species, however, exhibit a remarkable similarity.^[19]

CONCLUSION

There is a need to adjust the amount and timing of N application to crops to ensure that the maximum growth rate is obtained, while at the same time preventing wastage and hence possible pollution. As earlier, if the

actual N content of the crop falls below the critical N content there is a reduction in the growth rate. A small decrease in the uptake of N by wheat could cause a reduction in the grain N content from 11.5% to 10.5%, thus preventing its use for bread making. Thus methods have been developed to establish the N content of the crop, which preclude the use of complex and expensive analyses. Simple colorimetric tests for the concentration of nitrate in leaves are now available, which may be used in conjunction with an analysis of chlorophyll concentration using handheld photometers. Such techniques give a clear result and may be carried out rapidly in the field with a large number of samples.^[6]

Nonchemical Weed Control: New Directions

Bo Melander

Danish Institute of Agricultural Sciences, Slagelse, Denmark

INTRODUCTION

Nonchemical weed control involves a wide range of methods and tactics used to control weeds without any support from herbicides. Mechanical and thermal methods, including mulching with dead or living mulches, are currently the most common nonchemical methods for direct use in crops. These methods are most often applied as part of a strategy that also involves cultural factors such as fertilizer placement, stale seedbed techniques (repeated soil cultivation prior to planting), and competitive crop varieties. Besides improving existing methods and weed control strategies, recent research has been oriented toward the development of high-technology solutions such as automatic steering systems for steerage hoes, global positioning system (GPS) for electronic mapping of crop seed positions for subsequent guidance of selective weeding devices, and computer vision for identification of crop and weed seedlings to guide highly accurate devices for physical targeting of weed seedlings. Band steaming prior to crop sowing is another area of interest for row crops with dense intrarow crop stands, where spacing is too limited for automatic and selective guidance of weeding tools.

WHY NONCHEMICAL WEED CONTROL?

Research on methods for nonchemical weed control in agriculture and horticulture has steadily increased up to the 1990s in many European countries, notably Sweden, The Netherlands, Germany, Italy, UK, Switzerland, and Denmark, mainly as a consequence of an increasing concern about herbicide usage among European populations. Both ground water and surface water have been unacceptably polluted in many cases owing to intensive pesticide usage, especially in The Netherlands and Denmark. Herbicides have often been the main reason for those contaminations; moreover, they may contribute significantly to a general impoverishment of the flora and fauna in agricultural landscape.^[1] Governmental actions have been taken in countries such as Denmark, Sweden, and The Netherlands to impose legislated directives to cut pesticide usage significantly. Similar concerns and

subsequent actions also can be found in some states and provinces in the United States and Canada.

Other factors driving interest in nonchemical weed control are: the development of herbicide resistance, health risks for humans exposed to chemicals, and an increasing conversion to organic farming in several European countries, favorably subsidized by some European governments.

CURRENT NONCHEMICAL METHODS

Mechanical weed control methods are the most common nonchemical methods used in practice, and a wide range of implements is available for agricultural and horticultural crops. They are considered low-technology solutions with relatively low purchase and operation costs. The weeding mechanism of mechanical tools is mainly by uprooting and/or burying the weeds.^[2,3] Interrow cultivators, such as ordinary hoes with hoe blades mounted on either S-tines or shanks, rotary hoes, rolling cultivators, or power take-off (PTO)-driven cultivators, are used worldwide for controlling weeds growing between the rows (interrow weeds) in row crops such as maize, sugar beets, sorghum, potatoes, and many vegetables. The weeds growing in the crop rows (intrarow weeds) are better controlled by other mechanical means such as weed harrowing, torsion weeding, brush weeding, and finger weeding (images in Ref. [4]). However, mechanical intrarow weed control generally operates with low selectivity whether in cereals grown at narrow row spacing, or in typical row crops at wider row spacing.^[5] Low selectivity means that a high weed control level might be associated with severe crop damage, particularly if large weeds are to be controlled satisfactorily in a weakly anchored crop.

Flame weeding prior to crop emergence has been the predominant thermal weed control method in slowly establishing row crops such as direct-sown onions, leeks, carrots, and maize.^[6] There are two fundamental types of thermal weeders on the market: the covered flamer, flaming to 1900°C, or the infrared weeder, with essentially no visible flame and heating to 900°C. Both use liquefied petroleum gas or propane/butane mixtures as fuel. Flaming kills weeds that have emerged prior to the crop, mainly by rupturing the cell membranes causing the

Fig. 1 Automatic steering of an interrow cultivator in radish using a camera (yellow box on the cultivator) for electronic row detection. (View this art in color at www.dekker.com.)

indirect effect of subsequent desiccation. Hot water, hot foam, and vapor jet systems are other thermal methods that are used to control aboveground vegetation on hard surfaces, along roadsides, and in orchards and nurseries. These methods involve no fire risk, but fossil energy consumption can be very high.

Mulching with materials such as plastics, fibers, straws, and wood debris can be used in orchards, nurseries, and some vegetables. Light is excluded and the mulches constitute a physical barrier through which weed growth is strongly prevented. Mulches may provide complete weed control over long periods but are quite laborious to handle. The term “living mulches” covers a wide range of agronomic systems, but basically a living mulch acts as a cover crop. A cover crop is a secondary crop that is grown to suppress weed growth. It can be planted either before, with, after, or later than the main crop, depending on the purpose and tolerance of the main crop.

IMPROVEMENTS OF EXISTING METHODS

Recently, research has been conducted to better understand the mechanisms behind the killing effect of mechanical weeding principles to improve implements.^[2] A number of investigations have focused on the tactical use of mechanical and thermal methods, and how they can be combined with cultural methods that mainly improve crop competitiveness and crop tolerance to withstand physical impact from weeding tools. Some promising weed control strategies in spring barley, onion, and pulse have been achieved from this work.^[7] Results with mechanical weed control have been particularly good in transplanted row crops, where transplantation itself creates very favorable conditions for mechanical weeding because large crop plants are established in a newly

cultivated soil. However, current techniques for transplantation are only profitable in some highly valuable vegetable crops and need to be further developed to become cost-effective in other row crops.

NEW DIRECTIONS

Within the last 5 years, three new steering systems have been developed and commercialized for hoes and other implements, where accurate steering along a crop row is required.^[8,9] The systems are based on image analyses and have been developed for automatic steering with no need for an extra person to steer the implements (Fig. 1). The manufacturers claim a steering precision down to ± 15 mm deviation from a center line at a driving speed of up to 10 km/hr. However, an experimental verification of those claims still remains to be seen for a number of crops and field situations such as sloping fields, different crop leaf architectures and growth habits, and poor crop stands blurring the row structure.

The new steering technology could be the first step in the development of more advanced image analysis systems able to distinguish crop plants from weed plants. This could be a breakthrough for the development of a robot weeder for row crops. Research in Europe is focusing on the possibilities of developing sensors or cameras that might handle such a task.^[10] One of the visions is to develop an implement that can remove weeds selectively using a cutting device based on either laser technology^[11] (Fig. 2), water jet systems, or mechanical cutters.

So far, the prospects of robotic weeding have only been studied in situations with abundant spacing among clearly visible crop plants such as Christmas tree plantations^[12] and transplanted cauliflowers.^[13] Requirements for a robotic weeder to operate with high accuracy and speed become crucial in poorly competitive row crops with

Fig. 2 Dose–response curves for CO₂ laser cutting of *Solanum nigrum* at the two-true leaf growth stage with stem thickness <1.8 mm or >1.8 mm, respectively. (From Ref. [11].)

limited spacing between individual crop plants. Research has shown that the closer to individual sugar beet plants the weed plants grow, the more they suppress the beet plants and thus have to be removed to preserve yield. To further increase accuracy and reliability of robotic weeding under such difficult circumstances, new research is focusing at the prospects of using electronic crop seed mapping to assist subsequent computer vision for identification of crop and weed seedlings.^[14] Crop seed positioning at sowing uses the technology of real-time kinematics GPS to create an electronic field map with geographical coordinates for each individual crop seed.

Soil steaming has acquired additional interest, realizing that the potential for robotic weeding in row crops with very dense intrarow crop stands (e.g., carrots and direct-sown onion and leek) appears to be very limited. Soil steaming prior to crop sowing can eliminate weed seedling emergence in the crop row by killing viable weed seeds in the heated soil volume provided that a maximum soil temperature of 70–80°C or more can be reached. A major goal is to develop an applicable technique for applying steam in bands corresponding to the intrarow area of a row crop, typically bands of 70–80 mm width and 50–60 mm soil depth.^[15] Band steaming is expected to use much less energy compared with current steaming techniques for arable usage, where the entire surface is treated down to 100–150 mm soil depth.

CONCLUSION

Research in nonchemical weed control methods has gained a renewed interest up to the 1990s in many western countries because of increasing environmental concerns. Several nonchemical methods have been introduced and studied in more detail, some of which are new principles, whereas others are old principles that have been subjected to new research. Some methods have become true alternatives to herbicides both in terms of effectiveness and economic feasibility, whereas others only have interest for organic cropping. New high-technology solutions have become increasingly important in recent years and several research projects are now looking at the potential of high technology to improve physical weed control methods.

Non-Infectious Seed Disorders

INTRODUCTION

Noninfectious seed disorders are nonpathogenic and nontransmissible unless genetically controlled. The disorders can be genetic, physiogenic, or caused by injuries. The genetic disorders are usually inherited and transmitted through seeds from one generation to another. The physiogenic disorders are mainly due to environmental conditions, nutrient deficiencies, and aging. In some cases, aging may be genetically controlled and also environmentally influenced. The injuries can be mechanical, chemical, or the result of insect damage.

Seed disorders can be visible or invisible. Visible disorders include cracking or splitting in seed coat; shrunken or wrinkled seeds; discolored seeds; and seeds with holes, abnormal shape, and reduced size. The invisible seed disorders include some genetic disorders, embryoless or embryo-damaged seeds, aging, and some micronutrient deficiencies.

Seed disorders can affect seed germination or produce weak seedlings and plants with symptoms of different kinds. Books such as *Seed Pathology* by P. Neergaard and *Principles of Seed Pathology* by V. K. Agarwal and J. B. Sinclair provide reviews on noninfectious seed disorders. *An Annotated List of Seed-borne Diseases* by M. J. Richardson also provides some relevant information on the topic.

VISIBLE SEED DISORDERS

Seed Coat Cracking or Splitting

This is one of the most common types of seed disorders. It can be either genetic or caused by mechanical injuries or environmental effects. Seed coat cracking due to genetic effects is common in eggplant, pepper, and tomato.^[1] Seed coat splitting occurs in flax and is more common in yellow-seeded cultivars.^[2] Similar disorder is also found in some cultivars of bean.

Mechanical injuries during harvesting, threshing, processing, and postharvest handling may result in seed coat
