splitting or cracking of many crops.^[1,3] Seeds with low moisture content and thinner seed coat have a higher chance of such damage. Machines with high-cylinder speeds result in damaged seed coats.

Desiccation of seeds during maturation results in cracking of soybean seed coat. Seeds harvested with high moisture and then stacked result in softening or cracking of seed coats.^[1]

The major concern over such seed coat abnormality is that it provides entry points for various types of organisms, pathogens, and saprophytes (Fig. 1). Entry of saprophytes is important because such organisms multiply under bad storage conditions (improper ventilation, high temperatures, high humidity). The effect is pronounced when seeds are stored at high seed moisture.

Discolored Seeds

Seed discoloration is often associated with environmental factors and nutritional deficiencies. Cold-damaged canola seeds become brown^[1] (see also [shrunken seeds](#), discussed later). Frost-injured peanut seeds are off-white, water soaked or translucent, and off-flavor.^[4] Severely damaged seeds can only be used for oil stock. Under humid conditions, radish seeds develop a gray discoloration due to swelling of the subepidermal parenchyma, which results in distortion or cracking of the epidermis.^[3] This facilitates invasion by fungi. Seeds that are moist or immature when stored may become discolored due to heat (see also wrinkled and [embryo-damaged seeds](#), discussed later).^[3]

Boron deficiency in peanuts results in seed discoloration (see also [hollow heart](#), discussed later). Seed coat browning of broad bean is caused by calcium deficiency.^[2] Peanut seeds deficient in calcium often have darkened plumule, and the viability of seeds is directly related to their calcium concentration.^[4]

Reduced Seed Size

In general, plants grown in nutrient-deficient conditions produce seeds of reduced size. Soybean seed size is

Fig. 1 Soybean seed showing seed coat cracking (right) that may facilitate the entry of downy mildew fungus, *Peronospora manshurica*, seen as oospore crusts on the surface of both seeds.

reduced when plants are grown in molybdenum-deficient conditions.^[5] Such seeds may produce plants that show deficiency symptoms when grown in soils with a marginal supply of this nutrient.

Shrunken and Wrinkled Seeds

Cold-damaged canola seeds become brown and shrunken.^[1] Wrinkling of soybean seeds may occur due to moderate desiccation during maturation, resulting in lower field emergence than in seeds with sound coat.^[3] Self-heating of seeds during storage, particularly when the seed is moist or immature, may lead to wrinkling and discoloration.^[3] Severe potassium deficiency tends to result in wrinkled, misshapen soybean seeds.^[5]

Hollow Heart

Hollow heart, characterized by cavities or depression on the adaxial face of cotyledons (Fig 2), is a widely known seed disorder of pea.^[1,3] The disorder is caused by sudden drying of immature seeds at high temperatures. It is common in wrinkled pea seeds and peas having compound starch grains. Hollow heart symptoms are seen when seeds are soaked in water for 16–18 hours at 20–25°C, testae are separated, and the spilt cotyledons are stored for 24 hours at 20–25°C.^[6]

Seeds with hollow heart germinate normally under ideal conditions, but the disorder predisposes seedlings to attack by pathogenic fungi or results in poor emergence.^[1,3]

Hollow heart symptoms also occur in peanut seeds, in which case it is caused by boron deficiency. The

Fig. 2 Hollow heart symptom showing cavitation on the adaxial face of cotyledons of pea (right) and normal seed (left) (From Ref. 14). (View this art in color at www.dekker.com.)

symptoms include discoloration and rotting. The inner face of the cotyledon is depressed in the center, which region often turns brown, especially when peanuts are roasted.^[4]

Marsh Spot

Marsh spot of pea—characterized by discolored lesions in the center of the adaxial face of the cotyledon—is due to manganese deficiency (Fig. 3). The disorder is common in cultivars having simple and large starch granules in the cotyledons.^[1] Similar disorder due to manganese deficiency is found in seeds of broad bean, haricot bean, and runner bean.^[7] Marsh spot symptoms are also seen by the method described for hollow heart symptoms.^[6]

Fig. 3 Marsh spot symptom showing discolored lesions in the center of the adaxial face of cotyledon of pea (right) and normal seed (left) (From Ref. 14). (View this art in color at www.dekker.com.)

Fig. 4 Holes in pea seeds made by insects. (View this art in color at www.dekker.com.)

Yellow Berry

Yellow berry is the term given to wheat grains that are light-yellow in color, opaque, soft, and starchy. They differ from the normally hard, flinty, translucent grains—clear and dark and reddish-amber in color—described in the U.S. state of Kansas.^[8] Yellow berry is associated with nitrogen deficiency and warm temperatures during heading and seed maturation.^[9] Such seeds germinate normally, but may result in poor market value. They are also high in starch content, but low in protein. The incidence of yellow berry differs among wheat genotypes.

Seeds with Holes and Pits

This disorder is caused by a wide range of insects feeding on seeds, causing holes and pits and sometimes leaving seeds completely empty (Fig. 4). Examples of such insects are species of *Bruchus*, *Heliothis*, *Lygus*, and *Sitophilus*.^[3]

INVISIBLE SEED DISORDERS

Genetic Disorders

These disorders are transmitted through seeds, and include fruit pox, gold fleck, and corky stunt of tomato.^[1] Fruit

pox appears as incipient lesions on immature fruit, which later rupture and become necrotic before the fruit turns red. Gold fleck appears as small lesions on immature fruit, that turn golden-yellow on ripe fruit. Corky stunt is expressed as shortened internodes, proliferated axillary buds, malformed petioles, roughened lower petiole surfaces, and malformed and corked fruit. See the *Annotated List of Seed-borne Diseases*^[10] for other examples of seed-transmitted disorders such as bud failure of almond and stem distortion of wheat.

Embryoless or Embryo-Damaged Seeds

Embryoless or embryo-damaged seeds are often found. The disorder is expressed in the form of either no germination or abnormal seedlings. Embryoless seeds are encountered in carrot, celery, coriander, dill, fennel, parsley, and parsnip seeds when insects such as lygus bugs (various species of *Lygus*) eat embryos but leave the seed coat and endosperm undamaged.^[3] Due to some genetic effects, defective fertilization may take place in some crop plants, e.g., barley and wheat, resulting in embryoless seeds.^[1]

Embryo damage may be caused by mechanical injuries, and results in abnormal seedlings. For example, mechanical damage of lima bean embryo during threshing results in balhead or snakehead seedlings that may lack a growing point, radicle, or cotyledon.^[1,3] Similar damage occurs in peas and clover.^[3] Heating of seeds due to metabolic activities during storage may lead to embryo damage and result in the production of abnormal seedlings.^[3]

Seed Aging

Old seeds gradually decline in germination capacity and develop plants of reduced vigor and yield. Seeds stored under adverse conditions may also have reduced viability as a result of induced aging. Seeds stored at higher temperatures generally age early and show increased production of lipid peroxidase. This has been demonstrated in seeds of *Phaius tankervilleae*.^[11] Blind plant problem (i.e., the lack of normal meristem) in tomato is mostly associated with old seeds.^[12] Loss of viability with aging of niger seeds is associated with reduced radicle growth and abnormalities in hypocotyl development.^[13] Aged seeds may also exhibit delays in germination, as in the case of meadow steppe grass seed.^[14]

Chemical Injuries

Seeds treated with chemicals at excessive doses, stored at higher temperatures after treatment, and stored for a long period after treatment may undergo damage. Such seeds

either do not germinate or produce abnormal plants. For example, seed treated with organomercurial fungicides at excessive rates or high moisture either do not germinate or show hypertrophy of the coleoptile and poor root development.^[9] Some chemicals may cause phytotoxicity regardless of moisture content of treated seeds, time of sowing after treatment, and temperature, because they are toxic to certain kinds of seeds but beneficial to others. For example, fungicides like carbendazim + thiram and imidacloprid are found to be toxic to pea seeds.^[15]

Nutrient Deficiencies

Seeds that look normal may be deficient in nutrients, especially micronutrients. Such seeds may produce abnormal seedlings when sown. Pea seeds deficient in boron develop seedlings with pale stunted shoots without plumule bud.^[10] Phaseolus bean seeds produced under molybdenum deficiency conditions give seedlings with scald symptoms.^[10]

CONCLUSION

Noninfectious seed disorders can be genetic, physiogenic, or caused by injuries. Although the disorders are non-pathogenic, they may predispose the seeds to invasion by pathogenic and saprophytic organisms. The disorders are responsible for low germination, production of abnormal or diseased plants, and low market value. The types of disorders and their causes suggest that they can be managed by selecting proper genotypes of crop plants; adopting proper measures during harvesting, processing, and storage; and correcting nutrient deficiencies in soil and plants.

Non-Wood Plant Fibers: Applications in Pulp and Papermaking

Joseph E. Atchison

Atchison Consultants, Inc., Sarasota, Florida, U.S.A.

INTRODUCTION

It is well known that due to a plentiful supply and reasonable costs, the economics of pulp and paper production in North America, and in most other industrial countries, have favored wood as the fibrous raw material, in the past and up to the present time. However, many of the developing countries, as well as a few of the industrial countries, do not have adequate supplies of wood, but they do have large quantities of non-wood plant fibers available. Fortunately, we have found that by choosing the proper blend of non-wood plant fibers, almost all grades of paper and paperboard—ranging from tissue to linerboard, including newsprint—can be produced with as much as 100% fibrous content of these materials. Furthermore, every type of reconstituted panel board—ranging from insulating board to hardboard, including medium-density fiberboard—can likewise be produced, and is being produced, from non-wood plant fibers.

INCREASE IN CAPACITY IN PULPS PRODUCTION FROM NON-WOOD PLANT FIBERS: 1975–1998

As shown in the annual Pulp and Paper Capacities Surveys by the Food and Agriculture Organization of the United Nations for the periods 1975–1980,^[1] 1981–1986,^[2] 1990–1995,^[3] 1993–1998,^[4] and 1998–2003,^[5] the worldwide capacity for production of non-wood plant fiber pulps for papermaking has increased dramatically since 1975, going from 6.8% of total capacity in 1975 to 11.0% of capacity in 1998.

Table 1 shows this rapid growth in production capacity for non-wood plant fiber pulps. It can also be seen that the average increase in non-wood plant fiber pulping capacity has been greater for many years (up until 1998) than the average increase in wood pulping capacity. For example, during the five-year period from 1988–1993, non-wood pulping capacity increased by 6.0% annually, whereas wood pulping capacity increased by only 2.0% annually.

Then during the 1993–1998 period, non-wood pulping capacity increased by 2.7% annually, in contrast to an increase of only 1.6% for wood pulping capacity.

Unfortunately, due to the financial crisis that began in 1997 in the Asian countries and some other developing countries that were major producers of non-wood plant fiber pulp, along with the worldwide recession in the pulp and paper industry (which continues today) and the fact that China has closed several thousand small non-wood plant fiber-based mills that did not have recovery systems, there has been no increase in non-wood plant fiber pulping capacity since 1998. Furthermore, no increased capacity is projected through 2003, as shown in the annual FAO Pulp and Paper Capacities Survey for 1998–2003.^[5] However, it is the author's opinion that as soon as the economic situation improves sufficiently in these countries, which are the major producers of non-wood plant fiber pulp, the previous trend upward will resume.

MINIMUM UTILIZATION OF NON-WOOD PLANT FIBERS IN THE UNITED STATES

In contrast to the worldwide use of non-wood plant fiber pulps, the capacity for producing these pulps for papermaking in the United States amounted to only 219,000 metric tons in 2001, whereas wood pulping capacity amounted to 64 million metric tons, as reported in the FAO Pulp and Paper Capacities Survey for 1998–2003.^[5] No increase in either non-wood plant fiber pulping capacity or wood pulping capacity in the United States is projected through 2003, due to the continuing worldwide recession in the pulp and paper industry.

WORLDWIDE USE OF NON-WOOD PLANT FIBERS FOR PAPERMAKING PULP

The non-wood plant fibers currently being used worldwide and those which offer potential for future use in

Table 1 World papermaking pulp capacities (1975–1998): Non-wood pulping capacity vs. total and average annual increases

Raw materials	Total papermaking pulp capacity (millions of metric tons)				Average annual increases (percent)		
	1975	1988	1993	1998	75–80	88–93	93–98
Total papermaking pulp—all raw materials	136.1	175.7	197.1	214.9	2.2	1.6	1.4

(Compiled from Refs. 1–6.)

papermaking pulps include the agricultural residues such as sugar cane bagasse, straw, and corn stover; the naturally growing plants such as reeds, bamboo, and certain grasses; and the fibers grown specifically for

their fiber content, such as kenaf, crotalaria, jute, abaca (Manila hemp), sisal, cotton and flax fibers, and cotton linters. In the past, almost every known non-wood plant fiber has been tried for the manufacture of pulp and paper,

Total: All Countries	20,736	10.6%	23,600	11.0%

(Compiled from Refs. 1–6.)

and a great many of them result in a product having some desirable properties. However, when all of the economic factors and technical problems are taken into consideration, only a very few of the hundreds of thousands of non-wood plant fibers can qualify.

At the present time, on a worldwide basis, straw, sugar cane bagasse, and bamboo are the leading non-wood plant fibers being used. However, many others are being used in countries such as China and India that do not have adequate wood supplies, even for the mass-production grades. These include reeds and grasses of various types. In addition, many other high-cost non-wood plant fibers are being used all over the world, including in the United States. They produce pulps with special properties that are not found in any wood pulps. Such pulps, including flax fibers, cotton fibers, abaca, sisal, and cotton linters, are being used for the production of relatively small quantities of many high-priced specialty papers and paperboards.

WORLDWIDE NON-WOOD PLANT FIBER PULPING CAPACITY BY COUNTRY (1993 AND 1998)

Table 2, shows the total worldwide capacity for production of non-wood plant fiber pulp by the leading producers of such pulps, along with the percentage of their total papermaking pulp capacity devoted to using these raw materials in 1993 and 1998. These figures are based on data from the FAO Pulp and Paper Capacities Survey for 1993–1998,^[5] combined with individual reports received

by Atchison Consultants in personal correspondence with some of the Pulp and Paper Associations of major non-wood plant fiber pulp-producing countries.^[6] As mentioned earlier in this chapter, there has been no increase in non-wood plant fiber pulping since 1998.

Some 42 countries are now producing some papermaking pulp from non-wood plant fibers, with the total capacity approaching 24 million metric tons (Table 2), or 11.0 % of total worldwide papermaking pulp capacity. It can be seen that China is by far the leader, with 84% of its total papermaking pulp capacity devoted to pulping non-wood plant fibers. India is second, with over 64% of its capacity based on pulping non-wood plant fibers. Among the countries shown in Table 2, non-wood plant fiber represents 100% of the pulping raw materials in four of them, and nine of them depend upon these raw materials for more than 50% of their pulping capacity. Table 3 a summary of worldwide papermaking pulp capacities based on using specific non-wood plant fibers, as well as the total of wood-based pulping capacities and the overall percentages of pulping capacities based on using non-wood plant fibers.

CONCLUSION

There appears to be no doubt that non-wood plant fibers will play an increasing role in the world's pulp and paper industry. Certainly, the necessary fiber resources either already exist or can be grown in the wood-poor countries, in order to sustain the pulp and paper requirements in those areas. It has been proved that by selecting the proper

Table 3 Summary of worldwide papermaking pulp capacities using non-wood plant fibers and pulpwood (1983–1998)

Raw materials	Total papermaking pulping capacities (millions of metric tons)			
	1983	1990	1993	1998
A. Total wood-based papermaking pulp capacity	151,000	168,600	176,000	191,292
B. Non-wood plant fiber papermaking pulp capacity by raw material				
Straw	6,166	6,787	9,566	10,705
Sugar cane bagasse	2,339	2,739	2,984	3,206
Bamboo	1,545	0.987	1,316	1,474
Miscellaneous non-wood plant fibers	3,302	5,049	6,870	8,174
Subtotal: non-wood plant fiber pulping capacity	13,352	15,562	20,747	23,559
Grand total: papermaking pulping capacity	164,352	184,162	197,736	214,851
Percentage for non-wood plant fiber pulps	8.1	8.5	10.6	11.0

(From Refs. 1–6.)

mixture of these fibers and by the appropriate collecting, handling, storing, and pulping processes, any grade of paper, paperboard, or reconstituted panelboard can be produced from non-wood plant fibers. If circumstances require it, all grades can be produced without the addition of wood pulp. In fact, some grades are already being produced with 100% non-wood plant fiber, especially bagasse pulp. However, for most of the mass production grades it is expected that non-wood plant fiber pulps will be used in blends with at least a small proportion of wood pulp, even in the wood-poor countries.

In regard to the greater use of non-wood plant fiber pulps in North America, the time may be approaching when their greater use will become a reality. With 100 million metric tons of available straw; the potential of some 5 million tons of bagasse, with large concentrations of it available in Louisiana; 150 million metric tons of corn stover; and the exciting possibilities of kenaf, non-wood plant fiber certainly should be considered as supplementary raw materials to be blended with wood pulp.

Nucleic Acid Metabolism

Hiroshi Ashihara

Ochanomizu University, Tokyo, Japan

INTRODUCTION

Nucleic acid metabolism includes biosynthesis of nucleotides (phosphate esters of ribose or deoxyribose in which a purine or pyrimidine base is linked to C1' of the sugar residue) for RNA and DNA, and degradation of these nucleic acids to simple molecules. The processes of DNA replication and repair, as well as the synthesis of various RNAs related to gene expression, are not included in this review. Compared with microorganisms and mammals,^[1–3] only limited research has been carried out on the synthesis and degradation of nucleic acids in higher plants; some reviews of the subject have been published.^[4–9]

DE NOVO BIOSYNTHESIS OF RIBONUCLEOTIDES

The pathways in the biosynthesis of nucleotides from their small molecule precursors are traditionally referred to as de novo pathways. In contrast, nucleotide synthetic pathways from preformed purine bases and nucleosides are called salvage pathways.

Pyrimidine Nucleotide Biosynthesis

The de novo pyrimidine biosynthetic pathway, also known as the orotate pathway, is defined as the formation of uridine 5'-monophosphate (UMP) from carbamoyl phosphate. The orotate pathway consists of six reactions, as shown in Fig. 1. The pyrimidine ring is assembled from carbamoyl phosphate and aspartate. The C-2 and N-3 atoms originate from carbamoyl phosphate; N-1, C-4, C-5, and C-6 originate from aspartate. In mammals and many other eukaryotes, the first three enzymes—carbamoyl-phosphate synthetase, aspartate transcarbamoylase, and dihydroorotase—are present as a multifunctional protein called CAD (after the initial letter of the three constituent enzymes). However, no such complex has been detected in plants, although most of the encoding genes for the individual enzymes have been cloned. Some of the genes contained chloroplast transit sequences. Thus, in higher

plants, pyrimidine biosynthesis seems to be operative in chloroplasts.

Although there are two different types of carbamoyl phosphate synthetases that provide substrates for pyrimidine and arginine biosynthesis in most eucaryotes, including mammals, only one is present in higher plants. Therefore, the plant enzyme provides carbamoyl phosphate for both pathways. UMP, an end product of the orotate pathway, is a feedback inhibitor of plant carbamoyl phosphate synthetase, but this inhibition is overcome by ornithine, leading to the utilization of carbamoyl phosphate for arginine biosynthesis. The second enzyme— aspartate transcarbamoylase—is also inhibited by high concentrations of UMP. This seems to be feedback control of pyrimidine biosynthesis.

The fourth enzyme—dihydroorotate dehydrogenase—is not well characterized. Subcellular localization studies with heterotrophically cultured tomato cells suggested that it is located in mitochondria. The fifth and sixth enzymes—orotate phosphoribosyltransferase and orotidine-5'-monophosphate decarboxylase—from plants, reside in a single polypeptide. Recently, a new term, UMP synthase, has been given to this multifunctional protein, which is also observed in animals. UMP produced by the orotate pathway is further phosphorylated by UMP kinase and nucleoside diphosphate kinase to UTP via UDP. CTP is formed from UTP by a one-step reaction catalyzed by CTP synthetase.

Purine Nucleotide Biosynthesis

The de novo purine biosynthetic pathway is defined as the pathway that is responsible for the synthesis of inosine 5'-monophosphate (IMP) from 5-phosphoribosylamine (PRA). PRA is formed from 5-phosphoribosyl-1-pyrophosphate (PRPP), a common phosphoribosyl donor for purine and pyrimidine nucleotide synthesis. The purine ring is assembled from several small molecules. The N-1 atom originates from aspartate; C-2 and C-8 are from activated derivatives of tetrahydrofolate; N-3 and N-9 come from the amide group of the side chain of glutamine; and C-4, C-5, and N-7 are from glycine. Fig. 2 shows the 10 steps of the IMP synthetic pathway from PRPP. Precise details of this pathway in plants are still obscure, but the

Fig. 1 De novo biosynthetic pathway of pyrimidine biosynthesis in plants. Participating enzymes and genes are as follows: (1) Carbamoyl phosphate synthase (EC 6.3.5.5, *carA*, *carB* or *pyrAA*, *pyrAB*); (2) aspartate transcarbamoylase (2.1.3.2, *pyrB*); (3) dihydroorotase (3.5.2.3, *pyrC*); (4) dihydroorotate dehydrogenase (1.3.99.11, *pyrD*); (5) orotate phosphoribosyltransferase (2.4.2.10, *pyrE* or *umps*); (6) orotidine 5'-monophosphate decarboxylase (4.1.1.23, *pyrF* or *umps*); (7) UMP kinase (2.7.4.4, *pmk* or *umpk*); (8) Nucleoside diphosphate kinase (2.7.4.6, *ndk*); (9) CTP synthetase (6.3.4.2, *pyrG*). Large and small subunits of carbamoyl phosphate synthase are coded in *carA* and *carB*, respectively. Bifunctional protein consists of orotate phosphoribosyltransferase and orotidine 5'-monophosphate decarboxylase is recently called as UMP synthase. Gene names for plant pyrimidine metabolism have not yet standardized.

same biosynthetic pathway for IMP has been established in animals and microorganisms. In animals, enzymes of the de novo purine nucleotide biosynthetic pathway and those of hydrofolate metabolism are present as a multi-enzyme complex called a metabolon. However, such a complex has not been observed in higher plants. IMP is further converted to AMP and GMP. These two purine nucleoside 5'-monophosphates are phosphorylated to nucleoside diphosphates and finally to nucleoside triphosphates. Feedback control of the de novo purine biosynthetic pathway is performed in at least three steps: 5-phosphoribosylamine synthase activity is inhibited by IMP, AMP, and GMP. Activities of adenylosuccinate synthetase and IMP dehydrogenase are inhibited by AMP and GMP, respectively.

BIOSYNTHESIS DEOXYRIBONUCLEOTIDES

Synthesis of Deoxyribonucleotides

A single plant ribonucleotide reductase catalyses the reduction of the ribose moiety of the ribonucleotide diphosphates, and deoxyribonucleoside diphosphates (dNDP) are produced. With the exception of dUDP, dNDP are further phosphorylated and the resultants—dCTP, dATP, and dGTP—are utilized as direct precursors for DNA synthesis. For dTTP synthesis in plants and in microorganisms such as *E. coli*, dUDP formed by the ribonucleotide reductase is first converted to dUTP, and then hydrolyzed to dUMP. In contrast, dUMP is formed from dUDP in animals.

Fig. 2 De novo biosynthetic pathway of purine nucleotide biosynthesis in plants. Participating enzymes and genes are as follows: (1) amido phosphoribosyltransferase (2.4.2.14, *pur1*) (2) glycineamide ribonucleotide (GAR) synthetase (6.3.4.13, *pur2*); (3) GAR formyl transferase (2.1.2.2, *pur3*); (4) formyl glycine amidine ribonucleotide (FGAM) synthetase (6.3.5.3, *pur4*) (5) 5-imidazole ribonucleotide (AIR) synthetase (6.3.3.1, *pur5*); (6) AIR carboxylase (4.1.1.21, *pur6*); (7) 5-aminoimidazole-4-*N*-succinocarboxamide ribonucleotide (SAICAR) synthetase (6.3.2.6, *pur7*); (8) adenylosuccinate (SAMP) lyase (4.3.2.2, *pur8*); (9) 5-aminoimidazole-4-carboxamide ribonucleotide (AICAR) formyl transferase (2.1.2.3, *pur9*); (10) inosine 5'-monophosphate (IMP) cyclohydrolase (3.5.4.10, *pur10*); (11) SAMP synthetase (6.3.4.4, *pur11*); (12) SAMP lyase (4.3.2.2, *pur12*), (13) IMP dehydrogenase (1.2.1.205, *pur13*); (14) GMP synthetase (6.3.4.1, *pur14*). Gene names for plant purine metabolism have not yet standardized.

Synthesis of Thymidine Nucleotides

Thymidine nucleotide is synthesized from dUMP by the following reaction catalyzed by thymidylate synthase:

In this reaction, $\text{N}^5, \text{N}^{10}$ -methyltetrahydrofolate produced by dihydrofolate reductase acts both as donor of the methyl group and as reducing agent. A bifunctional protein that consists of thymidylate synthase and dihydrofolate reductase has been detected in plants.

SALVAGE PATHWAYS

Free nucleosides (nucleobases with sugar attached in a glycosidic linkage) and nucleobases (purines and pyrimidines that are incorporated into nucleic acids and nucleotides) are produced as degradation products of nucleic acids and nucleotides. Pyrimidine and purine nucleotides can be resynthesized using these preformed pyrimidine and purine skeletons by various salvage reactions.

Pyrimidine Salvage

Uracil, one of the pyrimidine bases, is salvaged by uracil phosphoribosyltransferase, but another base—cytosine—is not salvaged by any enzymes. Pyrimidine nucleosides, uridine, cytidine, deoxycytidine, and thymidine are salvaged to their respective nucleotides, UMP, CMP, dCMP, and dTMP. Uridine and cytidine are phosphorylated by a single enzyme, uridine/cytidine kinase, which is present in all plants investigated to date. Deoxycytidine kinase and thymidine kinase may be present in plants, but details of their activity have yet to be reported. Nonspecific nucleoside phosphotransferase activity also participates in the salvage of pyrimidine nucleosides as well as purine nucleosides. Thymidine kinase activity measured in crude plant extracts seems to be due to the activity of nucleoside phosphotransferase and phosphatases.

Purine Salvage

Three purine bases—adenine, guanine, and hypoxanthine—are salvaged to AMP, GMP, and IMP, respectively. Two distinct enzymes—adenine phosphoribosyltransferase and hypoxanthine/guanine phosphoribosyltransferase—participate in these salvage reactions. Purine bases may also be salvaged to nucleotides via nucleosides. Adenosine phosphorylase and inosine-guanosine phosphorylase convert adenine, hypoxanthine, and guanine to

respective ribonucleosides using ribose-1-phosphate, but activities of these enzymes are very low in higher plants.

Purine nucleosides, adenosine, guanosine, and inosine are salvaged by kinases and/or nucleoside phosphotransferase. Adenosine kinase is distributed ubiquitously and its activity is high, but inosine-guanosine kinase has only been found in limited plant species. In some plants, inosine and guanosine are mainly salvaged by the non-specific nucleoside phosphotransferase.

NUCLIC ACID SYNTHESIS

Four ribonucleoside triphosphates—UTP, CTP, ATP, and GTP—are used for the precursor of the synthesis of various RNAs, whereas dTTP, dCTP, dATP, and dGTP are used as the building blocks of DNA. Pool sizes of individual ribonucleotides vary greatly because they are not only the building blocks for RNA but also have other important functions, such as energy transfer. Thus, the ATP pool is always higher than other nucleotide pools, and the CTP pool is very small. The size of deoxyribonucleotide pools is extremely small compared with ribonucleotides; as a consequence, no direct measurements of these nucleotides have yet been carried out with plants.

DEGRADATION OF NUCLEIC ACIDS

DNA and RNA are hydrolyzed by deoxyribonucleases (DNases) and ribonucleases (RNases), respectively. Oligonucleotides formed by these enzymes further hydrolyzed to nucleoside monophosphates by phosphodiesterases with 2', 3', and 5'-nucleoside monophosphates being produced. Some of these nucleotides are catabolized by nucleotidases and/or phosphatases and nucleosides accumulate. Furthermore, in plants, nucleosides are hydrolyzed exclusively by nucleosidases to nucleobases. Significant amounts of free nucleosides and nucleobases are produced, because the degradation products of nucleic acids seem to be salvaged within the same cells or transported to other organs, e.g., from senescent leaves to young shoots. The remainder will be completely degraded to CO_2 and NH_3 .

DEGRADATION OF NUCLEOTIDES

Pyrimidine Catabolism

In plants, pyrimidine nucleotides are degraded to nucleoside and nucleobases. Pyrimidine bases, uracil, and thymine are catabolized by a reductive pathway. There is

A) Pyrimidine catabolism

B) Purine catabolism

Fig. 3 Catabolic pathways of pyrimidine and purine nucleotides in plants. Pyrimidine and purine catabolism are shown in A and B separately. Participating enzymes are as follows: A: (1) 5'-nucleotidase (3.1.3.5); (2) cytidine deaminase (3.5.4.5); (3) uridine nucleosidase (3.2.2.3); (4) dihydrouracil dehydrogenase (1.3.1.1); (5) dihydropyriminase (3.5.2.2); (6) β -ureidopropionase (3.5.1.6). B: (1) AMP deaminase (3.5.4.6); (2) IMP dehydrogenase (1.1.1.205); (3) 5'-nucleotidase (3.1.3.5); (4) inosine-guanosine nucleosidase (3.2.2.2); (5) guanosine deaminase (3.5.4.3); (6) guanine deaminase (3.5.4.3); (7) xanthine dehydrogenase (1.1.1.204); (8) uricase (1.7.3.3); (9) allantoinase (3.5.2.5); (10) allantoicase (3.5.3.4); (11) ureidoglycolate lyase (4.3.2.3); (12) urease (3.5.1.5); (13) allantoin deaminase (3.5.3.9); (14) ureidoglycine amidohydrolase (no EC number given); (15) ureidoglycolate hydrolase (3.5.3.19). Gene names for most enzymes of nucleotide catabolism in plants have not yet been given.

no catabolic pathway of cytosine in plants; thus, catabolism of CMP must be performed after conversion of cytidine to uridine. Plants have cytidine deaminase, but not cytosine deaminase, so conversion at nucleoside level is essential. Uracil and thymine are catabolized by the same three sequential reactions. The end products of this catabolic pathway are either β -alanine or β -aminoisobutyrate (Fig. 3A). In both cases, CO_2 and NH_3 are produced as by-products. Because β -alanine is a precursor of the pantothenate moiety of coenzyme A, uracil catabolism seems to be important as the biosynthetic pathway of β -alanine in plants.

Purine Catabolism

Plants possess the complete oxidative purine catabolic pathway to CO_2 and NH_3 via uric acid and allantoin. A key starting compound of purine catabolism is xanthine; thus, all purine nucleotides must be converted to xanthine before their purine ring cleavage is initiated. Deamination, dephosphorylation, and glycosidic bond cleavage are included in this process. In contrast to animals, in most plants no adenosine deaminase is found, and AMP deaminase and guanosine deaminase are the predominant deamination enzymes for adenine and guanine nucleotides, respectively. Guanine deaminase is also detected in plants, but its activity is low. GMP reductase, which catalyses the conversion of GMP to IMP, is not present in plants. There are many enzymes for dephosphorylation reaction. Various phosphatases, 3'-nucleotidase, and 5'-nucleotidase appear to produce purine nucleosides. Adenosine nucleosidase and inosine-guanosine nucleosidase seem to participate in glycosidic bond cleavage (Fig. 3B).

Xanthine is converted to uric acid by xanthine dehydrogenase. Uricase catalyzes the formation of allantoin, and allantoic acid is produced by an allantoinase-catalyzed reaction. Some plant organs, such as roots of the tropical legumes and maple trees, accumulate allantoin and/or allantoic acid, which play an important role in the storage and translocation of nitrogen. Different metabolic fates of allantoic acid are proposed in plants.

In the classic allantoinase pathway, allantoic acid is degraded to CO_2 , NH_3 , and glyoxylate via urea and ureidoglycolate. Recently an alternative route, an allantoic acid amidohydrolase pathway, has been proposed in which allantoic acid is initially converted to ureidoglycine, CO_2 , and NH_3 . The NH_3 is released directly and urea formation is not involved.

Nutraceuticals and Functional Foods: Market Innovation

Nicholas Kalaitzandonakes

James D. Kaufman

Lucy Zakharova

University of Missouri, Columbia, Missouri, U.S.A.

INTRODUCTION

Functional foods are foods that provide health benefits beyond basic nutrition. Functional foods cater to both ill and healthy, and target prevention and treatment of illness, as well as maintenance of one's well-being. Products in the market range from complete portfolios of prepared meals that battle cardiovascular and type II diabetes, to fortified drinks and cereals that provide supplemental minerals, vitamins, and fiber.

Nutraceuticals are isolates that provide concentrated nutrients in the form of pills, tablets, liquids, or powders for direct consumption or for use as ingredients in functional foods. Nutraceuticals include micro- and macronutrient isolates, herbs and botanicals, and isolated reagents (e.g., hormones).

DRIVERS OF INNOVATION

Traditional remedies utilizing plants and animals to cure disease and improve health and well-being have existed for centuries and have been passed down through generations. In the mid-1980s, clinical studies began to formalize the relationship between nutrition and healthfulness, attracting significant attention from both media and consumers. First among these studies was the 1984 National Cancer Institute certification that high-fiber cereals foster cardiovascular health. Since that time, the body of literature connecting nutrition to specific health benefits and disease treatment has increased substantially, and other foods (e.g., calcium, omega-3 fatty acids, whole oats, and soy protein) have gained similar certification by the U.S. Food and Drug Administration (FDA).

Scientific discovery in the development of new products capable of delivering specific health benefits has also advanced rapidly. Cholesterol reduction, cardiovascular disease, and osteoporosis have become the most frequent targets for functional foods and nutraceuticals, followed by child development, moodiness, low energy, high blood pressure, diabetes, gastrointestinal (GI) disorders, menopause, and lactose intolerance.

Consumer interest has bolstered new product development of nutraceuticals and functional foods.^[1–3] An aging and wealthier population in Japan, the European Union (E.U.), and the United States has become increasingly interested in the prevention of disease and health maintenance, representing a receptive audience to health claims. Similarly, escalating health care costs and increasing interest in self-medication have shifted attention to health maintenance and disease prevention instead of treatment. [Table 1](#) provides some examples of nutraceuticals and functional foods introduced in recent years.

MARKET SIZE AND GROWTH

In 2001, the global market for functional foods was estimated at over \$47.6 billion. Well developed food markets accounted for the majority of the global consumption of functional foods. The U.S. functional foods market alone was valued at \$18.25 billion, representing 3.7% of the \$495 billion spent for food at home by U.S. consumers. The European Union and Japan followed with \$15.4 billion and \$11.8 billion in functional food sales, respectively.^[4] Consumer spending on functional foods is expected to grow at a fast rate although not evenly across all food categories. In recent years, functional beverages have experienced the fastest growth ([Table 2](#)).

Not all functional foods have been successful in the marketplace. Some products have seen diminished consumer demand due to unexpected negative side effects (e.g., the fat substitute Olestra). Others have been quietly removed from supermarket shelves due to lack of sufficient consumer demand (e.g., McNeil's Benecol in the United States; Kellogg's Ensemble; and Cambell Soup Company's Intelligent Cuisine).

The global market for nutraceuticals reached \$50.6 billion in 2001. Vitamin/mineral supplements accounted for 40% (\$20.6 billion) of those sales, followed by herbs and botanicals (\$19.6 billion) and sports/specialty supplements (10.4 billion).^[7] Vitamins are especially important in the U.S. market, whereas herbs are relatively more important in the European and Asian markets, which have a long tradition of herbal use and remedies.

Table 1 Nutraceuticals and functional foods

Category	Product name	Product form	Claim
<i>Health foods (Foods with approved health claims)</i>			
	Tofu	Food	Cardiovascular health
	Oatmeal	Food	Cancer prevention
<i>Nutraceuticals (Food ingredients with specific claims of benefit)</i>			
	Glucosamine	Food ingredient	Joint health
	Soluble fiber	Food ingredient	Cancer prevention
	Ginseng	Herb/ingredient	Physical performance
	Soy protein	Food ingredient	Cardiovascular health
<i>Functional foods (Foods or drinks with specific claims of benefit)</i>			
	Yakult Honsha's Yakult	Probiotic active cultures	Improved digestion
	McNeil's Benecol	Margarinelike spread	Lowers LDL cholesterol
	Proctor & Gamble/Olean's	Fat substitute	Weight loss
	Olestra		
	Tropicana's Tropicana calcium	Calcium fortified juice	Skeletal health
	Kellogg's Ensemble	High-fiber cereal	Cholesterol reduction
	Campbell Soup Company's	Line of prepared meals	Nutritionally balanced
	Intelligent Cuisine		
<i>Drug delivery foods (Food as clinical drug delivery mechanism)</i>			
	(Not yet commercialized)	Potato, banana, tomato	Vaccine for hepatitis B, etc.

PRODUCT INNOVATION AND INDUSTRIAL DEVELOPMENT

For continuing growth in the nutraceuticals and functional foods markets, sustained technological innovation will continue to be critical. The scope of innovation will likely range from product functionality, to taste characterization and manufacturing. This will require the pooling of knowledge, skills, and infrastructure from industries that have not worked closely together in the past. For example, nutraceutical startups and biotechnology firms may contribute discoveries in new products and attributes. Food companies may provide product formulation, man-

ufacturing, and distribution capabilities. Pharmaceutical companies may contribute discovery and knowledge in amplification of efficacy, as well as experience in the validation of safety (e.g., clinical trials).

Major food companies making significant investments in functional foods are already pursuing integration of skills and assets. Many of these companies have moved to acquire diverse skills through acquisitions or strategic alliances. For instance, PepsiCo recently acquired Gatorade and Sobe functional beverage brands; Heinz acquired a share in Hain Foods, a processor of soy and natural foods; and Quaker and Novartis entered into a joint venture to form Altus Food Company, which is dedicated to the development of functional foods.

To be successful, this emergent industry will have to learn how to develop products that deliver functionality in ways that appeal to changing consumer tastes and lifestyles. It will also have to learn how to protect and recoup its investments (e.g., R & D) through patents, brands and trademarks, and other marketing strategies. Finally, this new industry will have to learn how to position functionality claims within an uncertain and fragmented regulatory environment.

INSTITUTIONAL INNOVATION

It will be up to governments to establish relevant institutional environments that create appropriate incentives

Table 2 U.S. retail sales of functional foods by category (\$billion)

Category	1998 ^a	2000 ^b
Beverages	4.9	8.2
Breads and grains	6.1	4.8
Packaged/prepared foods	1.1	1.6
Dairy	1.7	1.1
Meat, fish, and poultry	0	0
Snack foods	0.8	1.4
Condiments	0.1	0.2
Total	14.8	17.2

^aFrom Ref. 5.

^bFrom Ref. 6.

for research and development in nutraceuticals and functional foods while they protect public health and consumer interests. Meaningful institutional innovation will therefore be necessary in coming years. Current regulation lacks clear standards on health claims (efficacy), product quality, and safety that can impede market development. For instance, the slow market development experienced in herbs/botanicals (a flat 1.2% rate of growth in 2000) has been attributed to the high incidence of low-quality (and occasionally unsafe) products introduced during the boom market of the late 1990s.^[7] Herbs contaminated with heavy metals, heart problems attributed to Ephedra, and safety concerns with sports supplements (e.g., Androstenedione, or Andro) attracted significant negative public attention and reduced consumer interest.

Development of a proper regulatory framework has been complicated by the dualistic food and drug nature of nutraceuticals and functional foods. Complexities are likely to increase in the future as active ingredients become more powerful, requiring some foods to be regulated as pharmaceuticals. For instance, pharmaceutical foods (such as edible vaccines) are already under development. These bioengineered foods are being developed to express specific pharmaceutical compounds, providing a convenient drug manufacturing and delivery mechanism. Accordingly, an institutional environment capable of efficiently regulating both foods as drugs and drugs as foods will be necessary.^[8]

Currently, there are few regulatory standards, and those that exist fail to transcend national borders. The U.S. system is characterized by a dichotomy of regulatory stringency, wherein some products can be commercialized with minimal regulatory oversight, while others are strictly regulated. Less-regulated products are allowed by the Dietary Supplement Health and Education Act (DSHEA), which shifted the burden of proving an ingredient unsafe from the manufacturer to the FDA. Under DSHEA guidelines, a dietary supplement may include a vitamin, mineral, herb/botanical, amino acid, metabolite, or an extract. Laws allow nutritional support statements such as those relating to classical nutrient-deficiency diseases, structure/function, or well-being, provided they include the following disclaimers: "This statement has not been evaluated by the Food and Drug Administration" or "This product is not intended to diagnose, treat, cure, or prevent any disease."

In order to make health claims linking a food or dietary supplement to a disease or health-related condition, premarket approval by the FDA is required. The FDA approval process is dependent on scientific consensus identifying a specific functional component responsible for physiological action. The approved health claim

must include the appropriate dietary context (e.g., low in saturated fat and cholesterol), which can then be used with any similar product, not just those produced by the petitioner.

The main obstacle for the European system is the lack of standard protocols across national borders. For example, France and Germany differ from the United States and many other European countries in that French and German herbal drugs are distributed via pharmacies, allowing for doctor mediation and reimbursement by health insurance.

In contrast to the U.S. and European models, the Japanese nutraceuticals and functional foods markets are highly regulated and supported. Since 1991, the Japanese government has actively promoted the development of functional foods through the Foods for Specialized Health Use (FOSHU) system. Foods in this product category can secure regulatory approval to make specific health claims, and are educationally supported by the program. FOSHU is an umbrella label for all functional foods, and ensures safety and efficacy; however, FOSHU is not mandatory and the manufacturers of some functional products opt to circumvent it, suggesting that subpar products may still be commercialized. This Japanese system has been popularly proposed as a potential template for the development of international standards. The development of such international standards, however, has progressed slowly (until now).

CONCLUSION

It is clear that both scientific discoveries and consumer interest are creating opportunities for an expanding menu of foods and supplements that claim health benefits beyond nutrition. In globalized markets where products are traded across national borders at an increasing pace, a proper regulatory framework for how such claims are brought forward will be increasingly important. Hence, consumers, scientists, entrepreneurs, and regulators will all shape the rate and direction of product innovation in the nascent markets of nutraceuticals and functional foods for many years to come.

Oomycete-Plant Interactions: Current Issues in

O

Mark Gijzen

Agriculture and Agri-Food Canada, London, Ontario, Canada

INTRODUCTION

The oomycetes (water molds) are related to the brown algae and diatoms. Oomycetes resemble fungi morphologically, but are now classified separately based on their natural phylogeny. Oomycetes have coenocytic hyphae with cell walls consisting mainly of cellulose and glucans. They are diploid throughout most of their life cycle and reproduce sexually by formation of thick-walled oospores, or asexually by zoospores or sporangia. Heterothallic species require different mating types to produce oospores, whereas homothallic species are self-fertile. Oomycetes include hundreds of plant pathogenic species distributed across several genera, including *Albugo*, *Aphanomyces*, *Bremia*, *Peronospora*, *Phytophthora*, *Plasmopara*, and *Pythium*. Plant pathogenic oomycetes may be necrotrophic, biotrophic, or hemibiotrophic species. Many studies on oomycete–plant interactions focus on the *Phytophthora* species, an especially destructive and widespread genus. Genetic and molecular-level research on oomycetes is gaining momentum; new insights into processes that control virulence and pathogenicity are emerging.

OOMYCETES AS PLANT PATHOGENS

Oomycetes display a range of pathogenic strategies in colonizing host tissues. Necrotrophs such as *Pythium* are considered facultative parasites that kill host cells in advance of infection. *Pythium* also include many saprophytic species that simply live off dead tissue and are not true pathogens. Obligate biotrophs such as *Bremia* and *Peronospora* require living host cells and cannot be grown in culture. Many *Phytophthora* spp. are intermediate types (hemibiotrophs) that first establish in living cells as biotrophs but more closely resemble necrotrophs at later stages of infection.^[1] An evolutionary sequence has been proposed whereby saprophytes give rise to necrotrophic organisms, which in turn may further evolve into hemibiotrophs, and ultimately, into obligate biotrophs. The oomycetes present compelling evidence in support of this theory because their spectrum of pathogenic strategies is generally concordant with their phylogeny.^[2] It is clear that these different colonization strategies result in different mechanisms of infection, but there may remain

commonalities among different pathogen types. For example, the subversion of host plant metabolism and the suppression of many chemical and structural defense responses would benefit any pathogen, whether biotroph or necrotroph. In contrast, pathogen-induced host cell death by secretion of toxins or by manipulation of endogenous cell death programs may be predicted to benefit the pathogen in necrotrophic but not biotrophic interactions.

The oomycetes are considered versatile and adaptable plant pathogens for other reasons as well. These organisms attack a wide range of herbaceous and woody plants in many different environments. Host specificity may be broad or restricted to a single plant species. Most *Pythium* species have wide host ranges, whereas the biotrophic species *Bremia* and *Peronospora* are highly specialized with one or few host plants. *Phytophthora* species may have broad or narrow host ranges.

Contemporary studies on plant pathogenic oomycetes address many different species, but a few organisms are attracting a critical mass of researchers and resources. Emerging as model systems for molecular genetic and genomic studies on oomycetes are *Phytophthora infestans* and *Phytophthora sojae*. *P. infestans* is a heterothallic species that causes late blight of potato and tomato. This is predominantly a foliar pathogen, but is also able to infect tubers. Outbreaks of *P. infestans* are spread via airborne sporangia. *P. sojae* is a homothallic oomycete that causes root and stem rot of soybean, as shown in Fig. 1. This soilborne pathogen produces motile zoospores that spread in water and are attracted to soybean roots. Oospores are also abundantly produced in infected tissues, and these propagules are long-lived in soil and may be spread by animals or machinery.

Genetic studies on oomycetes have benefited from advances in molecular biology.^[3] It is now possible to distinguish hybrid progeny from self-fertilized individuals based on DNA markers, and to create F₂ progeny sets. This has enabled researchers to perform classical genetic analyses of oomycetes, and has confirmed that many oomycete–plant interactions are governed by complementary avirulence (*Avr*) and resistance (*R*) genes. Genetic analyses of *Bremia lactucae*, *P. infestans*, *P. sojae*, and *Peronospora parasitica* indicate that, although exceptions have been noted, *Avr* genes segregate as single dominant loci and some *Avr* genes occur in clusters or

Fig. 1 A field infestation of *Phytophthora sojae* on soybean plants, photographed near Windsor, Ontario. (View this art in color at www.dekker.com.)

as tightly linked loci. Various *Avr* loci comprise targets for positional cloning projects in these species.^[4]

OOMYCETE ELICITORS AND TOXINS

Interactions between pathogens and their hosts involve multiple signaling cues that ultimately determine whether the infection is successful. Elicitors and toxins have overlapping activities and each may trigger a similar set of plant defense responses, such as necrosis, phytoalexin accumulation, and cell death. Functionally, elicitors are generally regarded as molecules that aid the host by initiating defense reactions that contain the pathogen, whereas toxins are considered virulence factors produced by the pathogen to disable the host.^[5] Among the first elicitors purified and characterized from a plant pathogen was a β -glucan elicitor from *P. sojae*. This is released from the cell walls of *P. sojae* by glucanase enzymes secreted by soybean cells. As a counter-defense, *P. sojae* produces inhibitors of the soybean-secreted glucanase enzymes, to slow cell wall digestion and elicitor release. This example provides evidence for the “escalating arms race” hypothesis of plant-pathogen interactions.

Many oomycetes, including *Phytophthora* and *Pythium* species, secrete small cysteine-rich proteins called elicitors. These 10 kD proteins elicit the hypersensitive response in certain plants, most notably in tobacco and other *Nicotiana* species. Larger proteins containing elicitor domains fused to other sequences may also be active. Most *Phytophthora parasitica* strains that are pathogenic on tobacco do not secrete elicitors because these proteins may act as host-specific avirulence determinants, limiting *Phytophthora* infections on tobacco

plants. Elicitors have been shown to possess sterol- and lipid-binding activity, and their elicitor activity is also dependent on sterol binding. It is possible that elicitors function as carriers for the acquisition or transport of sterols or lipids. The elicitor protein family is large and diverse, and it is likely that this diversity is also reflected in their functional roles.

Several other *Phytophthora* proteins with elicitor or toxin activity have been described^[3] as follows:

- A 42 kD transglutaminase protein secreted by *Phytophthora* species induces phytoalexin accumulation and other defense responses in parsley. The elicitor activity of the protein is dependent on the same residues that are necessary for catalytic activity, and this peptide signature has been proposed to constitute a pathogen-associated molecular pattern for *Phytophthora*.
- A 34 kD glycoprotein first purified from *Phytophthora parasitica* induces necrosis and defense gene expression in tobacco. This protein has cellulose-binding activity and plays a role in the adhesion of *Phytophthora* to plant cells.
- A 25 kD protein purified from *Pythium* and *Phytophthora* species is remarkable in its ability to cause plant cell death in a wide range of dicotyledonous plants. It is similar to proteins discovered in unrelated organisms that are also plant pathogens or saprophytes, such as fungi and bacteria.
- A 5.6 kD phytotoxic protein from *Phytophthora cactorum* has been shown to cause necrosis on strawberry and tomato plants.

These examples illustrate that many different factors may contribute to disease symptoms and cell death in oomycete-plant interactions. The proteins may be important factors that enable *Phytophthora* to invade host plants, or alternatively, provide cues for host plant surveillance systems aimed at limiting pathogen spread.

PLANT RESISTANCE TO OOMYCETE PATHOGENS

Because it is a host to several different oomycetes, including *Per. parasitica* and *Phytophthora brassicae*, *Arabidopsis thaliana* provides a powerful model for genetic dissection of mechanisms of plant resistance to oomycete pathogens. Resistance to the downy mildew pathogen has been most intensively studied and several different *RPP* genes, conditioning resistance to *Per. parasitica*, have been isolated from *A. thaliana*.^[6] Other plant genes resistant to oomycete pathogens that have been isolated include the lettuce *Dm3* gene, controlling

Fig. 2 A scanning electron micrograph showing zoospores of *Phytophthora sojae* on the surface of a soybean hypocotyl, 12 hours after inoculation. The zoospores have formed germ tubes and are penetrating the host tissues. (A: Appressorium like structure; G: Germtube; H: Soybean hypocotyl surface; Z: Encysted zoospore.) (View this art in color at www.dekker.com.)

resistance to *Bremia lactucae*, and the potato *R1* gene, for resistance to *P. infestans*. There are common features among these resistance genes, as they all encode proteins that are predicted to occur within the cell, with nucleotide-binding site (NBS) and leucine-rich repeat (LRR) motifs.

The hypersensitive response (HR)—a programmed cell death of plants—has been proposed as a general mechanism conditioning plant resistance to oomycete pathogens. This occurs in the early stages of infection during initial penetration of host cells. Zoospores or sporangia germinate on the surface of host tissues and may form appressoria like structures at penetration points, as shown in Fig. 2. Studies on *P. sojae* and *P. infestans* indicate that when host cells at the initial infection site undergo HR quickly, much more effective containment of pathogen spread results. A lack of host recognition—as evidenced by no HR or a slow HR upon infection—permits the pathogen to grow further and colonize adjacent cells, resulting in disease. Later during the infection process, host cell death occurs extensively but does not limit pathogen

spread, especially in the case of hemibiotrophic pathogens such as *P. infestans* and *P. sojae*. At this stage host cell death may even accelerate disease.

CONCLUSION

Oomycetes are destructive plant pathogens that harm crops, ornamental plants, and natural environments. Many have the potential to spread rapidly and cause severe epidemics when presented with suitable conditions. Nineteenth century disease outbreaks caused by oomycetes were important in the development of plant pathology as a scientific discipline and changed the practice of agriculture. Oomycetes continue to cause epidemics and serious problems to this day, most recently exemplified by the emergence of sudden oak death (*Phytophthora ramorum*) in central California. Oomycetes are successful pathogens that present many challenges as experimental organisms in the laboratory, but concerted efforts and advances in technology are leading to a better understanding of their biology. This holds the promise that more effective control measures will be developed to limit the damage caused by oomycetes throughout the world.

Organic Agriculture as a Form of Sustainable Agriculture

John P. Reganold

Washington State University, Pullman, Washington, U.S.A.

INTRODUCTION

During the past decade, organic farming became one of the fastest growing segments of agriculture all over the world.^[1,2] Organic agriculture, sometimes called biological or ecological agriculture, combines traditional conservation-minded farming methods with modern farming technologies. It virtually excludes such conventional inputs as synthetic fertilizers, pesticides, and pharmaceuticals. Instead, it uses naturally derived chemicals or products as defined by organic certification programs, and it emphasizes building up the soil with compost additions and animal and green manures, controlling pests naturally, rotating crops, and diversifying crops and livestock.^[3] The goal of organic agriculture is to create sustainable agricultural systems. This article discusses organic agriculture and sustainability, organic agricultural practices, the history and extent of organic agriculture, and organic certification.

ORGANIC AGRICULTURE AND SUSTAINABILITY

Organic agriculture addresses many serious problems afflicting world food production: high energy costs, groundwater contamination, soil erosion, loss of productivity, depletion of fossil resources, low farm incomes, and risks to human health and wildlife habitats. However, just because a farm is organic does not mean that it is sustainable. For any farm to be sustainable, whether it be organic or conventional, it must produce adequate high-quality yields, be profitable, protect the environment, conserve resources, and be socially responsible over the long term.^[4] So, if an organic farm produces high yields of nutritious food and is environmentally friendly and energy efficient, but is not profitable—then it is not sustainable. Likewise, a conventional farm that meets all the sustainability criteria but pollutes a nearby river with sediment because of soil erosion is not sustainable.

Organic farming systems have been shown to be energy-efficient, environmentally sound, productive, stable, and tending toward long-term sustainability.^[5,6] Organic farming systems do not represent a return to the past. They use modern equipment, certified seed, soil and

water conservation practices, improved crop varieties, and the latest innovations in feeding and handling livestock. Organic farming systems range from strict closed-cycle systems that go beyond organic certification guidelines by limiting external inputs as much as possible, to more standard systems that simply follow organic certification guidelines. They rely largely on available resources found on or near the farm. The protection of soil and the environment is fundamental to organic farming.

Yields from organic farms are usually somewhat lower than, but sometimes equal to, those from conventional farms, but they are frequently offset by price premiums that lead to equal or greater net returns. Research comparing the agronomic, economic, and ecological performance of organic and conventional farming systems confirms this. In fact, studies^[5,7,8] generally have found that organic systems have equal or somewhat lower yields, but less variability in production from year to year; are equally, if not more profitable; cause less erosion and pollution; have better soil quality; are more energy efficient; and rely less on government subsidies than their conventional counterparts. In other words, the organic systems are more sustainable.

ORGANIC AGRICULTURAL PRACTICES

Organic farming systems rely on ecologically based practices. A central component of organic farming systems is the rotation of crops—a planned succession of various crops grown on one field. When crops are rotated, the yields are usually about 10% higher than when they grow in monoculture (growing the same crop on the same field year after year). In most cases, monocultures can be perpetuated only by adding large amounts of fertilizer and pesticide. Rotating crops provides better weed and insect control, less disease buildup, more efficient nutrient cycling, and other benefits. Alternating two crops, such as corn and soybeans, is considered a simple rotation. More complex rotations require three or more crops and often a four- to seven-year (or more) cycle to complete. In growing a more diversified group of crops in rotation, a farmer is less affected by price fluctuations of one or two crops. This may result in more year-to-year financial stability. There are disadvantages, too, however. They include the

need for more equipment to grow a number of different crops, the reduction of acreage planted with government-supported crops, and the need for more time and information to manage more crops.

Organic agriculture not only has a diverse assortment of crops in rotation, but also maintains diversity from mixing species and varieties of crops and from systematically integrating crops, trees, and livestock. When most of North Dakota experienced a severe drought during the 1988 growing season, for example, many monocropping wheat farmers had no grain to harvest. Organic farmers with more diversified systems, however, had sales of their livestock to fall back on or were able to harvest their late-seeded crops or drought-tolerant varieties.

Maintaining healthy soils by regularly adding crop residues, manures, and other organic materials to the soil is another central feature of organic farming. Organic matter improves soil structure, increases its water storage capacity, enhances fertility, and promotes the tilth, or physical condition, of the soil. The better the tilth, the more easily the soil can be tilled or direct-drilled with seed, and the easier it is for seedlings to emerge and for roots to extend downward. Water readily infiltrates soils with good tilth, thereby minimizing surface runoff and soil erosion. Organic materials also feed earthworms and soil microbes.

The main sources of plant nutrients in organic farming systems are green manures, composted animal manures and plant materials, and plant residues. A green manure crop is a grass or legume that is plowed into the soil or surface-mulched at the end of a growing season to enhance soil productivity and tilth. Green manures help to control weeds, insect pests, and soil erosion, while also providing forage for livestock and cover for wildlife.

Organic farmers use disease-resistant crop varieties and biological controls (such as natural predators or parasites that keep pest populations below injurious levels). They also select tillage methods, planting times, crop rotations, and plant-residue management practices to optimize the environment for beneficial insects that control pest species, or to deprive pests of a habitat. Organically certified pesticides, usually used as a last resort to control insects, diseases, and weeds, are applied when pests are most vulnerable or when any beneficial species and natural predators are least likely to be harmed.

HISTORY AND EXTENT OF ORGANIC AGRICULTURE

European organic agriculture emerged in 1924 when Rudolf Steiner held his course on biodynamic agriculture. In the 1930s and 1940s, organic agriculture was developed in Britain by Lady Eve Balfour and Sir Albert Howard, in Switzerland by Hans Mueller, in the United States by J. I.

Rodale, and in Japan by Masanobu Fukuoka. Since the beginning of the 1990s, development of organic agriculture in Europe has been supported by government subsidies. In many other countries of the world, organic agriculture was established because of the growing demand for organic products in Europe, the United States, and Japan. Today, organic farming is gaining increasing acceptance by the public at large.

Organic agriculture is practiced in almost all countries of the world, and its share of agricultural land and farms is growing everywhere. In 2001 more than 17 million hectares were managed organically worldwide.^[9] The major part of this area is located in Australia (7.7 million hectares), Argentina (2.8 million hectares) and Italy (more than 1 million hectares). Oceania holds 45% of the world's organic land, followed by Europe (25%), and Latin America (22%). In North America more than 1.3 million hectares are managed organically. In most Asian and African countries the area under organic management is still low. Tables 1 and 2 show the top 20 countries in the world with the most organically managed land and with the greatest proportion of total agricultural land in the country in organic production.

ORGANIC CERTIFICATION

Growers are turning to certified organic farming systems as a potential way to lower input costs, decrease reliance on nonrenewable resources, capture high-value markets and premium prices, and boost farm income. Organic certification provides verification that products are indeed produced according to certain standards. For consumers who want to buy organic foods, the organic certification standards ensure that they can be confident in knowing what they are buying. For farmers, these standards create clear guidelines on how to take advantage of the exploding demand for organic products. For the organic products industry, these standards provide an important marketing tool to help boost trade in organic products.

“Certified organic” means that agricultural products have been grown and processed according to the specific standards of various national, state, or private certification organizations. Certifying agents review applications from farmers and processors for certification eligibility, and qualified inspectors conduct annual onsite inspections of their operations. Inspectors talk with producers and observe their production or processing practices to determine if they are in compliance with organic standards.

Organic certification standards detail the methods, practices, and substances that can be used in producing and handling organic crops and livestock, as well as processed products. For example, in December 2000 the

Table 1 Top 20 countries ranked by highest total area (hectares) under organic management, followed by the percentage of total agricultural land in organic production

(From Ref. 9.)

U.S. Department of Agriculture announced final national standards that food labeled “organic” must meet, whether it is grown in the United States or imported from other countries.^[10] These standards specifically prohibit the use of genetic engineering methods, ionizing radiation, and sewage sludge for fertilization. They went into labeling effect in October 2002.

On a broader scale, the International Federation of Organic Agriculture Movements (IFOAM) established the IFOAM Accreditation Programme to provide international equivalency of certification bodies worldwide.^[2] IFOAM accreditation is based on the international IFOAM standards, which are developed continually by the IFOAM membership, a democratic structure open to all who work in the field of organic agriculture and production. In 2000 the first products with the “IFOAM-accredited” logo came on the market. By early 2002, 17 organizations had been IFOAM-accredited.

Osmotic Adjustment and Osmoregulation

Neil C. Turner

CSIRO Plant Industry, Wembley, Australia

INTRODUCTION

Water deficits and lowering the osmotic potential of the external solution have long been known to induce a decrease in the osmotic potential or an increase in the osmotic pressure of higher plant cells.^[1–3] This occurs as water is extracted from the cell from the *passive* concentration of the solutes present in the fully turgid cells. Under these circumstances, the osmotic pressure (Π) of a cell is inversely related to the osmotic volume (V):

$$\Pi = \frac{\Pi_{100}V_{100}}{V} \quad (1)$$

where Π_{100} and V_{100} are the osmotic pressure and osmotic volume, respectively, at full turgor.

RECENT DEVELOPMENTS

More recently it was recognised that higher plants can *accumulate* solutes in response to a water deficit, a process termed osmotic adjustment or osmoregulation. Although previous studies had shown that root turgor was maintained as soil-water deficits increased and seasonal changes in osmotic pressure mirrored seasonal changes in water potential,^[3] the possibility of solute redistribution, uptake of solutes from the soil, and changes in elasticity could not be eliminated in these previous studies.^[3] The first unequivocal increase in osmotic pressure in response to a soil-water deficit was reported by Jones and Turner,^[4,5] who showed that osmotic adjustment in sorghum and sunflower leaves arose from an accumulation of solutes.^[5,6]

Osmotic adjustment has now been shown to occur in the leaves of many species^[7–10] and has also been observed to occur in roots and fruits.^[10–12] Additionally, osmotic adjustment in leaves has been shown to vary among genotypes in a range of species.^[13,14] Yield benefits associated with osmotic adjustment^[13,14] have led to the suggestion that osmotic adjustment is a desirable trait for turgor maintenance at low water potentials.^[15] In cereals, osmotic adjustment appears to be under the control of a single gene or a small number of genes that are simply inherited.^[16,17] Studies with rice have identified a single quantitative trait locus (QTL) for osmotic

adjustment that appears to be homologous with the single gene for osmotic adjustment in wheat.^[16,17] However, to date the only crop in which the gene for osmotic adjustment has been used by breeders is wheat, where a cultivar incorporating the gene for osmotic adjustment has been released in Australia.

BENEFITS OF OSMOTIC ADJUSTMENT

Osmotic adjustment is important because it aids in the maintenance of the turgor pressure of the plant as water deficits develop.^[7] As growth is a turgor-dependent process, maintenance of turgor is important in maintaining growth.^[3] Osmotic adjustment has been shown to maintain photosynthesis and stomatal conductance, defer leaf rolling and leaf death, and maintain root growth to lower water potentials.^[18] In turn, this has been shown to induce root growth into deeper soil layers and increase water uptake.^[13]

Osmotic adjustment does not necessarily maintain full turgor. Partial turgor maintenance has been documented in a number of species^[7] and leads to zero turgor being reached at lower water potentials than when no osmotic adjustment occurs, but at higher water potentials than in the case of full turgor maintenance (Fig. 1). Also, it should be recognized that water potentials below a threshold may decrease before osmotic adjustment is initiated. Jones and Rawson^[19] showed that osmotic adjustment reduced the water potential at which the rate of leaf photosynthesis in sorghum reached low values, but did not prevent the decrease in photosynthesis accompanying a decrease in the leaf water potential. Also, chickpea genotypes have been shown to vary in the degree of osmotic adjustment, but this occurred too late into a drying cycle to influence the rate of leaf photosynthesis.^[20]

Additionally, the degree of osmotic adjustment is finite. While osmotic adjustment maintains turgor, there appears to be a point beyond which no further solutes accumulate. Further, because the solutes required for osmotic adjustment may also be required during grain filling, it may be undesirable for the solutes accumulated to remain in the leaf. In chickpea, the degree of osmotic adjustment decreased during late seed filling,^[20] presumably so that the solutes could be mobilized to the grain.

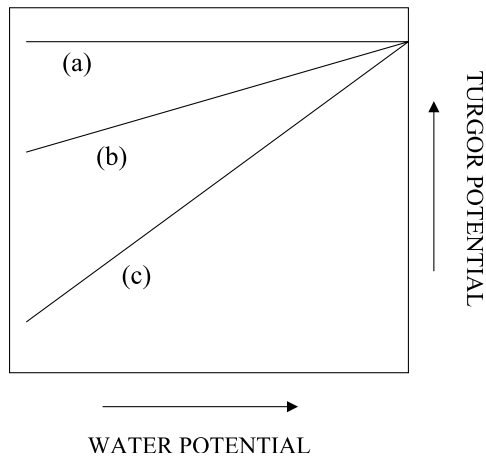

Fig. 1 Schematic representation of the relationship between turgor potential and water potential for (a) full turgor maintenance, (b) partial turgor maintenance, and (c) no turgor maintenance. (Adapted from Ref. 7.)

Indeed, pigeonpea genotypes with high osmotic adjustment toward the end of pod filling had lower yields than those that lost solutes during late pod fill.^[21]

Nevertheless, higher yields of wheat, chickpea, and pigeonpea have been associated with greater degrees of osmotic adjustment.^[13,14,21,22] In chickpea and pigeonpea, different genotypes were compared, so traits other than osmotic adjustment may have contributed to yield. In wheat, however, comparisons have been made in families selected for differences in osmotic adjustment.^[22] In other species, analysis of the benefits to yield of high osmotic adjustment still needs to be undertaken in near-isogenic lines.

SOLUTES INVOLVED IN OSMOTIC ADJUSTMENT

A wide range of solutes have been observed to increase during osmotic adjustment. Jones et al.^[6] showed that sucrose, glucose, fructose, potassium, chloride, and amino acids all contributed to osmotic adjustment in sorghum, whereas amino acids, potassium, calcium, magnesium, and nitrate contributed to osmotic adjustment in sunflower. While the amino acid proline has been widely shown to increase when water deficits develop, its contribution to overall osmotic adjustment is small. However, it is considered to be a compatible solute that increases in the cytoplasm to balance organic and inorganic solute changes in the vacuole that would be detrimental if they occurred in the cytoplasm.

It is not clear that the same solutes increase in a particular genotype under a range of environmental

conditions. Thus, without further investigation it is not possible to say whether a particular solute can be used as a selection tool in genotypic studies of osmotic adjustment.

MEASUREMENT OF OSMOTIC ADJUSTMENT

In order to measure the extent of osmotic adjustment, the change in osmotic pressure induced by the concentration of solutes resulting from water loss needs to be distinguished from the change induced by solute accumulation. To do this the osmotic pressure at a particular turgor pressure—normally at full turgor—is measured or calculated. To measure or estimate the osmotic pressure at full turgor requires either measurement after rehydration or calculation from measured values of osmotic potential and relative water content (equivalent to the relative osmotic volume in Eq. 1). Because the osmotic pressure at full turgor can change with age and even diurnally, samples from plants subjected to water deficits and those kept adequately watered are taken on the same day, and the degree of osmotic adjustment is considered the difference in osmotic pressure at full turgor between stressed and unstressed plants.

There are errors associated with both of the foregoing methods of measurement. Rehydration may not be complete, or the time required for rehydration may differ between plants that have been stressed to different degrees, so that comparison after the same rehydration time may not be reliable. Also, in some species it is known that solute loss occurs during rehydration, or solutes may be metabolised from osmotically-active solutes to osmotically-inactive solutes—or vice versa—leading to errors in the measurement of osmotic pressure. While such errors in osmotic pressure do not occur when the tissue is not rehydrated, similar errors of rehydration can occur in measured values of relative water content.^[23] The osmotic pressure is usually measured by vapor pressure osmometry or freezing-point depression osmometry.^[23] However, the osmotic pressure at full turgor can be estimated from pressure/volume relations using the pressure chamber technique.^[24] Rehydration is necessary and the rehydration errors discussed above are also relevant with this method. Additionally, the osmotic pressure at full turgor is extrapolated from pressure/volume data below zero turgor, and errors can occur in this range, particularly in tissue that is not woody.^[24]

Whether the pressure chamber or osmometry is used to measure the osmotic pressure, the procedures are relatively slow, particularly if watered and unwatered plots are required in order to measure the degree of osmotic adjustment. Where a large number of plants need to be compared, measured values of osmotic pressure and either

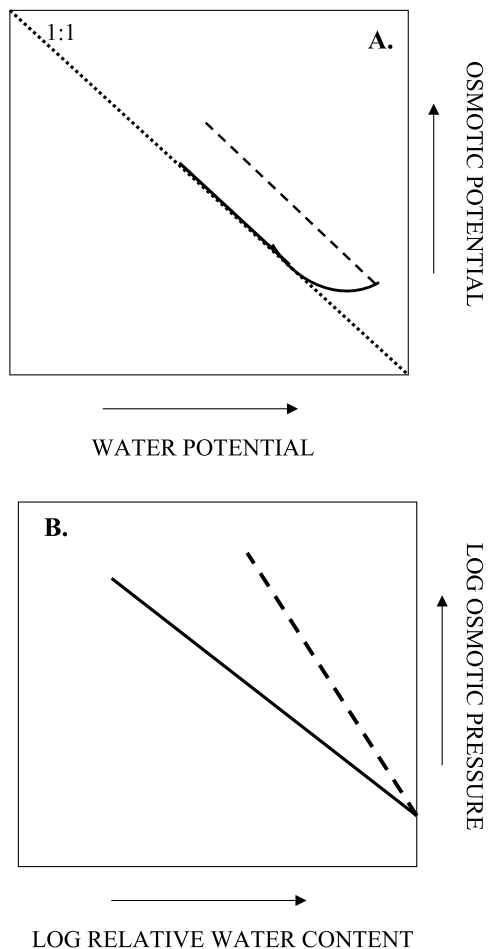

Fig. 2 Schematic representation of the relationship between (A) osmotic pressure and water potential and (B) \log_n osmotic pressure and \log_n relative water content in osmotically adjusting (dashed line) and nonadjusting (solid line) plants. (Adapted from Refs. 27,28.)

relative water content or water potential during a drying cycle have been used to compare the measured values against ones predicted from the concentration of solutes from water loss.^[25,26] Fig. 2 shows the changes in osmotic pressure with relative water content and with water potential in nonadjusting and osmotically adjusting plants. Alternatively, at points during the drying cycle leaves may be sampled for osmotic pressure after rehydration. By this method at least 200 plants can be sampled, and it is feasible to screen breeding populations for osmotic adjustment. However, it needs to be recognized that these methods do not account for changes in osmotic pressure induced by age or phenological development, and they are subject to the dehydration errors mentioned above.

Recently, Morgan^[29] showed that pollen grains of wheat in the presence of potassium chloride accumulated solutes and became swollen when exposed to stress

imposed with polyethylene glycol. Only pollen grains from genotypes that showed osmotic adjustment in their leaves accumulated solutes, so Morgan^[29] suggested that the technique could be used as a simple screening technique for osmotic adjustment in breeding programs. The technique needs to be explored in other species that show genetic differences in osmotic adjustment.

CONCLUSION

The maintenance of turgor as water deficits develop through the accumulation of solutes is termed osmotic adjustment or osmoregulation and is widely observed in some higher plant species and genotypes. The maintenance of turgor aids in the maintenance of physiological activity, such as photosynthesis and seed growth, and has been shown to benefit crop yields in water-limited environments. The lack of rapid selection methods has hindered the use of the trait in dryland breeding programs, except in the case of wheat, where a cultivar has been developed with high osmotic adjustment. The identification of a marker for osmotic adjustment in wheat and rice should enable the trait to be used in future marker-assisted breeding programs.

Oxidative Stress and DNA Modification in Plants

Alex Levine

The Hebrew University of Jerusalem, Jerusalem, Israel

INTRODUCTION

Oxygen constitutes 21% of the atmosphere and is the most abundant chemical in and near the earth's crust. The concentration of oxygen in the atmosphere has risen dramatically since the beginning of life due to the evolution of oxygen during photosynthesis. Because of its chemical properties as an electron acceptor whereby each molecule of dioxygen can accept four electrons producing water, oxygen is fundamentally essential for energy metabolism and respiration in the predominantly aerobic modern biosphere. However, if the gradual reduction process that proceeds by a consecutive addition of electrons is not complete, the partially reduced dioxygen forms highly reactive molecules (Fig. 1). Collectively these molecules are termed reactive oxygen species (ROS) or intermediates (ROI).

The continuous flow of electrons in the cell—especially but not exclusively in the energy producing organelles such as mitochondria or chloroplasts—creates a constant leakage of electrons to oxygen, forming superoxide and other ROS derivatives. The leakage of electrons to oxygen is exacerbated during stresses, invoking a complex array of plant responses.

To counteract the potentially dangerous reactions of the oxidants, organisms have evolved elaborate detoxifying systems. Due to the high internal oxygen concentration and the generation of high-energy electrons by photo-activation, plants are particularly prone to damage by the ROS, and have therefore developed effective antioxidant systems.^[1]

The major natural as well as anthropogenic environmental factors that cause damage to living organisms arise from pollution of water, soil, and air, and from solar (UV) and ionizing radiations. These conditions cause ROS accumulation and oxidative stress. In addition, ROS are produced during upward or downward shifts in the surrounding temperature, especially when coupled with strong light.

FORMATION OF OXYGEN RADICALS AND ANTIOXIDANT DEFENSES

ROS formation is part of normal cellular metabolism. For example, $O_2^{\cdot-}$ and H_2O_2 are the by-products of en-

zymatic reactions in nucleotide and sugar metabolism. However, the majority of ROS in nonpathogenic conditions are produced by leakage of electrons from the electron transport chains in mitochondria, chloroplasts, and even in the plasma membrane.^[2] Another major source of ROS in plant cells occurs in response to pathogen attack and to mechanical stress, which activate the plasma membrane-localized NADPH oxidase.^[3,4] A cell wall peroxidase was also implicated in pathogen-induced generation of ROS.^[5] These mechanisms of ROS production are not mutually exclusive.

Plants and other organisms possess elaborate systems to detoxify ROS. However, during environmental stress the rate of ROS production can exceed the rate of their removal.^[6] Plants possess ROS-detoxifying enzymes that are also found in animals and other organisms, as well as numerous small-molecule antioxidants (e.g., vitamins C and E) that are products of the secondary metabolism unique to plants. The two systems act in cooperation, whereby the antioxidant molecules react with ROS as a first line of defense and are later regenerated by specific enzymes. Adverse environmental conditions affect the redox metabolism in the cell by interfering with the electron flow in the organelles or with the functioning of the antioxidant systems.

REACTIONS OF OXYGEN RADICALS: DNA DAMAGE AND REPAIR

The initially produced ROS (such as superoxide and hydrogen peroxide) react relatively weakly with the majority of biological molecules. Among their main targets are oxidation of the thiol groups in proteins that can later be reduced back by glutaredoxin or thioredoxin systems. However, $O_2^{\cdot-}$ and H_2O_2 derivatives (such as hydroxyl radicals) react with many biological substrates at a diffusion-limited rate. The $\cdot OH$ damage includes protein oxidation, lipid peroxidation, and formation of DNA adducts and strand breaks. The $\cdot OH$ radicals also cause cross-linking of the DNA to DNA-binding proteins, leading to a replication block.

Although the damage caused to proteins and lipids may be repaired by removal of the impaired molecules and

Fig. 1 Sequential reduction of oxygen to water.

replacement with new ones, such a mechanism is not feasible for DNA because the genetic information must be reproduced precisely. The $\cdot\text{OH}$ radical reacts with little specificity and can cause mutations in any nucleotide (Fig. 2).

The formation of $\cdot\text{OH}$ radicals is greatly promoted by Fenton reaction in the presence of heavy metals such as iron, lead, copper, and cadmium. These metals are common soil pollutants. Due to its negative charge, DNA has a high affinity for binding heavy metals, thus promoting hydroxyl radicals' formation in close proximity to the DNA. The most common form of DNA damage is the $\cdot\text{OH}$ -mediated formation of 8-hydroxyguanosine, which leads to mutagenesis and DNA strand breaks.^[7] Especially problematic are the repair of double strand breaks and of mismatches during replication that result in "fixed" mutations. ROS are also involved in DNA strand breaks caused by UV radiation.^[8]

In plants, a particularly high rate of mutation occurs during repair of double strand breaks by direct end-joining as part of a nonhomologous recombination.^[8] Increased mutation rate is therefore a direct consequence of abiotic/environmental stresses.^[9,10] In accord with this, improved antioxidant defenses and decreased oxygen tension were shown to reduce mutability.^[11] Interestingly, overexpression of superoxide dismutase is not always beneficial and can even increase DNA damage via accelerated production of H_2O_2 , which promotes formation of $\cdot\text{OH}$ radicals.^[12] Thus, a coordinated antioxidant response that includes specific enzymes as well as small molecule antioxidants is essential for genome stability.

Fig. 2 Structures of oxidatively damaged DNA bases.

GENE SELECTION AND DEVELOPMENT

Evolution depends on genetic variability and subsequent selection of the individuals that are better adapted for the given conditions. In plants, the germ cells differentiate from somatic cells in a process that may take many cycles of mitotic division. Thus, somatic mutations can enter germ cells and be transmitted to the progeny.

Being both sessile and lacking a system that regulates internal temperature, plants are continuously impelled to adapt to changes in their surroundings. Environmental stress results in a reduction of photosynthesis and inhibition of growth, resulting in diminished competitiveness against other members of the same species and against other competitors. Such constantly changing environmental factors constitute a strong selection force. Studies have shown that growth of plants in soils polluted with heavy metals induces phenotypic alterations that stem from stress-dependent mutations.^[13] More recently it has been shown that ROS-associated (abiotic) stresses enhance both the rate of recombination and mutagenicity in *Ara-bidopsis* plants.^[14]

SUMMARY

The sessile nature of plants makes them particularly sensitive to the surrounding environment. During evolution plants have developed sophisticated mechanisms to sense changes in environmental conditions and adapt to them. Almost all environmental stresses are associated with the accumulation of reactive oxygen species (ROS), resulting in secondary oxidative stress. Some of the ROS (such as the hydroxyl radical), are highly reactive molecules that can damage cellular components such as lipids, proteins, and DNA. Moreover, the DNA adducts promote strand breaks, augmenting the damage. Whereas the damaged lipids and proteins can be replaced by new molecules, the repair of DNA is prone to introduce mistakes and result in mutations. In eukaryotes the nuclear DNA exists in dynamic association with histones, forming chromatin.

During transcription the active chromatin unfolds, allowing access of the transcription machinery, while the inactive chromatin remains compacted. Thus, genes that are active during stress are specifically exposed to attack by the hydroxyl radicals, leading to a higher mutation rate. Any favorable mutation that will reduce the primary stress will decrease the oxidative stress and stabilize the genome.

CONCLUSION

Changes in environmental conditions invoke an oxidative stress in plant cells. The reactive oxygen species that are generated during stress react with the cellular components. Particularly damaging is the formation of the hydroxyl radical, which reacts with DNA. In addition to causing direct mutations, DNA adducts produce strand breaks resulting in additional mutagenicity through non-homologous recombination.^[8,9] The open state of the transcribed genes^[15] makes them particularly prone to oxidative damage. Thus, the genes that are expressed during environmental stresses associated with ROS accumulation undergo an increased mutation rate. Improvements in resistance to primary environmental stress by favorable mutations also decrease the oxidative stress and mutagenicity, stabilizing plant adaptation to the surrounding environment.

Oxygen Production

Charles F. Yocum

University of Michigan, Ann Arbor, Michigan, U.S.A.

INTRODUCTION

The ability to oxidize water to oxygen is a unique property of the metabolism of oxygenic photosynthetic organisms. An enzyme complex called photosystem II, which is a component of the thylakoid membranes found in chloroplasts of eukaryotes and in cyanobacteria, catalyzes the reaction. The driving force for oxygen production from water is light absorption by photosynthetic pigments. The absorbed energy causes a special pair of chlorophyll molecules (called P680) to release electrons that are ultimately used to reduce CO₂ to carbohydrate. Electron deficient, oxidized P680 regains electrons by oxidizing manganese atoms that are part of the active site of oxygen production. This site contains four atoms of manganese, as well as one atom each of calcium and chloride. Although the specific details of the mechanism of the oxygen-evolving reaction are still being sought, it is clear that oxidation of the manganese atoms in photosystem II constitutes the key step in oxygen production. Calcium may bind water molecules destined for oxidation by manganese, while chloride is proposed to regulate the oxidation/reduction activity of the manganese atoms.

OXYGENIC PHOTOSYNTHESIS

Oxygenic photosynthesis is the process by which light energy is converted into chemical energy, and oxygen is released as a byproduct.^[1] Light-driven electron transfer reactions are localized in the stacked layers of membranes—called thylakoids—of chloroplasts and cyanobacteria. The ultimate electron source is water, which is oxidized to oxygen. This reaction is presented in Eq. 1, which shows that a key step in the process is absorption of light by an enzyme system called photosystem II. The electrons that are withdrawn from water reduce a quinone molecule called plastoquinone, abbreviated as PQ in the equation. Subsequent oxidation of PQH₂ is accomplished by cytochromes and a second light reaction—called photosystem I—that are also found in all organisms that carry out oxygenic photosynthesis.^[1]

PHOTOSYSTEM II AND THE S-STATE CYCLE FOR OXYGEN PRODUCTION

Oxygen production by photosystem II is catalyzed by a linear sequence of reactions.^[2] Detection of oxygen produced by illuminating a sample with very short (~10 μs) light flashes gives the result shown graphically in Fig. 1. Upon excitation by three sequential flashes, photosystem II emits a gush of oxygen, and does so again on the seventh and eleventh flashes in a series, although the oscillations become less pronounced with larger numbers of flashes. This oscillating pattern is modeled on a cycle containing intermediate states of the oxygen-producing reaction, called S states.^[2] Each state is numbered, S_{*i*} (*i* = 0–4), and a flash of light advances the S-state system from S_{*i*} to S_{*i*+1}. The S-state hypothesis is represented schematically by Eq. 2, where *hν* is used to signify the individual flashes of light.

To explain the burst of oxygen on the third flash of light, it has been necessary to postulate that the S₁ state is stable in darkness, and this hypothesis is widely accepted. Higher S states can be deactivated to S₁ by imposing darkness on the system after one or two flashes of light. Typical lifetimes of S₂ and S₃ are about one minute. The gradual loss of the oscillating pattern of oxygen release is due to the intrinsic behavior of the enzyme system, which leads to a random distribution of S states after a large number of light flashes or after exposure of the enzyme to continuous light.

LIGHT-DRIVEN ELECTRON TRANSFER REACTIONS

Advancement of S states requires a series of reactions that are initiated by light. The membrane-associated proteins of photosystem II bind the necessary organic cofactors,

Fig. 1 Oxygen yield from photosystem II as a function of the number of light flashes. The maximum yields of oxygen are obtained on the third, seventh, and eleventh flashes. (See text for details.)

which include tyrosines, chlorophylls, pheophytin (a chlorophyll *a* molecule lacking the central Mg^{2+} atom), and plastoquinone molecules called Q_A and Q_B .^[3] Four atoms of manganese and one atom each of calcium and chloride are also bound to the membrane-associated proteins of photosystem II, to form the active site for oxygen

production. Additional water soluble proteins assist in stabilizing the binding of these inorganic ions. A 3.8 Å resolution crystal structure of the enzyme is available,^[4] which shows the arrangement of the various cofactors that are involved in light-driven electron transfer and oxygen production.

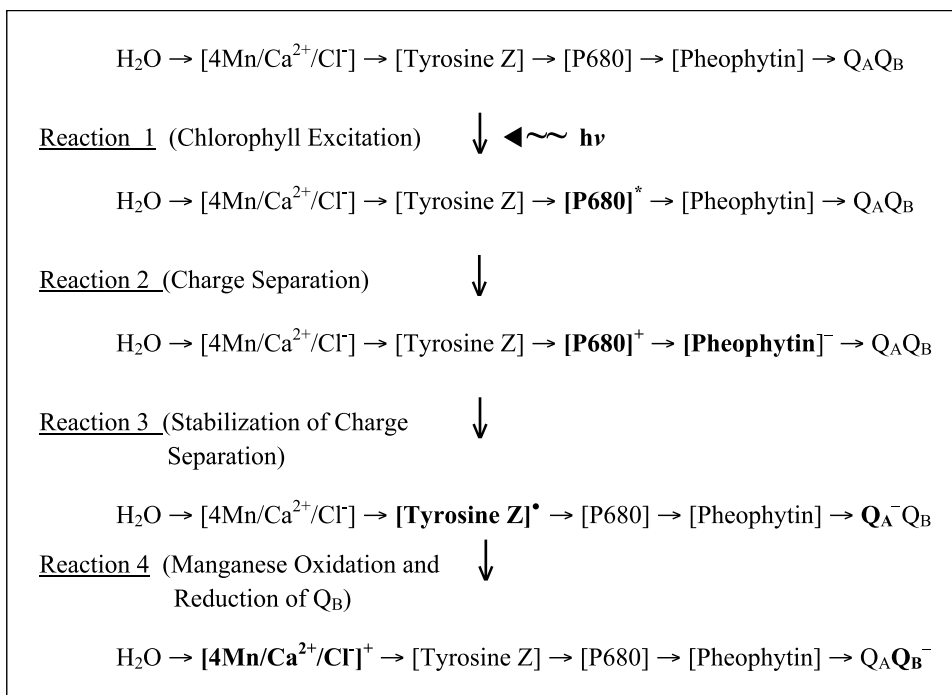

Fig. 2 A schematic representation of the electron transfer reactions in photosystem II that precede oxygen production. **Boldface** type identifies the chemically reactive species at each step in the reaction sequences. (The electron transfer species are identified in text.)

The sequence of electron transfer events that lead to oxygen production is shown in Fig. 2. Light absorption by a special pair of chlorophyll *a* molecules, called P680 after the wavelength of light (680 nm) that it absorbs, triggers a cascade of chemical reactions. The excited chlorophyll molecule created by light absorption in Reaction 1 ($[\text{P680}]^*$) is very reactive, and within a few picoseconds ($\sim 10^{-12}$ s) loses an electron to the acceptor pheophytin molecule, forming $[\text{Pheophytin}]^-$, as shown in Reaction 2. Oxidized P680 ($[\text{P680}]^+$) is also very reactive, and removes an electron from a tyrosine residue, called tyrosine Z, forming a radical $[\text{Tyrosine Z}]^\bullet$ (Reaction 3). Tyrosine Z is one of the amino acids in the sequence of a membrane-associated protein of photosystem II called D1. In a second part of Reaction 3, $[\text{Pheophytin}]^-$ passes its electron on to the first special quinone molecule, to form Q_A^- . The formation of two stable products is shown in Reaction 4. First, the electron removed from P680 by light absorption reduces a plastoquinone molecule called Q_B to form Q_B^- . Second, an electron is removed from a manganese atom that is part of the group of inorganic ions that make up the active site of the enzyme, forming $[\text{4 Mn/Ca}^{2+}/\text{Cl}^-]^+$. As a result, the energy of the photon absorbed by P680 now resides in two stable species; in a reducing agent, Q_B^- , that forms PQH_2 after accepting another electron and binding two H^+ ; and in an oxidizing agent, an electron deficient manganese ion. The lifetimes of these species enable them to carry out chemical reactions.

ROLES OF MANGANESE, CALCIUM, AND CHLORIDE IN OXYGEN PRODUCTION

In the dark stable S_1 state, the oxidation states of the four manganese atoms have been determined to be $\text{Mn}^{3+}/\text{Mn}^{3+}/\text{Mn}^{4+}/\text{Mn}^{4+}$.^[5] Physical techniques for assessing oxidation state changes in these metals indicate that a Mn^{3+} is oxidized to Mn^{4+} on advancement of the S states from S_1 to S_2 , and from S_2 to S_3 . The oxidation state of S_4 has not been determined, but that of S_0 is currently believed to be $\text{Mn}^{2+}/\text{Mn}^{3+}/\text{Mn}^{4+}/\text{Mn}^{4+}$. Removal of either Ca^{2+} or Cl^- from photosystem II inhibits the S-state cycle after formation of S_2 . Proposals that calcium may act as a binding site for the water molecules that are oxidized by photosystem II and that Cl^- is present to regulate the oxidation/reduction properties of the manganese atoms^[6] may be relevant in explaining why these ions are needed to advance beyond S_2 .

The most important question that remains to be answered about photosystem II is how oxidized manganese atoms regain electrons by reacting with water to

produce oxygen. One possibility is that an electron deficiency first accumulates among the manganese atoms, after which these atoms regain electrons by oxidizing water to oxygen in a single step. In this mechanism, the manganese atoms would function as a charge accumulator.^[7] In the second hypothetical mechanism, water molecules bind to manganese and undergo partial oxidation as the S states advance. In this mechanism, the sequential removal of electrons from water would permit manganese atoms to undergo oxidation, but there would be no accumulation of charge on the system because neutral hydrogen atoms (H^\bullet) rather than electrons would be transferred.^[8] There is insufficient evidence at present to choose a correct mechanism, and the possibility must remain open that a hybrid system, combining features of both types of hypothetical mechanisms, is responsible for oxygen production.

CONCLUSION

Photosystem II extracts electrons from water to form oxygen by carrying out a highly organized set of reactions. Light absorption by chlorophyll initiates a set of electron transfer reactions. These reactions produce two results. The first of these is formation of reduced quinone molecules that shuttle electrons to other components of the photosynthetic electron transfer apparatus. The second consequence of light absorption is that electrons are withdrawn from a cluster of inorganic ions; loss of four electrons results in oxygen production from two water molecules. The reaction is catalyzed by manganese ions, but requires calcium and chloride as well. The precise mechanism for oxidation of water is unknown, but current models favor either charge accumulation by oxidation of manganese followed by water oxidation, or a sequential oxidation of water by abstraction of hydrogen atoms.

Paper and Pulp: Agro-based Resources for

George A. White (Retired)

USDA—ARS, Beltsville, Maryland, U.S.A.

INTRODUCTION

Non-wood crops and specialty fiber sources have been utilized for thousands of years in papermaking and other pulp applications. Their use greatly predates that of wood, which now composes about 90% of the worldwide production. As early as the late 1920s in the United States, a mill for producing corrugating medium based on straw began operation. Other mills followed in the Midwest, some of which operated throughout World War II. Unfortunately, they succumbed to high collection, transportation, and storage costs, and to prolonged use of outdated pulping equipment and processes.

Straw, sugarcane bagasse, and bamboo are the leading agricultural fiber sources presently used. China and India, both wood-poor countries, are the main users of straw and bamboo. Several countries use only non-wood fiber resources for papermaking. However, there exists a largely untapped and vast worldwide inventory of these three, plus other crop residues. Additionally, many plant species are suitable for pulping applications. A few, such as kenaf and sunn hemp, have been grown successfully and hence have the potential to add to the overall fiber inventory.

CROP RESIDUES FOR PULPING

Cereal Grain and Flax Straws

By using grain production, the amount of associated straw can be estimated. Data about the 2001 U.S. crop harvest^[1] were used to estimate the straw yields for barley, oats, proso millet, rice, rye, and wheat. This computation resulted in an estimated 100 million metric tons (mt) that could be utilized in pulping applications. Most of the straw is either plowed under or used for feed and bedding. On a worldwide basis, the estimate for production of cereal and flax straws is 1.26 billion mt.^[2] Straw represents the largest potential supply of crop residues suitable for pulping. The straw from most of the flaxseed oil production in the United States and Canada is processed into high-quality paper products.

Straw from Grass Seed Production

The primary region for grass seed production in the United States is in the tristate area of Oregon, Idaho, and Washington, but is concentrated in the Willamette Valley of Oregon [Banowetz, G.M. Personal communication, U.S. Department of Agriculture; Agricultural Research Service (USDA-ARS): Corvallis, OR, 2002]. The involved grass species include most of the commonly grown lawn grasses and certain types of forage. The resultant straw from about 202,000 hectares (ha) amounts to about 1.4 million mt based on a yield of 6.7 mt per ha. None of this straw is utilized for pulping purposes. About 85% is baled and exported; the remainder is either burned or chopped and plowed under. Future plans include retooling a facility for pulping grass straw.

Stalks from Corn, Sorghum, and Cotton

These crops are widely grown worldwide and their residues are suitable for many pulping applications.^[2] Corn and sorghum stalks and the residue of cotton stalks, lint, and linters appear well suited for bleached pulp and corrugating medium. In 2001 in the United States, 27.8 million ha of corn, 3.3 million ha of sorghum, and 5.6 million ha of cotton were harvested.

Sugarcane Bagasse

Bagasse, the residue from sugar-extracted stalks of sugarcane, has long been recognized for its excellent fiber qualities for various grades of paper and board-type applications. Three Louisiana companies have utilized bagasse: One has produced insulator board since the 1920s, another produces a pressed board, and the third (now out of business) produced writing and printing paper for many years.³ The case for bagasse is unique in that the use for pulping competes with the use for fuel to power the

³Legendre, B.L. Personal communication, Louisiana State University; Sugar Research Station: St. Gabriel, LA, 2002.

sugar mill. The long-range prospect for increasing use of bagasse is promising because of the large worldwide inventory and the availability of superior harvesting, storage, and pulping equipment plus improved processes (Fig. 1). Crop estimates indicate that the 2001 U.S. harvest of 416,510 ha^[1] potentially resulted in 31.6 million mt of stalks (fresh weight basis).

STEM/CULM FIBER CROPS

Bamboo

There are many species of bamboo, ranging from the large, very tall, tropical types to the small, shrubby, hardier running types. All are perennial with woody culms (stems). Natural stands or groves, especially of tropical species, occur in many countries and could be exploited for pulping purposes. In more temperate countries, the running species of the genus *Phyllostachys* are fairly hardy and amendable to agricultural practices. Strip and rotational harvests help maintain the long-term productivity of the groves. India and China lead the world in bamboo pulping capacity.

Kenaf and Other Stem Fiber Sources

Kenaf, an old-world fiber crop, was best known as a jute substitute until identified as having good pulping characteristics. American interest in kenaf arose during World War II as imports of jute and allied fibers for maritime uses became jeopardized. In the early 1960s, research emphasis shifted from use for cordage to papermaking. A member of the mallow family, kenaf is a relative of

Fig. 1 Harvesting sugarcane in south Florida. (Photo by USDA-ARS, Beltsville, MD, 2002.) (View this art in color at www.dekker.com.)

Fig. 2 Stem fibers of kenaf suitable for newsprint and other pulp products. (Photo by USDA-ARS, Beltsville, MD, 2002.) (View this art in color at www.dekker.com.)

roselle, okra, flowering hibiscus, and cotton. The stalk is composed of outer bast fibers about 2.6 millimeters (mm) in length and an inner thick core of short fibers about 0.6 mm in length.

Kenaf has been grown successfully in many U.S. states on an experimental and semicommercial or larger scale in about a dozen states. Based on scattered reports, about 4000 and 1500 ha were planted during 2000 and 2001, respectively.^b

Innovative uses for the bast and core fibers—singularly or in blends—include newsprint (Fig. 2), various papers, absorbents, chicken and small-pet litter, soil amendments,

^bColumbus, E.P. Personal communication, USDA-ARS: Mississippi State, MS, 2002; Taylor, C. Personal communication, Kenaf Industries of South Texas L.P.: Raymondville, TX, 2002; Sij, J. Personal communication, Texas A&M University: Vernon, TX, 2002.

seeding, and erosion mats, etc. Decorticating systems have been developed to efficiently separate the bast and core fibers. One U.S. company produces papers consisting of about 80% bast and 20% core fibers.^c The diversity of products manufactured from these fibers should accelerate wider use of kenaf in the future.

The fiber characteristics of roselle and sunn hemp are similar to those of kenaf, but field yields of dry stalks are usually lower. These two crops are apparently immune to root knot nematodes, a kenaf nemesis. Kenaf (a diploid) and roselle (a hexaploid) can be crossed with difficulty. As a legume, sunn hemp production enriches soil through nitrogen fixation. Intense breeding to improve yield and stalk strength in sunn hemp would greatly enhance its potential to become a bona fide fiber crop in the United States. These three fiber sources are photosensitive, thereby requiring short days for floral initiation. Most plantings for seed production are made much later than for fiber. Late planting and lower seeding rates result in short, branched plants that are better suited for machine harvest.

Some other old-world fiber crops that are similar to kenaf in growth habit include hemp, jute, and ramie. Many recall having used jute string or rope. All of these crops are annuals except ramie, a perennial that contains very long fibers. Statistical production and fiber data often lump these four crops with kenaf.

Miscellaneous Fiber Sources

Many plant species are either harvested from natural stands or cultivated for fiber. Most of these are relatively unknown in the Western Hemisphere. The use of these specialty fiber sources, particularly those containing leaf and fruit fibers, is traditionally labor-intensive, thereby

tending to keep production low. Sources of these fiber types include leaf-abaca (manila hemp), henequen, maguey and sisal; fruit-coir and kapok; stem-reeds; and whole plants (esparto, papyrus and sabai grass).

CONCLUSION

A great diversity of fibrous plant species with variable fiber characteristics is suitable and potentially available for producing a wide range of pulp-related products. Specific uses have been identified to take advantage of fiber differences. In terms of quantity, the cereal straws, corn and sorghum stalks, and bagasse are predominant.

As the worldwide economic downturn and current recession in the pulp and paper industry eases, greater use of more diverse fibrous raw materials can be anticipated. The most immediate expansion will likely include cereal straws, bagasse, and bamboo. New fiber resources such as kenaf will gradually add to the base supply. Refs. 2 and 3 contain more detailed information about fibrous resources, U.S. and worldwide inventories, and end uses.

Parasitic Weeds

James H. Westwood

Virginia Tech, Blacksburg, Virginia, U.S.A.

INTRODUCTION

Parasitic plants acquire all or part of their nutrition through direct connections to a host plant. Parasitic weeds attack economically important crops and severely reduce crop yield and quality. The most destructive parasitic weeds are mistletoes, dodders, witchweeds, and broomrapes. Control of parasitic weeds is especially difficult because the parasites are closely associated with the host plant, even to the point of being largely concealed within the body of the host (e.g., mistletoes) or hidden underground for a significant part of their life cycle (e.g., broomrapes and witchweeds). The general biology and control of these organisms will be considered.

WHAT ARE PARASITIC WEEDS?

Some plant species have evolved the ability to obtain nutrients from other plants rather than rely on their own roots and photosynthetic systems (Fig. 1). Over 1% of plant species are parasitic, and parasitism has evolved multiple times, with 18 botanical families including parasitic members.^[1] The multiple evolutionary origins of parasitism account in part for the large diversity among parasite species in growth form, host preference, and reproductive strategy, but they all tend to be highly specialized and may lack leaves, roots, and the ability to photosynthesize. An important characteristic in categorizing parasitic plants is the level of dependency on the host. Some are facultative parasites, and opportunistically parasitize neighboring plants while retaining an ability to live independently. Obligate parasites, in contrast, have an absolute requirement for a host to complete their life cycles. Obligate parasites are further divided into hemiparasites, which are capable of some photosynthesis, and holoparasites, which lack any photosynthetic capacity and must derive all nutrients from the host.

Parasitic plants that use economically important crops as hosts are among the most destructive weeds.^[2] Unlike nonparasitic weeds, which merely compete with crops for resources such as light, water, and nutrients, parasitic weeds tap directly into the crop, removing resources and altering host physiology. Parasitic plants connect to their hosts through a specialized structure, called the haustorium,

which penetrates the host and forms a physiological bridge between the two plants. The haustorium serves as a conduit for the removal of water, minerals, and photosynthates from the host, thereby draining it of resources it needs to grow and reproduce.^[3] In addition to nutrient acquisition, parasite consumption of host water may cause the host to experience drought when environmental water levels are not limiting. The resulting water conservation efforts by the host only serve to suppress its own photosynthesis and arrest growth. Parasites may also disrupt hormone balance in the host, causing deformities and reallocation of resources away from shoots and fruits.

CLASSES OF IMPORTANT PARASITIC WEEDS

Relatively few species of parasitic plants cause most of the problems to agriculture. Three groups that account for the most destructive parasitic weeds are the mistletoes, dodders, and members of the Orobanchaceae, including broomrapes and witchweeds (Table 1). These parasites are quite different from each other, with distinct morphology and parasitic habits.

Mistletoes

The mistletoes are parasites of the shoots of trees and may grow invasively within the tissues of the host as well as externally. After host penetration, a parasite may grow within the host for as long as four years before emerging. Depending on the species of parasite, the shoots may have leaves that are broad (commonly termed leafy mistletoes) or scale-like (dwarf mistletoes) (Fig. 1A–C). Mistletoes are capable of photosynthesis and are generally green in color. Mistletoes may cause a problem in fruit trees and a wide range of deciduous trees, but the greatest economic impact is in coniferous forests parasitized by dwarf mistletoes. This is a major problem for the lumber industry, and several species of dwarf mistletoe decrease timber growth and quality, accelerate incidence of other diseases, and even kill trees. Mistletoes are found worldwide and the value in timber lost on an annual basis in North America alone is estimated to exceed several billion dollars.^[4]

(Photo credits: Gerhard Glatzel **A**, Dan Nickrent **B**, **C**, Yaakov Goldwasser **D**, Lytton Musselman **E**, and James Westwood **F**). (View this art in color at www.dekker.com.)

Dodders

Dodders are vining parasites that attack the stems and leaves of their hosts (Fig. 1D). These parasites consist of tendril-like stems that wrap around the host and form haustoria at points of contact, with each connection fueling further growth to find additional host shoots. In this way, dense mats of dodder may be formed that simultaneously parasitize many host plants. Although most species of dodder have functional photosynthetic systems, they are generally yellow in color and rely heavily on hosts for resources.^[2] Dodders can be very destructive, greatly reducing yields of parasitized crops, and can also be mildly toxic to livestock if consumed with infested forage. Dodders occur throughout the world and affect a wide range of woody and herbaceous dicotyledonous plants.

Broomrapes and Witchweeds

Broomrapes and witchweeds both parasitize plant roots, but while broomrapes are holoparasites that lack photo-

synthesis and developed leaves, witchweeds have green leaves and the capacity for photosynthesis after emergence from the soil (Fig. 1E–F). The tiny seeds of these parasites lie dormant in the soil until stimulated to germinate by chemical signals exuded from host roots. The haustorium is produced from the parasite radicle as it nears contact with a host root. Once the parasite has established connections to the host, it can grow. Whereas broomrapes develop a bulbous structure adjacent to the host root, witchweed initiates a vegetative shoot that grows out of the soil. The impact of these parasites on their hosts can be dramatic, with estimates ranging from partial to complete yield loss, depending on environmental conditions and level of infestation.^[2] Both species flower above-ground and may produce hundreds of thousands of seeds per plant. If measures are not taken to reduce the levels of infestations, seeds of these weeds can build up in the soil to the point that farmers must rotate to non-host crops or abandon the fields completely. These species present the greatest problems in the arid tropics, although their ranges are not restricted to these areas. Witchweeds are centered in Africa and India, while

Table 1 Examples of some of the most economically important parasitic weeds

Family and species	Common name	Host range (crops)
Convolvulaceae <i>Cuscuta campestris</i> <i>Cuscuta reflexa</i>	Field dodder	Alfalfa; many herbaceous dicot species Citrus, coffee, peach, litchi, and other woody perennials
<i>Cuscuta planiflora</i> Loranthaceae	Small-seed dodder Showy mistletoes	Alfalfa, clover, and other legumes
<i>Loranthus europaeus</i> <i>Dendrophthoe falcata</i>		Oak Teak, mango, citrus, eucalyptus, apple, peach, guava, custard apple
<i>Tapinanthus bangwensis</i> Orobanchaceae		Cocoa, cola
<i>Alectra vogelii</i> <i>Striga asiatica</i> <i>Striga hermonthica</i> <i>Striga gesnerioides</i> <i>Orobanche aegyptiaca</i>	Alectra Witchweed Purple witchweed Cowpea witchweed Egyptian broomrape	Many, but especially legumes Maize, sorghum, millet, rice, sugarcane Maize, sorghum, millet, rice, sugarcane Cowpea and other legumes Many herbaceous dicots, e.g., from Solanaceae, Fabaceae, Cruciferae
<i>Orobanche crenata</i>	Crenate broomrape	Broad bean and related legumes, carrot, tomato, and related species
<i>Orobanche cernua</i> (syn <i>O. cumana</i>) <i>Orobanche minor</i>	Nodding broomrape Clover broomrape	Solanaceous species, sunflower Clover and related legumes, Compositae species
Viscaceae <i>Viscum album</i>	Leafy and dwarf mistletoes European mistletoe	Many deciduous and conifer trees, e.g., apple, poplar, pine, fir, larch
<i>Phoradendron serotinum</i> <i>Arceuthobium americanum</i> <i>Arceuthobium tsugense</i>	American christmas mistletoe Lodgepole pine dwarf mistletoe Hemlock dwarf mistletoe	Pear, pecan, walnut, citrus Lodgepole and jack pines, other pines Western hemlocks, fir, spruce, pine

(Information from Refs. 2, 4, 5, and 7.)

broomrapes occur commonly in regions around the Mediterranean, Middle East, and Eastern Europe.

CONTROL OF PARASITIC WEEDS

Parasitic weeds are extremely difficult to control. Their connection to the host plant makes physical removal nearly impossible. For example, removal of mistletoe shoots or mistletoe-infected branches is common, but does not prevent subsequent regrowth from parasite tissue embedded in the host. Dodder is similarly problematic since the stem is tightly wrapped around and connected to the host, and pulling does not remove all tissue. Witchweed and broomrape are both concealed beneath the ground during the crucial early stages of their life, and are thus hidden from sight and from mechanical control measures.

Chemical control strategies are also challenging because of the close association of host and parasite. With the exception of dodder seedlings, which germinate in the soil and are susceptible to certain pre-emergent herbi-

cides, problems of herbicide delivery and selectivity prevent easy control of parasites.^[5] While innovations in herbicide formulation and delivery enable some herbicides to be used effectively, the development of crops with resistance to translocated herbicides such as glyphosate holds promise for parasitic weed control.^[6] However, until such crops are widely available, soil fumigation (e.g., methyl bromide) remains the most effective chemical control against root parasites. Soil injection of ethylene gas induces germination of witchweed seeds in the absence of a host (termed "suicidal" germination because the parasite cannot survive without a host present) and can be effective where economics justify the high expense.

Cultural practices can reduce parasite populations. Rotations including nonhost crops disrupt the cycle of parasitism. Also, altering planting dates, improving soil fertility, and intercropping have been used to reduce witchweed and broomrape damage. For mistletoes, the selective removal of infected trees and maintenance of distance between trees can reduce spread. Breeding for

parasite-resistant crop varieties has received considerable attention and is an ideal solution to the problem, although currently few durably resistant varieties are available for most affected crops. Considering the difficulty in controlling parasitic weeds, preventive practices are important in stopping the spread of parasite seeds to new areas and limiting reproduction where parasites populations are low.

FUTURE DIRECTIONS

Important areas of future research for parasitic weed control include mechanisms of host detection by the parasite, parasite-environment interactions, biological control, and development of resistant host crops. Ironically, it is possible that the close relationship between host and parasite that makes them so difficult to control may lead to new ways to protect crops. This has already been illustrated by the chemical control strategy mentioned above, in which lethal doses of herbicide are delivered to attached parasites via translocation through crops that have been engineered to resist the herbicide.^[6] A more direct strategy, requiring no chemical input, is to engineer host crops that are able to prevent parasite attachment and growth at the earliest stages of infection. This may harness the host's own pathogen defense machinery (e.g., phytoalexins or hypersensitive response) or may use entirely novel mechanisms to disrupt parasite growth. Greater understanding of parasitic weeds, including their physiology and host interactions, will facilitate the development of new parasite-resistant crops.

Pharmaceutical Overproduction and Purification of Biopharmaceuticals Through His-Tagged GUS Fusion Expressions in Chloroplasts

Vanga Siva Reddy

Sadhu Leelavathi

International Center for Genetic Engineering and Biotechnology, New Delhi, India

INTRODUCTION

Transgenic plants offer an excellent expression system to produce foreign proteins useful in the pharmaceutical industry in bulk quantities at low costs. High-level expression and efficient recovery of recombinant protein at low costs are two critical factors that determine the use of transgenic plants as natural bioreactors. A number of proteins/peptides that are highly useful in the pharmaceutical industry are currently being expressed in plants. So far, most of these proteins were expressed through nuclear integration of transgenes—a method that has been well established for a number of plant species. However, the nuclear transformation method has several limitations, the most important being the low-level expression of foreign genes in transgenic plants. This disadvantage can be overcome by integrating transgenes into the chloroplast genome.

CHLOROPLASTS IN PLANTS

Majority of biopharmaceuticals that have been expressed in plants through nuclear transformation^[1–9] can also be expressed through chloroplast transformation^[10–15] where a very high level of expression can be reached as plant cells contain 50–100 chloroplasts per cell, and each chloroplast contains multiple copies (50–100) of the plastid genome.^[11,14] When a foreign gene is transformed and integrated into the chloroplast genome, it results in high-level expression, which is 100-fold to 500-fold higher when compared with the same gene transformed into nuclear genome.^[10] Furthermore, unlike in nuclear transformation where a transgene normally integrates randomly in the genome, the foreign gene can be integrated at a predetermined site in the chloroplast genome through recombination based on homology, thus promoting uniformity of expression in independently transformed plants. Furthermore, chloroplasts in most crop species are maternally inherited; therefore, this approach reduces the risk of transgene transfer to related species through

pollen. Another possibility with plastid transformation is the ability to modify metabolic pathways that are chloroplast-encoded, including photosynthesis.

PLASTID TRANSFORMATION

Typically, a chloroplast transformation vector contains a small plastome (chloroplast genome) of intergenic DNA flanking the transgenes for their site-specific integration, and transgenes are linked to regulatory DNA sequences (promoters and terminators) derived from the genes coded by the plastid genome to drive their expression.^[16] To isolate transformed cells and eventually regenerate a complete transformed plant, a selectable marker gene, usually aminoglycoside adenine transferase (*aadA*), which confers resistance to spectinomycin/streptomycin, is also placed in the vector next to the transgene of interest.^[17] When such vector DNA is delivered into plant cells via a gene gun (an apparatus that is used to bombard the target tissue with vector DNA coated onto tungsten/gold particles; Fig. 1), transgenes are integrated into the plastome through two possible homologous recombinations between flanking regions provided in the vector and the endogenous plastome (Fig. 2). Transformed cells/plantlets are obtained after continuous selection on the nutrient medium containing spectinomycin (Fig. 1). Following such a technique, a number of foreign genes have been transformed into tobacco chloroplasts and their expression has been studied in detail.

BACILLUS THURINGIENSIS TRANSGENIC PLANTS

The *Bacillus thuringiensis* (Bt), a soil bacterium, produces crystal toxins that are considered to be safe as biological insecticides. Transgenic crop plants that are resistant to insects have been developed through the genetic transformation of Bt genes. Production of effective levels of these

Particle gun mediated chloroplast transformation of tobacco plants

Particle gun ready to bombard the leaf tissue with vector DNA coated onto tungsten particles. (B). Accelerated tungsten particles hitting the leaf tissue after the bombardment. (C). Bombarded leaf cut into pieces and placed on selection medium. (D). Regeneration of green transformants after a 4-week period. Most of the leaf tissue turns to yellowish white due to spectinomycin selection. (E). Repeated selection and regeneration produce transgenic plants with homoplasmic plastomes (plants with uniformly transformed chloroplast DNA). (F). Transformed plant with roots ready for transfer to soil. (View this art in color at www.dekker.com.)

proteins in plants required resynthesis of the genes encoding them. Stable integration of an unmodified *cryIA* (c) gene into the plastid genome was shown to amplify the copy number of Bt gene in chloroplasts producing high levels of insecticidal protein.^[18] Another Bt protein, Cry2Aa2, was also shown to overexpress when transformed into a plastid genome, reaching up to 2–3% of the total soluble protein (TSP).^[19] Later, the same group reported the accumulation of Cry2Aa2 at a very high level (45.3% of TSP) when an operon containing a putative chaperon along with the Bt gene was transformed into chloroplast.^[20] This was the highest level of expression reported for any foreign protein in plants so far.

CONTAINMENT OF TRANSGENE SPREAD TO WILD-RELATED SPECIES

The potential of transgene transfer from transgenic plant to related plant species through pollen is currently a major environmental concern that limits the widespread accept-

ance of genetically modified (GM) crops. As plastid genome is inherited maternally in the majority of crop plants, the introduction of foreign genes into the chloroplast genome may be an alternative approach to contain transgene spread to wild relatives through cross-pollination. Svab and Maliga^[17] demonstrated the maternal inheritance of a selectable marker gene (*aadA*) used to transform tobacco chloroplasts. Later, Daniell et al.^[21] demonstrated the maternal inheritance of a plastid-integrated transgene from petunia coding for an enzyme 5-enol-pyruvyl shikimate-3-phosphate synthase (EPSPS) that confers resistance to a potent herbicide.

CHLOROPLAST GENETIC ENGINEERING FOR PHYTOREMEDIATION

Chloroplast genetic engineering was also used to enhance the capacity of plants for phytoremediation. The organic form of mercury (Hg) is a highly toxic pollutant affecting both plants and animals. Tobacco plants engineered to

Site-specific integration of *uidA:ifnG* gene into tobacco plastid genome through homologous recombination

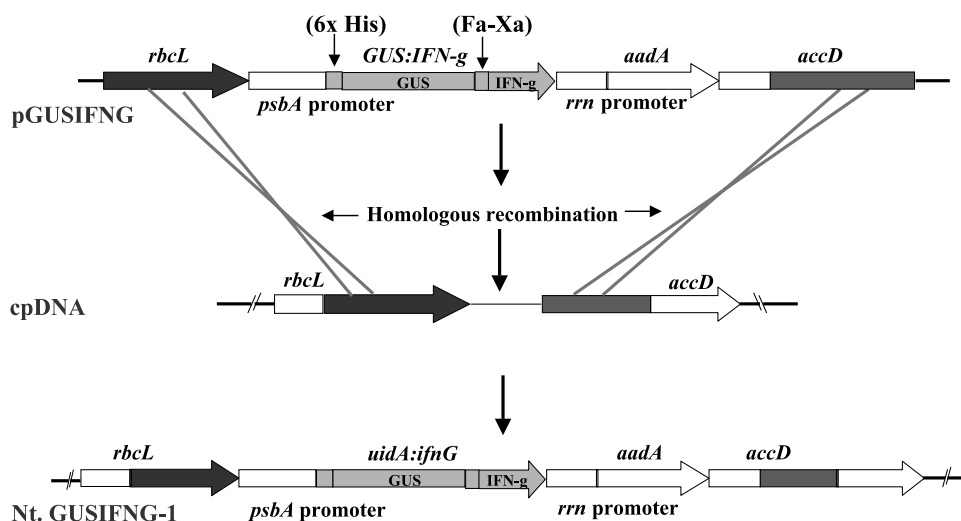

Fig. 2 Restriction map of vector pGUSIFNG, partial chloroplast genome of untransformed (cpDNA) and transformed tobacco plant (Nt. GUSIFNG-1). Positions of the His tag (6 × His) and factor Xa site (Fa-Xa) are indicated. A possible mechanism for site-specific integration of *aadA* and *uidA:ifnG* through two homologous recombinations (crossed lines) was also shown. (View this art in color at www.dekker.com.)

overexpress mercuric ion reductase (*merA*) and organomercurial lyase (*merB*) as an operon in chloroplasts were shown to tolerate the presence of high concentrations (even up to 400 mM) of the organomercurial compound, phenylmercuric acetate (PMA), in soil.^[22]

VACCINE PRODUCTION

Potentially, chloroplast genetic engineering offers a major advantage over conventional nuclear transformation for the production of biopharmaceuticals in plants due to gene amplification in plastids. Daniell et al.^[23] expressed a vaccine candidate gene, the cholera toxin B (CTB) subunit, in tobacco chloroplasts. About 4.1% of TSP was found to be of CTB and the expressed protein assembled into a functional oligomeric form. Similarly, Tregoning et al.^[24] achieved the expression of another vaccine candidate gene, fragment C (TetC)—a nontoxic polypeptide fragment of tetanus toxin that can be used as a subunit vaccine against tetanus. Of the two variants of the same gene, they have expressed: 1) a native bacterial AT-rich (72.3% AT) gene, and 2) a synthetic GC-rich gene; the native gene was found to be expressed at high levels (25% of TSP) when compared with the synthetic gene that was expressed at relatively low levels (10% of TSP). This could be due to the fact that the chloroplast genome is AT-rich, similar to bacterial genomes. Mucosal immunization

of mice with the plastid-produced TetC was found to induce protective levels of TetC antibodies. In a separate study, Staub et al.^[25] have shown the feasibility of the production of a human therapeutic protein, somatotropin, in tobacco chloroplasts. High concentrations of recombinant protein accumulation were observed (7% of TSP) in protein extracts from the leaf tissue. The plastid-produced somatotropin was found to fold correctly with proper disulfide bonds and exhibited biological properties.

BIOPHARMACEUTICAL PRODUCTION

More recent studies have shown that the human interferon γ (IFN- γ), also known as immune interferon,^[26] can be produced at high amounts in chloroplasts and the recombinant protein can be recovered efficiently.^[27] In this procedure, the IFN- γ gene was fused to a reporter β -glucuronidase gene (*uidA* or *GUS*)^[28] and a protease (factor Xa) recognition site was placed between IFN- γ and *GUS* to separate the IFN- γ after purification (Fig. 3). To facilitate the purification of *GUS:IFN- γ* fusion protein from a large number of plant proteins, a six-histidine amino acid (His tag) coding region was added at the amino terminal region of the fusion protein. The expression of *GUS:IFN- γ* fusion protein can reach up to 8% of TSP.^[27]

Expression and purification strategy for GUS:IFN-g fusion protein from transgenic plants

Fig. 3 Schematic diagram showing the expression and purification strategy for IFN- γ in tobacco chloroplasts. (View this art in color at www.dekker.com.)

EXTRACTION OF RECOMBINANT PROTEINS

Purification of recombinant proteins is potentially an expensive step for the production of biopharmaceutical products in plants. Purification of recombinant IFN- γ was achieved following a three-step procedure (Fig. 4). In the first step, ion exchange chromatography (DE-52) was used to purify partially a fusion protein from a crude plant extract. In the second step, affinity-based chromatography was employed to purify the fusion protein to homogeneity. To achieve this step, a ligand (nickel nitrilotriacetic acid, or Ni-NTA) that has a high affinity to six or more histidine residues at a stretch (His tag) is used to immobilize the recombinant protein.^[29] The recombinant protein is engineered to contain the His tag at the amino-terminal end or carboxy-terminal end. When the plant extract containing a recombinant protein with a His tag is passed through the Ni-NTA column, the recombinant protein is retained, whereas plant proteins pass through the column. The recombinant protein is then eluted from the column using imidazole, which has relatively more affinity toward Ni-NTA. Although His tag and Ni-NTA combination was used to demonstrate the power of affinity chromatography, any other tag with a high binding specificity to a ligand can be used for this purpose. In the third step, the fusion protein is digested with factor Xa to cleave the IFN- γ from the GUS protein and purified further using an S-Sepharose column. The purified IFN- γ protein retained its biological activity.^[26]

In molecular biofarming, the recombinant protein must not only be purified, but it should also be purified rapidly as the recombinant protein can be degraded during the purification period due to harsh and lengthy processing conditions. In plants, the afterstep is equally important, as plant cells contain a number of proteases that can potentially degrade the recombinant protein during the purification stage. Identification of a recombinant protein containing fractions during downstream processing by conventional sodium dodecyl sulfate polyacrylamide gel electrophoresis (SDS-PAGE), enzyme-linked immunosorbent assay (ELISA), and Western blot analysis is laborious and time-consuming. The *uidA* (GUS) system is a highly sensitive reporter gene system used extensively to follow the transformation and expression of foreign genes in transgenic plants. One of the key advantages of GUS is its ability to accept both N-terminal and C-terminal fusions without losing enzyme activity. Such a versatile reporter gene system can be extended to recombinant protein purification by simple GUS fusions. The fractions containing a GUS:IFN- γ protein can be identified during the purification process by using a simple and inexpensive GUS assay based on rapid development of color (in less than 5 min). Therefore, the GUS fusion system, combined with chloroplast transformation, offers two key advantages: 1) it increases the yields of low-accumulating and fast-degrading recombinant proteins by providing stability; and 2) it reduces downstream processing time significantly. Therefore, these new strategies have high

Fig. 4 Schematic diagram illustrating various steps involved in the purification of IFN- γ from tobacco leaf tissue. (View this art in color at www.dekker.com.)

potential to convert plants to “natural bioreactors” for the large-scale production of a number of pharmaceutically important proteins/peptides in the near future.

CONCLUSION

Foreign genes are expressed at very high levels in chloroplasts, ranging from 3% to 45% of TSP. The recombinant proteins can be expressed as fusion proteins of GUS, which is very useful in the purification process. The purified recombinant proteins are folded accurately and exhibit their biological functions. Therefore, chloroplast genetic engineering can play a major role in the production of biopharmaceuticals using plants as natural bioreactors.

Pharmaceuticals in Plants

Kazuhito Fujiyama

Osaka University, Osaka, Japan

INTRODUCTION

The potential of production of recombinant proteins in plant represents a new green revolution. Compared to conventional host systems such as *Escherichia coli*, baculovirus, yeast, and animal cells, plants have many advantages, such as production costs and scale up, safety, multimeric protein assembly, and posttranslational modification. Until now, cytokines, antibodies, hormones, and vaccine proteins have been produced and tested for their efficacy. In particular, antibodies produced in plants will be good examples of the first molecular farming products, because plant-antibodies (plantibodies) have been clinically examined and proven functionally similar to those produced by animal systems.

RECOMBINANT ANTIBODIES

The expression and assembly into functional antibodies of two antibody peptide subunits, heavy and light chains, was demonstrated in transgenic tobacco plants.^[1–3] Since then, full-sized or chimeric IgG, IgM, IgA, and other recombinant antibody forms including heavy-chain variable domains, fragment antigen binding (Fab), and single-chain antibody fragment (scFv) have been produced. Secretory IgA (sIgA) is a remarkable example, because sIgA is a decameric immunoglobulin peptide subunits composed of four α -heavy chains (Hc), four light chains (Lc), a joining chain (J), and a secretory component (Sc). Two immunoglobulin molecules, 2 (2Hc2Lc), are associated with J and Sc. Full size of secretory antibodies were properly assembled in plants, and successfully used for clinical trial.^[4,5] Antibody expression in plants has been also used for other objectives. Expression of antipathogen antibodies conferred more pathogen resistance to plants. In other cases, antibodies produced in plant bound to some compounds, such as substrates or phytohormones, and resulted in the alteration of metabolic pathway or hormone-regulated pathways.

PLANTS

Plants used for antibody factory include tobacco, potato, Petunia, soybean, rice, alfalfa, pea, tomato, corn, and

Arabidopsis.^[1,3] Expression levels vary depending on plants, plant tissues, and expression systems including promoter, terminator, and the gene used. In a case of scFv against carcinoembryonic antigen, rice showed 20 times higher expression in seeds than wheat and tobacco,^[6] and produced 32.0 $\mu\text{g/g}$ seed, and 29.0 $\mu\text{g/g}$ leaves and 3.8 $\mu\text{g/g}$ callus.

EXPRESSION LEVELS AND SYSTEMS

Transgenic-plant proteins with possible vaccine applications for human and animal showed maximum expression level from <0.01% to 1.00% of total soluble proteins (TSP).^[1–3,7] In tobacco plants, heat-labile toxin B-subunit was <0.01% of TSP; Norwalk virus capsid proteins, 0.23%; transmissible gastroenteritis coronavirus glycoprotein S, 0.20%. The expression levels of human biopharmaceutical proteins for human health in transgenic tobacco plants were also different; protein C, <0.01% of TSP; serum albumin, 0.02%; hemoglobin α , β , 0.05% of seed protein; glucocerebrosidase, 1.00–10.00%; somatotropin, 7.00% in chloroplast.^[1–3,7] Generally, however, expression levels of recombinant antibodies in transgenic plants lie between 0.5% and 2% of TSP.^[1–3,7]

SUBCELLULAR LOCALIZATION

The higher expression of recombinant antibody has been a challenge. Functional full-length antibodies produced in plant are translocated through the cell wall and accumulate in the intercellular space of leaf tissue when no retention signals are present. It has been reported that recombinant antibody yield increased when antibodies were targeted to the secretory pathway, and not produced in the cytosol. Endoplasmic reticulum (ER) retention expression yielded significantly higher level of productivity. Furthermore, localization in the ER avoided plant-specific complex glycosylation and degradation by protease in the secretory pathway and apoplast.^[8]

Production of scFv fragment in the cytosolic fraction or cytoplasm was very low. Targetting of scFvs toward the apoplast or cytosol resulted in expression level below 0.1%, while scFvs retained at the ER were higher, generally more than 1%.^[1,7] The formation of disulfide

bridges by scFv antibody in the plant cytosol has been recently confirmed.^[9]

Intracellular organelles used for antibody production were vacuolar and nucleolus.^[1] Transformation of chloroplast has been shown to accumulate numerous recombinant proteins and facilitate purification procedures.^[10] It remains unclear if chloroplasts can synthesize recombinant proteins which need complex posttranslational modifications.

PRODUCT STABILITY AND QUALITY

The effect of physiological conditions and developmental-stage was shown to influence antibody production.

For antibody production, climatic condition and developmental stage are important factors. High light growth conditions induce better production of biomass, total soluble protein, and antibody. The plants incubated at 25°C grew faster and produced less antibody per amount of leaf tissue than the plants incubated at 15°C.^[11] Both endogenous protein and antibody content declined remarkably as leaf developed.^[11]

Like other proteins, functional antibodies produced in plants have been stored in dried leaves, seeds, and tubers.^[1,2] Expression in seeds can confer not only long life properties of the recombinant proteins, but also more the flexible chance of downstream processing strategy, such as purification.

The stability of antibodies produced in tobacco was examined. A substantial part of the antibody H-subunit was degraded during leaf development. The proteolytic degradation of plantibody H-subunit occurred faster than the H-subunit of antibodies from hybridoma cells. The proteolytic degradation in plants, mainly found in extracellular compartment (apoplast) of shoot and root tissues, and in cytoplasm, resulted from the senescence process.^[5] However, the antihuman IgG monoclonal antibodies produced in transgenic alfalfa plants were stable in plant extracts.^[12]

The physiological conditions of the plants themselves should also be taken into consideration for greater production of antibodies with higher quality.

GLYCOSYLATION, IMMUNOGENICITY, AND ALLERGENICITY

Structures of N-linked glycans on plant- and hybridoma-produced antibody have been determined and compared. Plant-antibody carried typical plant glycans with β 1,2-xylose and α 1,3-fucose residues, but not animal-type sugar residues, such as galactose and sialic acid. The

immunogenicity of this plant-produced monoclonal antibody was tested in mice, and results showed that the plant-antibody was not immunogenic.^[13]

An IgG produced in alfalfa had a serum half-life in mice that was indistinguishable from that of the hybridoma-produced antibody.^[12]

However, there is some concern about the potential immunogenicity and allergenicity of plantibodies used as human therapeutics.^[12]

The H-subunit of transgenic-plant antibody showed a higher degradation rate than the hybridoma cells H-subunit.^[11] The N-linked oligosaccharide on antibody contributed to protein stability. Susceptibility is considered to stem from the fact that plantibodies have plant-typical glycan structures. Thus glycosylation also affects protein stability.

COST

The cost of producing an IgG from alfalfa grown in a 250-m² greenhouse are estimated to be \$500–600/g, compared with \$5000/g for the hybridoma-produced antibody.^[12]

FUTURE OF ANTIBODIES PRODUCED IN PLANTS

Recently, the production of more than 100 antibodies has been tried in various plants by using different expression systems. Plant expression systems constitute a promising technology, because it offers numerous advantages compared to other systems. However, glycosylation and productivity are two of the main disadvantages of this technology. Clinical trials of some plant-produced antibodies have been successfully conducted. In the next decade or two, it is projected that this production system will take over conventional production systems.

Phenylpropanoids

Kevin M. Davies

New Zealand Institute for Crop and Food Research Limited, Palmerston North, New Zealand

INTRODUCTION

Plant phenylpropanoids are a major group of secondary metabolites derived from phenylalanine. They have a wide range of functions in plants, both as structural compounds and in interactions with the environment and other organisms. The importance of phenylpropanoids in general biology can be illustrated by a few observations on just one of the phenylpropanoid subgroups, the lignins. Lignins are the second most abundant polymer in plants, after cellulose, and are required for xylem formation and strengthening of cell walls. The evolution of lignin biosynthesis is thought to have been a key step in the colonization of land by plants. Today it is estimated that phenylpropanoids account for over 30% of all organic carbon in the biosphere, and that the majority of this is lignin. Furthermore, the degradation of lignin is a major rate-limiting step in the carbon cycle.

BIOSYNTHESIS AND FUNCTION

The proposed biosynthetic pathway of the major phenylpropanoid groups is represented in Figs. 1 and 2. The initial compounds, hydroxycinnamic acids (HCAs), are formed from phenylalanine by phenylalanine ammonia lyase (PAL), cinnamate 4-hydroxylase (C4H), and 4-coumarate:CoA ligase (4CL). All the other phenylpropanoid types arise from the HCAs. A core section of the phenylpropanoid biosynthetic pathway is common to most plants, including ferns, in particular to the formation of HCAs, flavonoids, lignins, and proanthocyanins (tannins). However, based on these core compounds a huge diversity in structure occurs. For example, about 5000 flavonoid types can arise through glycosylation, hydroxylation and substitution with methyl, sulphur, and aliphatic or aromatic acyl groups. While the functions of the major phenylpropanoid groups are known, the roles of the many variant structures is often unclear. Several excellent in-depth reviews of phenylpropanoid biosynthesis and diversity are available.^[1–3]

Lignins and Lignans

Lignins and lignans are polymeric molecules formed by different biosynthetic routes from the same monolignol

precursors (Fig. 1). Lignins are high-molecular-weight polymers found in cell walls. Lignans are commonly dimers, although they can form higher oligomers, and are found in abundance in wood resins, in which they may play a plant defence role. Monolignol biosynthesis from the HCAs involves a network of aromatic hydroxylations, NAPH-dependent reductions, CoA ligations, and O-methylations. For lignin biosynthesis, the monolignols are transported from the cytosol to the cell wall, where polymerisation occurs, probably on a proline-rich protein template and catalyzed by peroxidases and laccases. The structures formed can vary much between species, and even within a plant, and the mechanisms that control the process are unclear. However, a dirigent protein was recently characterized that can determine the type of stereospecific coupling linkages that occur between the monolignol precursors.

Flavonoids

The first committed step of flavonoid biosynthesis occurs with the formation of chalcones by chalcone synthase (CHS), when three units of acetate-derived malonyl-CoA combine with the phenylalanine-derived 4-coumaroyl-CoA (Fig. 2). The subsequent steps of flavonoid biosynthesis, resulting in the formation of the anthocyanins, proanthocyanins, flavones, and flavonols, are common to nearly all flowering plants. The notable exception are most species of the Caryophyllales, in which the colored anthocyanins are substituted with betalain pigments. Along with chlorophylls and carotenoids, anthocyanins are major pigments of plants, capable of providing color to all plant tissues. There are three common anthocyanin groups, pelargonodin-derivatives, cyanidin-derivatives and delphinidin-derivates, which usually result in pink-red, red-purple, and mauve-blue colors, respectively. They are typically glycosylated, often further substituted, and localised to the vacuole. However, rare and highly modified anthocyanin forms occur in nature, with over 600 individual anthocyanins reported to date.

Many biosynthetic branches occur in the flavonoid pathway. Of particular note are the action of chalcone reductase (CHR) with CHS forming 6'-deoxychalcones, the aureusidin synthase forming aurones, flavone synthase (FNS) forming flavones, flavanone reductase (FNR)

Fig. 1 Diagrammatic representation of a section of the phenylpropanoid pathway leading to hydroxycinnamic acids, monolignols, and pinosylvin. Enzyme abbreviations are as given in the text, except PSS (pinosylvin synthase, a STS type enzyme). The sequence of some steps in monolignol biosynthesis is under debate, and no attempt has been made to represent the alternative pathways.

forming 3-deoxyanthocyanin precursors, flavonol synthase (FLS) forming flavonols, and isoflavone synthase (IFS) forming isoflavone precursors. Many of these enzymes and compounds are taxonomically restricted in their occurrence.

In addition to pigmentation, the functions of flavonoids are diverse. They can protect leaves from oxidative stress and ameliorate the impact of UV-B radiation. They are also key plant defence compounds. The isoflavonoids and flavone C-glycosides are involved in defence against fungal and insect attack, and proanthocyanidins can be herbivore deterrents. The flavonols are essential for fertility in some species, acting by an unknown mechanism during pollen growth in the stigma. Flavonoids are also key signal compounds, most notably to the soil bacterium *Rhizobium*, to trigger nodulation for symbiotic nitrogen fixation. The formation of heartwood in trees is marked by the accumulation of phenylpropanoid rich

resins, which are commonly a mix of flavonoids, lignans, and stilbenes. It will be obvious from this list that flavonoids are a key branch of plant secondary metabolism. However, these are probably only some of the functions for these compounds. The action of flavonols in plant fertility came to light only in the early 1990s and, given the great diversity of structural types, many flavonoid functions may yet be determined. For example, there is growing evidence that flavonoids influence auxin transport.

Coumarins, Stilbenes, and Related Compounds

In addition to lignins and flavonoids, a range of other compounds are derived from HCAs. Coumarins are a varied group of compounds, widespread in nature, whose primary function appears to be in plant defense. A well

Fig. 2 Diagrammatic representation of the flavonoid and stilbene sections of the phenylpropanoid pathway. Simplifications include showing only 4'-hydroxylated flavonoid types, no indication of the subsequent glycosylation or further modification of compounds, double arrows representing multiple enzyme steps, the absence of some rarer flavonoid types (e.g., aurones), and showing only one isoflavonoid (a pterocarpan phytoalexin). Enzyme abbreviations are as given in the text.

known example of their impact is the photosensitive skin blistering that can result from handling celery (*Apium graveolens*) or giant hogweed (*Heracleum mantegazzianum*). The coumarin biosynthetic pathway(s) have not been elucidated, although it is thought that the initial reactions are *cis/trans*-isomerisation and ring closure of a HCA.

The condensation of malonyl-CoA and HCAs can form compounds other than the flavonoids. A group of CHS-like enzymes use malonyl-CoA and a HCA-CoA to form a range of plant defense compounds.^[4] The best characterized are the stilbene synthases (STS) that form compounds such as resveratrol and pinosylvin. Like CHS, they carry out three condensation reactions followed by ring closure, but the nature of the ring closure differs. To date, over 300 different stilbenoid structures have been reported. Malonyl-CoA and HCA-CoA com-

pounds are also the precursors for the arylpyrones and styrylpyrones. These reactions involve only one or two condensations prior to ring closure, but little is known of the biosynthetic enzymes.

The Molecular Biology of Phenylpropanoid Biosynthesis

The colored flavonoids have provided model systems for scientists since the time of Mendel's inheritance studies. More recently, studies on flavonoids have been responsible for some of the most important breakthroughs in plant science, including the cloning of the first plant transcription factor gene, the isolation of one of the first cDNAs for a plant cytochrome P450 enzyme, the first demonstration of antisense RNA technology in a transgenic plant, and the first characterization of a transgene

cosuppression mechanism. Studies with the major model systems, *Antirrhinum majus*, *Arabidopsis thaliana*, *Petunia*, and *Zea mays*, have resulted in the isolation of cDNAs or genes for most of the core biosynthetic enzymes of phenylpropanoid biosynthesis, and for several transcription factors involved in the regulation of the pathway.^[2,5] Transposon-generated mutations have been key to the successful elucidation of the molecular genetics of phenylpropanoid biosynthesis. A more recent extension of the use of mutants is the linking of metabolic profiling to the genomics systems available for species such as *Arabidopsis* and *Medicago truncatula*.^[6] Research is now focusing on aspects such as the regulation of the biosynthetic genes, the subcellular interactions of the biosynthetic enzymes, the biosynthesis of rare phenylpropanoid types, and the control of lignin formation.

The Importance of Phenylpropanoids to Agriculture and Human Health

Phenylpropanoids affect the quality and quantity of the harvested products from most plant crops. Obvious examples include the impacts of lignin and heartwood resins on timber and pulping wood quality, lignin on forage crop digestibility, tannin production for the control of bloat in ruminants, flower and foliage color in ornamental crops, tannin production in wine, and flavor and fragrance compounds in spice crops and teas. Phenylpropanoids are also key plant defense compounds. However, perhaps the area of keenest research interest at present is the influence of phenylpropanoids on human health. Numerous *in vitro* experiments, animal trials, and epidemiological studies have linked the intake of specific phenylpropanoids with a reduced risk of conditions such as cancer and heart disease. The mechanisms behind such actions are generally unknown, although the antioxidant activity of many phenylpropanoids has often been implicated.

Given the importance of phenylpropanoids in agriculture it is not surprising that the pathway was one of the early targets for genetic modification approaches. Metabolic engineering in transgenic plants has been used to alter the production of nearly all of the different groups of phenylpropanoid compounds.^[7,8] Transgenic carnations

with modified flower color through the alteration of anthocyanin biosynthesis are on sale in a number of countries, and it is anticipated that these will be joined by some of the transgenic plant lines currently in field trials, such as trees with improved lignin characteristics, forage crops with improved digestibility, and food crops with high levels of health-promoting phenylpropanoids.

Phosphorus

Carroll P. Vance

USDA/ARS Plant Science Research Unit and University of Minnesota, St. Paul, Minnesota, U.S.A.

INTRODUCTION

Phosphorus (P) is one of 17 essential elements (nutrients) required for plant growth. The P concentration in plants ranges from 0.05 to 0.50% dry weight. It plays a role in a wide array of processes, including energy generation, nucleic acid synthesis, photosynthesis, glycolysis, respiration, membrane synthesis and stability, enzyme activation/inactivation, redox reactions, signaling, carbohydrate metabolism, and nitrogen (N) fixation. The concentration gradient from the soil solution orthophosphate (P_i) to plant cells exceeds 2000-fold, with an average free P_i of 1 μM in the soil solution. This concentration is well below the K_m for plant uptake. Thus, although bound P is quite abundant in many soils, it is largely unavailable for uptake. As such, P is frequently the most limiting element for plant growth and development. Crop yield on 30 to 40% of the world's arable land is limited by P_i availability. Phosphorus is unavailable because it rapidly forms insoluble complexes with cations, particularly aluminum and iron under acid conditions. The acid-weathered soils of the tropics and subtropics are particularly prone to P_i deficiency. Moreover, some 30 to 70% of the P can be bound in insoluble organic forms (such as phytate) due to microbial activity. Application of P-containing fertilizers is the recommended treatment for enhancing soil P_i availability and stimulating crop yields.

THE PHOSPHORUS CONUNDRUM

Application of P fertilizer, however, is problematic for both the intensive and extensive agriculture of the developed and developing worlds, respectively. In intensive agriculture, a grain crop yield of 7 metric tons $\cdot\text{Ha}^{-1}$ requires the addition of 90 to 120 kg P $\cdot\text{Ha}^{-1}$.^[1-3] But even under adequate P fertilization, only 20% or less of that applied is removed in the first year's growth. This results in P loading of prime agricultural land. Runoff from P-loaded soils is a primary factor in eutrophication and hypoxia of lakes and marine estuaries of the developed world.^[1,4,5] Another reason for alarm is that by some estimates, inexpensive rock phosphate reserves could be depleted in as little as 60 to 80 years.^[3,6] Phosphorus fertilizer use increased 4- to 5-fold between 1960 and 2000

and is projected to increase further by 20 Tg $\cdot\text{year}^{-1}$ by 2030 (Tables 1–3). Several authors have noted that a potential phosphate crisis looms for agriculture in the 21st century.^[1,4,6,7] A concern even greater than the overabundant use of P fertilizers by intensive agriculture is the lack of available P fertilizers for extensive agriculture in the tropics and subtropics where the majority of the world's people live. Lack of fertilizer infrastructure, money for purchase, and transportation make P fertilization unattainable for these areas. Sustainable management of P in agriculture requires that plant biologists discover mechanisms that enhance P_i acquisition and exploit these adaptations to make plants more efficient at acquiring P_i , develop P-efficient germplasm, and advance crop management schemes that increase soil P_i availability.

ADAPTATIONS TO LOW P

Because of its ubiquitous importance, plants have evolved two broad strategies for P acquisition in nutrient-limiting environments: 1) those aimed at conservation of use; and 2) those directed toward enhanced acquisition or uptake.^[1,8] Processes that conserve the use of P involve decreased growth rate, increased growth per unit of P uptake, remobilization of internal P_i , modifications in carbon metabolism that bypass P-requiring steps, and alternative respiratory pathways.^[1,8] By comparison, processes that lead to enhanced uptake include increased production and secretion of phosphatases, exudation of organic acids, greater root growth along with modified root architecture, expanded root surface area by prolific development of root hairs, and enhanced expression of P_i transporters and aquaporins.^[1,8-11]

By far the most prevalent evolutionary adaptation by land plants for acquiring P_i (80% of all species) is through mycorrhizal symbioses.

PROTEOID ROOTS OF WHITE LUPIN

Significance

Proteoid roots (also known as cluster roots) are third order lateral roots that resemble bottle brushes in appearance

Table 1 Phosphorus content of plants

Species	Content (% Dry weight)
Maize	0.20
Sunflower	0.28
Lupin	0.51
Barley	0.15
Alfalfa	0.47

(Fig. 1). They develop in response to low P in the Proteaceae, Fabaceae, Casuarinaceae, Betulaceae, Myricaceae, Eleagnaceae, and Moraceae.^[11] Along with mycorrhizal association and nitrogen-fixing root nodules, proteoid roots are the third major adaptation by plants for acquisition of scarce nutrients. The well-characterized legume white lupin is an illuminating model for understanding proteoid root formation and plant adaptations to low P habitats.^[1,9–11]

White lupin can effectively acquire P_i even though it does not form a mycorrhizal symbiosis.^[1,10,11] Instead, its adaptation to P stress is a highly coordinated modification of root development and plant metabolism resulting in proteoid roots that exude copious amounts of organic acids and acid phosphatase.^[1,9,10] Proteoid root formation is accompanied by extensive root hair formation that increases root surface area by greater than 100-fold. In addition, P_i uptake within proteoid root zones is much greater than that of normal roots. The developmental and metabolic changes that occur to give rise to proteoid roots are mediated in part by enhanced accumulation of transcripts encoding P_i transporters, exuded acid phosphatase, and enzymes of carbon metabolism.^[1,9,10]

Development

Several features distinguish proteoid root development and morphology from that of typical dicot lateral roots. First, lateral roots are randomly initiated from the pericycle of

Table 2 Phosphorus fertilizer application increases crop yield

P Application (Kg · ha ⁻¹)	Crop yield (Mt · ha ⁻¹)		
	Wheat	Corn	Alfalfa

primary roots near the zone of metaxylem differentiation,^[1,11] whereas proteoid roots are initiated in waves along secondary roots (Fig. 1). Second, lateral roots are initiated singularly opposite a protoxylem point, in contrast to proteoid roots that are in multiples opposite every protoxylem point within the wave of differentiation. Third, in typical lateral roots, root hair development is highly regulated and occurs from a discrete number of epidermal cells. By comparison, in proteoid roots self-regulation of root hairs has gone awry with superabundant formation. Last, contrasting with the indeterminate growth of lateral roots, proteoid root growth is determinate, ceasing shortly after emergence (Fig. 1). This highly synchronous developmental pattern indicates that proteoid root formation is a finely tuned process. Moreover, because root pericycle cells are arrested in the G2 phase of the cell cycle,^[1,11] proteoid root initiation must involve concerted release of multiple pericycle cells from the G2 phase in a wavelike pattern along second order lateral roots.

As might be expected, the internal balance and distribution of the plant growth hormones auxin, ethylene, and cytokinin are thought to play a role in proteoid root formation. Substantial support for the role of auxin in lateral root development is derived from evidence that: 1) exogenous auxin stimulates lateral root formation in most species; 2) auxin transport inhibitors block lateral root formation and this block can be alleviated by exogenous application of auxin; and 3) *Arabidopsis* mutants that overproduce auxin have enhanced lateral root formation, whereas mutants insensitive to auxin have impaired lateral root development. Gilbert et al.^[1] have shown that exogenous application of auxin to P-sufficient white lupin mimics proteoid root formation seen under P-deficient conditions. They also showed that auxin transport inhibitors block the formation of proteoid roots on P-deficient

Fig. 1 Proteoid root formation in phosphorus (P)-deficient white lupin and adaptive strategies for acquisition of P. (A) Development of proteoid roots in response to P deficiency. Roots (left to right) are taken from white lupin at 5, 7, 9, 10, 14, and 22 days after initiation of P-stress, respectively. Proteoid roots begin to emerge by day 9 and become more extensive as P-stress progresses. (B) Proteoid roots from P-deficient white lupin acidify the rhizosphere. Proteoid roots from 14-day P-stressed plants are placed on agar plates containing pH indicator. Zone of acidification (yellow color) occurs in the rhizosphere where proteoid roots are in contact with agar. (C) Secretion of acid phosphatase activity from proteoid roots of 14-day P-deficient plants. Normal (N) and proteoid (P) roots from P-sufficient (+) and P-deficient (–) plants are placed in contact with agar media containing acid phosphatase reagent. Photos are taken 15 minutes and 5 hours after roots have been placed in contact with reagents. Red color indicates acid phosphatase activity. Secretion of acid phosphatase from proteoid roots of P-deficient plants is quite evident at 5 hours, whereas normal roots from either P-sufficient or P-deficient plants show little to no secretion of acid phosphatase. (View this art in color at www.dekker.com.)

plants. Although the role of ethylene in lateral root formation is less clear, there is convincing evidence that ethylene plays a role in root hair formation and abundance. Consistent with the abundant root hairs found on P-deficient proteoid roots, Gilbert et al.^[11] found that ethylene production was increased twofold during the initiation and emergence of proteoid root initials of P-deficient plants compared to P-sufficient plants. Exogenous application of kinetin also inhibits proteoid root formation in P-stressed white lupin. Although we have not measured cytokinin content of P-stressed white lupin, it is

revealing that an abundantly expressed EST in white lupin responsive to P-stress is cytokinin oxidase.^[9]

Root Exudation of Organic Acids and Acid Phosphatase

Although there is a large reservoir of inorganic and organic P in soil, most of it is unavailable because it is complexed to metals and/or organic residues.^[1,10,12] Exudation of organic acids and acid phosphatases from roots is a hallmark adaptation of plants growing in soils with low available P_i .^[10] The release of organic acids from roots allows for the displacement of P from Al^{3+} , Fe^{3+} , and Ca^{2+} -phosphates, thus freeing bound P.^[1,10] Organically bound P, which can compose as much as 70% of the soil P pool, can be hydrolyzed by acid phosphatases, thus freeing a large pool of unavailable P_i . These root adaptations to insufficient P_i are strikingly displayed by proteoid roots of P-deficient white lupin.

Proteoid roots of P-deficient white lupin synthesize and exude copious amounts of malate and citrate (Fig. 1). In the rhizosphere of white lupin grown in calcareous soil, the citrate concentration can be as high as $50 \mu\text{mol} \times \text{g soil}^{-1}$. Between 10 and 25% of the total carbon fixed during P-stress can be released as malate or citrate. Radiolabeling studies show that nonautotrophic CO_2 fixation in proteoid roots can provide up to 30% of the carbon exuded in citrate and malate. The increased synthesis of organic acids in P-deficient proteoid roots is mediated by highly enhanced activity of malate dehydrogenase (MDH), phosphoenolpyruvate carboxylase (PEPC), and citrate synthase (CS) with an accompanying decrease in aconitase (AC) and respiration rates. Recent molecular studies show that increased PEPC and MDH activities are due in part to enhanced expression of PEPC and MDH genes.

Accompanying the acidification of the rhizosphere of P-deficient white lupin proteoid roots is the excretion of large amounts of acid phosphatase (Fig. 1). Although the release of acid phosphatase and phytase is a common response of plant roots to P_i -stress, only in white lupin proteoid roots have the biochemical and molecular events involved yielded to experimentation. Under P_i -stress, proteoid roots synthesize and secrete a novel isoform of acid phosphatase (SAPase).^[11] Characterization of SAPase protein and cDNA from white lupin exudates revealed that the enzyme was synthesized as a 52 kD protein having a 31 amino acid presequence. The presequence targets the protein to outside the cell. Upon exudation, cleavage of the presequence results in a 49 kD processed protein. The formation of a novel SAPase results from increased SAPase mRNA and protein synthesis in proteoid roots (Fig. 2). The promoter region of the SAPase gene has

Fig. 2 Expression of mRNA transcripts for secreted acid phosphatase (sAP) and phosphate transporter (LaPT1). The greatest expression of both genes occurred in proteoid roots (PR) of P-deficient (–) plants. There is very little expression of sAP in other tissue from either P-sufficient (+) or P-deficient (–) plants. By comparison, LaPT shows enhanced expression in P-deficient (–) normal roots (N) and stems (S), with little to no expression in P-sufficient (+) plants. Key: NR, normal roots; PR, proteoid roots; S, stems; L, leaves; F, flowers; Pd, pods; +, P-sufficient; –, P-deficient.

cis-acting element(s) that control P-stress-induced gene expression. Similar biochemical and molecular events appear to control P-starvation-induced acid phosphatases in suspension cell cultures of *Brassica nigra*.

Phosphorus Uptake

Inorganic orthophosphate (such as H_2PO_4^- and HPO_4^{2-}) is the form of P_i most generally taken up by plants.^[13,14] After diffusion through the soil to the root surface, P_i is

rapidly taken up, resulting in a P_i depletion shell of 0.2 to 1.0 mm around the root. Although the soil solution P_i concentration rarely exceeds 2 μM , that in plant cells is much higher, 2 to 20 mM.^[12,14] For the plant to surmount this concentration difference, active (energized) transport across the plasmalemma is required. The striking reduction in P_i accumulation of tissues treated with inhibitors reflects this energy requirement for uptake.^[12,13] Moreover, kinetic analysis of P_i uptake shows that plants have both a low- and high-affinity uptake system.^[10,12,14] The high-affinity system operating at low P_i concentrations has an apparent K_m ranging from 3 to 10 μM . By comparison, the low-affinity system operating at high P_i concentrations has a K_m ranging from 50 to 300 μM . Recently, functional complementation of yeast mutants defective in P_i transport has been used to isolate and characterize P_i transporters from a diverse array of plants.^[13,14] Molecular characterization of P_i transporters coupled to the discovery of as many as 16 within the genome of *Arabidopsis* confirms that plants have a multiplicity of P_i transporters functional in specific organs and tissues.

Uptake of P_i by P-deficient proteoid roots is much greater than that of P-sufficient plants.^[10] Moreover, the apparent K_m for P_i uptake of proteoid roots is 8.6 μM , compared to a K_m of 30.7 μM for P-sufficient controls. These results suggest that a high-affinity P_i uptake system is induced in proteoid roots of P-deficient plants. We have recently characterized a high-affinity type P_i uptake gene (LaPT1) from proteoid roots of white lupin that shows highly intensified expression in P-deficient plants.^[11]

Fig. 3 Deduced structure of white lupin phosphate transporter 1 (LaPT1). Note 12 membrane-spanning domains. Both the NH_2 and COOH termini are predicted to be on the outside of the cell. Internal to cell indicated by in; external of cell indicated by out. (View this art in color at www.dekker.com.)

Similar to other plant P_i transporters, the white lupin proteoid root P_i transporter has a 1620 base pairs (bp) open reading frame that encodes a protein of 540 amino acids with a Mr of 59 kD. The deduced protein contains 12 transmembrane domains that occurs as two groups (6+6) connected by a hydrophobic domain of 60 amino acid residues (Fig. 3). The deduced amino acid sequence of *LaPT1* is 85% similar to previously reported high-affinity type P_i transporters, but only 75% similar to low-affinity type P_i transporters. Transcripts of *LaPT1* are highly expressed in P_i -deficient proteoid roots, normal roots, and stems with little to no expression in P-sufficient plants (Fig. 2). Thus, the enhanced uptake of P_i displayed by P-deficient proteoid roots can be directly related to increased expression of a high-affinity type P_i transporter.

CONCLUSION

Phosphorus has and will continue to play a major role in crop productivity because of its role in all phases of plant growth. However, the adverse impact that excess P has on water quality, coupled with depletion of cheap sources and lack of availability in the developing world, necessitate that plant scientists unravel the mechanisms leading to improved P acquisition. Proteoid roots of white lupin offer an excellent model for understanding P-acquisition strategies that both improve acquisition and conserve use of the critical nutrient. By discovering how plants control adaptation to low-P environments through changes in metabolism, development, and gene expression, we can begin to identify targets to improve P acquisition through conventional and biotechnological methods.

Photoacoustics: Listening to Plants

Shumel Malkin

The Weizmann Institute, Rehovot, Israel

INTRODUCTION

Photoacoustics (PA) is a methodology concerning the measurement of minute transient pressure changes resulting from light absorption.^[1,2] For good detection the light intensity must vary rapidly, so light is brought in as a single pulse or flash or is modulated periodically. Several variations exist in PA, depending on the state of the sample (i.e., gas, liquid, homogeneous or porous solid) and the time-scale and time-profile of the light. The pressure changes are sensed by a suitable detector (e.g., a microphone, a piezoelectric device, or a similar gadget), which generates a measurable electrical signal (the PA signal). PA is applicable for spectroscopy and analytical determination down to very low concentrations (to the parts per billion range).^[1–6] A significant application is the measurement of (gross) photosynthesis^[5–11] and its related parameters, including energetic and regulatory aspects. PA is particularly unique in leaf measurements, being a noninvasive, rapid, and sensitive technique.^[8] The interested reader may find wider coverage of the subject using the small representative bibliographic list. While this list is very limited, it may serve as a starting point for a more comprehensive search.

THE PHOTOTHERMAL MECHANISM AND SPECTROSCOPY—ANALYTICAL APPLICATIONS

A universal mechanism that produces pressure changes is the temperature rise caused by the absorption of light energy and its conversion to heat (photothermal mechanism).^[1] If this is the sole mechanism and if the conversion of light energy to thermal energy is complete, the PA signal, being related directly to the extent of light absorption, may be used for spectral analysis of the sample. PA spectroscopy^[1–4] is a direct method, in contrast to conventional spectroscopy, in which the intensity of a transmitted beam is compared to that of an incident beam. PA spectroscopy has a clear advantage in two extreme cases: 1) for almost fully transparent materials, when the difference between the intensities of the incident and transmitted beams cannot be accurately

determined; and 2) for very opaque liquid or solid samples, in which conventional spectroscopy requires impractical very small optical lengths (usually in the order of micrometers). This problem is circumvented in PA. Solid and liquid samples can be analyzed by a conventional gas-coupled microphone PA cell, in which a microphone is placed in the gas (air) phase surrounding the sample. Light, modulated at some frequency (practically ca. 5–2000 Hz), is incident on the sample's cross-sectional side, which is in contact with the gas phase. There is a heat flow, from the light absorption path through the sample, toward the gas phase. The light modulations cause modulations in heat generation, which diffuses to the gas phase, and, in turn, causes modulated pressure changes in the gas phase. However, the modulation in the heat flow is strongly damped along its diffusion path, in accordance with the heat conductance equation. Accordingly, light absorption in only a limited small depth below the surface (in the order of micrometers, depending on the modulation frequency) is expressed as a PA signal.^[1]

The PA signal, obviously, depends on the thermal conduction and heat capacity, and might be used for their measurement. For a nonhomogenous sample it is possible to scan the PA signal through the sample's cross section at various frequencies and obtain information on the depth profile inhomogeneity of the thermal and optical parameters. These can be expressed by imaging.^[1,2] For illustrations of PA cells and systems see Figs. 12.1 to 12.6 in Ref. [1], Fig. 1a in Ref. [7] and Refs. [1,6] quoted in Ref. [7].

Gaseous materials are likewise analyzed in a gas-coupled microphone cell, where light is absorbed directly in the gas phase and pressure changes are developed momentarily therein. An example relevant to the plant sciences is the determination (down to sub parts per billion concentrations) of gases that are evolved from various metabolic processes in plants, fruits, and food stuff, e.g., ethylene, ammonia, methane, etc..^[3,4] Nitrogen fixation can also be monitored by the accompanying gas evolution. The PA cell is contained in a gas flow system, with a carrier gas passing through a sample chamber. A modulated infrared laser is passed through the flowing gas in a tube, after selecting a suitable wavelength absorbed by the analyzed gas in question. The PA signal is proportional to the concentration. Very suitable are CO

or CO₂ lasers, containing many wavelength lines, one of which at least is absorbed by the materials in question. For illustrations of the experimental system and details of the many applications, see Refs. [3,4]. (Notice that in Ref. [4] the legends to Figs. 3 and 5 were erroneously switched.)

Another example, relevant to water quality and primary production, is the determination of photosynthetic biomass in natural water.^[6] For this case, another version of a PA cell is used in which the pressure sensor (e.g., piezoelectric) is coupled to the analyzed water, either directly or through intervening solid or liquid materials and not through a gas phase. Usually, a laser pulse of a small cross section (relative to the cell dimension) is passed through the middle of the sample. It generates an acoustic wave pulse propagating from the light path through the suspension to the detector. A transient wave-form signal impulse is obtained, in the microsecond time range, which is a superposition of effects due to the various photochemical processes. This mode of PA^[2,5,6,10,13] may be called pulsed, time-resolved photoacoustics (PTRPA). An alternate name is laser-induced opto-acoustic spectroscopy (LIOAS).^[2] The PA-signal waveform depends on the light profile, the physical mechanisms that are expressed as pressure changes, and the physics of acoustic wave propagation. The PA signal in this case is a composite of the photothermal and another mechanism (cf. below). However, one may obtain conditions where only the photothermal mechanism is present. In any case the PA signal amplitude is proportional to the concentration of the photosynthetic pigments.^[6] There are accompanying methods that measure the photothermal effect alone, e.g., photothermal radiometry (PTR),^[1,2,7] based on the emission of modulated thermal radiation from the sample. This method was used only occasionally in photosynthesis.

PA-SIGNAL FORM AND ATTRIBUTES

The PA-signal form depends on the PA-cell arrangement and the light profile.^[2] For periodically modulated light the signal is characterized by its *amplitude* and *phase*, relative to the amplitude and phase of the exciting light. Mathematically, the modulated light intensity may be expressed by $I = I_0 (1 + \sin(2\pi ft))$, where I is the momentary light intensity, I_0 its amplitude, f the frequency, and t the time. The resulting PA signal is given as $S = S_0 \sin(2\pi ft - \phi)$, with S_0 the amplitude and ϕ the phase. Signal analysis is usually performed by a lock-in amplifier, yielding these signal attributes and their possible changes in a time scale longer than the period time. Light modulation is often produced by a chopper,

resulting in a periodic train of square pulses. Still, the above formulae are valid, selecting the first term in a Fourier series decomposition of the signal.^[7,8] This measuremental mode is called frequency-domain measurement (i.e., each single experiment is locked to one frequency and a frequency span is required for complete information). In a time-domain measurement mode, one uses a single (square) light pulse,^[9] or a short flash^[2,5,6,13] as described above. The pressure changes are measured vs. time, from their creation to their complete relaxation. Usually, signal averaging over several experiments is required.

LISTENING TO PHOTOSYNTHESIS

Photothermal Mechanism and Energy Storage

Originally, the idea to use PA measurements in photosynthesis was to estimate how much of the absorbed light energy in photosynthetic pigments is stored as chemical energy and not converted to heat. A comparison between an active sample and a reference, which has the same light absorption and thermal properties and in which light energy is fully converted to heat, shows that the photothermal PA signal from the former is smaller than that from the second. The difference is a measure of energy storage.^[2,5,7,8,10] This concept was initially applied successfully for suspensions of photosynthetic membranes and microorganisms. The reference is routinely obtained by adding temporarily strong nonmodulated light (“background light”). In this case electron transport is oversaturated and most of the absorbed photons do not perform photosynthesis, ending solely in prompt heat production. For an illustration, see Fig. 1 in Ref. [10].

Photobaric Mechanism—PA Signals Due to Photosynthetic Oxygen Evolution

PA measurements in plant leaves and lichens disclosed that photosynthetic oxygen evolution contributes also to PA-signal generation.^[5,7–11] This is because the input of a modulated stream of new gaseous material—the oxygen evolved by photosynthesis—into the restricted volume of a gas phase obviously results in modulated pressure changes. The PA signal from leaves is usually an independent superposition of the photothermal and oxygen evolution mechanisms, each with its own amplitude and phase. This is demonstrated in a frequency-domain PA experiment in a leaf, by alternately exposing the leaf to an additional background light, sufficiently strong to oversaturate

photosynthesis. Under the strong light, oxygen evolution becomes light-intensity independent and is not influenced by the modulated light. The oxygen evolution contribution to the PA signal is therefore eliminated by the background light, resulting in a significant decrease in the amplitude and a considerable phase change of the PA signal. A parallel PTR experiment, which monitors the photothermal effect alone, does not show this effect,^[8] confirming this interpretation. For an illustration, see Fig. 2 in Ref. [10].

A more direct demonstration is provided in a time-domain experiment showing the two PA-signal components separated in time,^[5,8,10] as illustrated in Fig. 26.2 in Ref. [8] and Fig. 3 in Ref. [10]. The photothermal component rises first. The oxygen evolution component lags, still increasing after light termination before its final decrease. The last component is eliminated with strong background light, as above. At the same time the background light causes an increase in the initial slope of the photothermal part. By assuming that the (photothermal) initial slope is proportional to the extent of light energy conversion to heat, energy storage can be estimated. The slowness of the oxygen evolution signal component results from its slow diffusion in the intervening aqueous phase (see below).

The mechanism where gas evolution or uptake forms a PA signal is termed photobaric.^[7] Under special conditions photobaric signals due to gas uptake also occur in leaves (cf. below). Many characteristics of the photobaric component confirm its assignment and locus of generation.^[7,8] At small frequencies (less than ca. 30 Hz), in frequency-domain measurements, it is often much stronger than that of the photothermal one, but it strongly decreases as frequency increases. At sufficiently high frequencies (greater than ca. 300 Hz) it is negligible compared to the photothermal component. Theory predicts indeed a frequency-dependent strong damping of the modulation in the oxygen evolution due to its diffusion in the aqueous phase toward the outer gas phase. From the measured dependence of the photobaric signal vs. frequency, an effective diffusion distance in the order of micrometers was found, consistent with PA-signal generation in the inner air phase. Indeed, the photobaric component is absent when the leaf is water infiltrated, because of the increase in the diffusion distance.

Parallel behavior of the assumed photobaric signal and photosynthetic oxygen evolution further confirms the above assignment.^[7,8] Examples are the brief oxygen evolution gush and the slow development of oxygen evolution (photosynthetic induction) following dark adaptation; the effect of inhibitors and environmental stress conditions; and the pattern of PA signals, in time-domain experiments, obtained with serial flash

excitations, which reflects the S-states advance of oxygen evolution.

Photosynthetic CO₂ uptake is not modulated at the ordinary frequency range and does not contribute to a PA signal. The photobaric signal therefore reflects gross photosynthesis. For good signal-to-noise ratio, PA cells must have small volumes (a fraction of a milliliter) and be tightly closed. The gas composition is therefore not well controlled. Under these conditions photosynthesis is maintained by CO₂ supplied by respiration. Hence steady-state PA measurements are performed at a compensation point. Special PA cells may be constructed for a better control of the gas composition either by adding input and output valves, with short periods of gas streaming, during which PA measurement is stopped, or by using a gas permeable wall.^[10] Another option is the open PA cell, with a leaf forming one of the enclosure walls.^[11]

Photobaric PA Signals Due to Gas Uptake

Under special conditions, photobaric signals due to gas uptake (rather than evolution) were noticed. One example occurs at very high ambient CO₂ concentrations (e.g., up to 5%), using a PA cell equipped with valves and filled with CO₂-enriched air.^[9] A similar situation arises also in a closed PA cell after a long dark adaptation, due to CO₂ enrichment by respiration.^[7-9,12] A similar effect occurs also when only a part of the leaf is enclosed in the PA cell and the expanded parts of the leaf outside the cell are exposed to CO₂-enriched air. In all the above cases, the signal direction becomes opposite (i.e., negative) to the normal photothermal or oxygen evolution signal. (The sense of the signal, positive or negative, is directly seen in time-domain measurement. In frequency-domain measurements, it is defined only at sufficiently low frequency.^[12]) It was shown that this effect requires the presence of carbonic anhydrase.^[9] Consequently, it was concluded that it reflects CO₂ uptake by changes in its solubility, following the light-induced modulated pH changes in the stromal space. For illustrations, see Fig. 5 in Ref. [9] or Fig. 26.18 in Ref. [8].

A different type of gas-uptake photobaric signal occurs after dark adaptation, which does not depend on CO₂.^[12] In this case modulated far-red light (ca. 700–740 nm), absorbed mainly by photosystem I, was used to excite the PA signal. With such light alone there is only a small photobaric signal. However, a large negative signal appears when (low-intensity) background light, absorbed in both photosystems, was added. The negative signal grows gradually to a considerable amplitude but finally dies away. This effect lasts about a minute or two. From various pieces of evidence it was concluded that this

signal is due to a transient oxygen uptake in photosystem I (oxygen photoreduction). For an illustration, see Fig. 2 in Ref. [12].

PA Signals in Algal Thalli

Algal thalli, like leaves, are very suitable for PA measurements in air-coupled microphone cells. Algal thalli do not produce detectable photobaric signals, behaving like water infiltrated leaves, because of the long diffusion distance in the aqueous medium.

PA Signals in Suspensions of Photosynthetic Microorganisms, Organelles, and Membranes: Signals Due to Photochemically Induced Volume Changes

Suspensions are not ideal samples of investigation in air-coupled microphone cells.^[7] The suspension must be impregnated into some flat porous solid support (e.g., filter paper). For a reasonable signal-to-noise ratio, very high concentrations must be used, which are inconvenient for sample manipulation. In most cases such suspensions produce only photothermal signals, with notable exceptions of half-dried cells.^[7] More suitable for suspensions is to use a liquid-filled PA cell with a directly coupled sensor and short flash excitation (PTRPA—cf. above).^[2,5,6,13] Obviously, in such a case no photobaric signal can be detected. The PA signal is then a composite of the photothermal signal with another contribution from a *change of molecular volume* (chroic mechanism), normally reflecting light-induced contraction, which results from the initial steps of electron transport.^[5,7,10,13] For illustrations, see Fig. 6 in Ref. [10] and Fig. 3 in Ref. [13].

Separation of the photothermal and chroic signals is based on the thermal properties of the aqueous medium, which are strongly temperature-dependent.^[5,10,13] The photothermal signal is proportional to the product of the derivative of the specific volume (volume per unit mass) vs. temperature and the reciprocal of the specific heat capacity. Therefore the photothermal effect disappears at the singular temperature of water (ca. 4°C; for buffer solutions the singular temperature may vary around this point), from which the chroic effect is isolated. Both the molecular volume change and energy storage can be deduced from plots of the PA signal vs. the above parameter, for the sample and a proper reference in which there is no molecular volume change and the conversion of light to thermal energy is complete. Such reference may be obtained by using a proper inert dye solution, using the

same buffer and the same light absorbance, or by adding strong background light to the investigated sample.

Applications

Energy storage and molecular volume changes yield important information regarding the thermodynamic, electrostatic interactions and energetic aspects of photosynthesis,^[5,7,8,10,13] in particular the initial electron-transfer steps.^[13] Time-dependent energy transformations are obtainable, in principle, from energy-storage measurements vs. frequency.^[5,7,8] Energy storage and the photobaric signal are markers of activity for monitoring plant productivity and condition in general.^[7,8,10] Light saturation profiles, wavelength dependence, and transient phenomena, signifying regulatory processes, are readily obtainable. The responsiveness of the method to modulated light only allows an interplay of modulated and background light of different wavelengths to measure specific properties as a function of the wavelength, e.g., light distribution between the two photosystems in leaves, cyanobacteria and various marine algae and processes that change this distribution;^[7,8] special wavelength dependence that gives a clue to monitor cyclic electron flow;^[7,8] oxygen photoreduction (cf. “[Photobaric Mechanism—PA Signals Due to Photosynthetic Oxygen Evolution](#)”); and CO₂ solubilization.^[9,12] The feasibility of microscopic scale PA measurements in leaf tissues and depth profile analysis was recently reported.^[10] The list of applications is probably not yet exhausted.

CONCLUSION

The photoacoustic method offers many advantages in analytical plant research and in particular in photosynthesis research. Plant products can be analyzed by the PA method with an unsurpassed detection limit. In photosynthesis, particularly leaf photosynthesis, PA serves as a unique noninvasive method, capable of several measuremental modes. The basic one is that of monitoring the rate of the process as such (following pressure changes due to oxygen evolution). However, in addition it measures in real time various other variables of the photosynthetic apparatus (energetic parameters, relations between the two photosystems, adjustment to the environment, etc.). On the other hand, this rich repertoire is also a drawback, requiring careful examination and separation of the conditions that influence each of the parameters. Another drawback is the present unsatisfactory control of gas composition around the leaf, which calls for serious technical development for its solution. In spite of these

drawbacks, PA may be regarded as an indispensable method, bringing new insights to the research.

Photoperiodism and the Regulation of Flowering

Isabelle A. Carré

University of Warwick, Coventry, U.K.

INTRODUCTION

Responses to day-length, or photoperiod, enable plants and animals to adapt their physiology in anticipation of seasonal changes in climatic conditions. Many aspects of plant development are regulated by photoperiod, including seed germination, bud dormancy, stem and leaf growth, and formation of bulbs and tubers. The appropriate timing of reproductive activity is particularly important in order to maximize survival of the offspring. Flowering and seed production rely on suitable light and temperature conditions, but are also affected by the degree of competition with other species. In order to minimize such competition, different species have evolved a range of day-length responses that enable them to flower at different times of the year and occupy different ecological niches. For example, short-day plants flower in the spring or autumn when the total duration of light within a day is shorter than a critical photoperiod, whereas long-day plants flower in the summer when the photoperiod is longer.

The discovery of photoperiodism in the early 1920s has had a profound impact on agricultural and horticultural practices. Many commercial crops exhibit day-length responsive flowering, and the systematic testing of photoperiodic requirements can prevent failure of new varieties. The manipulation of day-length using black-outs or supplementary lighting allows flowering to be induced at any time of the year and enables breeders to obtain multiple generations per year. Commercial growers can grow potted ornamental plants out of season and precisely schedule their flowering for commercially important dates. Poinsettia, chrysanthemum, Christmas cactus, and begonia are examples of crops managed in this manner.

Recent studies of *Arabidopsis* (a long-day plant) and rice (a short-day plant) have identified genes that mediate floral responses to day-length. Emerging models for the photoperiodic sensing mechanism are described.

THE TIMING MECHANISM

Perception of photoperiod requires a biological timer measuring the duration of light and (or) darkness. This function is mediated by a 24-hour pacemaker known as

the circadian clock. In *Arabidopsis*, the mutation or misexpression of any of the known components of this clock (including LHY, CCA1, TOC1, ELF3, GI, ZTL, LKP2, and FKF1) leads to abnormal floral responses to photoperiod.^[1]

Two different mechanisms have been proposed by which a circadian clock might mediate perception of seasonal changes in day-length.^[2] The effect of changes in photoperiod may be to bring two different rhythms to a more favorable phase-relationship (internal coincidence). Alternatively, responses may be triggered when light coincides with a sensitive phase of a photoperiodic response rhythm (external coincidence). The photoinducible phase may be determined by the temporal pattern of expression of a regulatory molecule, and rhythmic expression of the floral regulator *CONSTANS* (*CO*) has been proposed to play such a role in *Arabidopsis*.^[3] In support of this model, atypical light-dark cycles that altered the

Fig. 1 Rhythmic expression of the *CO* transcript under short and long-day conditions. Similar patterns were observed in *Arabidopsis* and rice.^[3,7] White and black boxes under the graphs represent intervals of light and darkness, respectively. Shaded areas under the curve indicate the levels of *CO* coincidence with light.

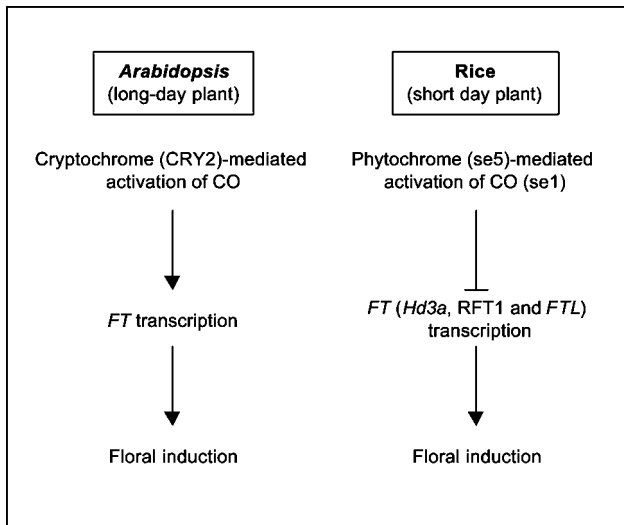

Fig. 2 Comparison of photoperiodic response mechanisms in *Arabidopsis* (a long-day plant) and rice (a short-day plant). Positive interactions are represented by pointed arrows, and negative interactions by blunted arrows. FT functions as a positive regulator of flowering in both species but activation of CO under long-day conditions has opposite effects on FT transcription.

phase-relationship between the *CO* expression rhythm and the photoperiod also altered floral responses.^[4]

DOWNSTREAM OF THE CLOCK: ROLE OF CONSTANS AND OF ITS TARGET GENES

In *Arabidopsis*, expression of the *CO* transcript is rhythmic.^[3] Under 24-hour light-dark cycles, accumula-

tion begins eight hours after dawn, and peak levels are reached after 16 hours. Thus, under noninductive short-day conditions, expression of *CO* is restricted to the dark interval, but the first half of the *CO* mRNA peak coincides with light under inductive long-day conditions (Fig. 1). The CO protein exhibits homology to transcription factors of the zinc finger family.^[5] As it is highly unstable, its expression pattern is predicted to resemble that of the mRNA. Coincidence of CO expression with light may lead to its post-translational modification. The light-activated CO protein may become capable of activating transcription of its immediate target genes, *FT* and *SOC1*^[3,6] and trigger conversion of vegetative meristems into floral meristems (Fig. 2).

Rice *FT*-like genes (*Hd3A*, *RFT1*, *FTL*) also function as positive effectors of flowering,^[7] and the rice counterpart of *CONSTANS* (*SE1*)^[8] is expressed rhythmically with a phase similar to that of *CO* in *Arabidopsis* (Fig. 1). However, *SE1* inhibits expression of *FT*-like genes under long days and promotes it under short-day conditions.^[7] Thus, the basic mechanism of day-length perception is conserved between rice and *Arabidopsis*, and the change of sign of the flowering response between short- and long-day plants may take place downstream of *CO* at the level of the regulation of *FT* transcription (Fig. 2).

PERCEPTION OF LIGHT SIGNALS

In the external coincidence model, light affects photoperiodic responses by two different mechanisms (Fig. 3). One effect of light is to mediate synchronization (entrainment) of the circadian clock to diurnal changes in

Fig. 3 Genetic interactions underlying photoperiodic time perception in *Arabidopsis* (a long-day plant). In *Arabidopsis*, the circadian oscillator constitutes a transcriptional feedback loop and the *LHY*, *CCA1*, and *TOC1* genes encode some of its key components. This oscillatory feedback loop is entrained to daily changes in environmental conditions via light input pathways from phytochromes and cryptochrome photoreceptors. The *GI*, *ELF3*, *ZTL*, *FKF1*, and *LKP2* genes encode downstream components of these input pathways. The central oscillator drives rhythmic expression of *CO*, a positive regulator of flowering under long-day conditions. Coincidence of *CO* expression with light is thought to result in the posttranslational activation of the protein, which becomes capable of promoting expression of floral activators *FT* and *SOC1*. Cryptochrome 2 (*CRY2*) is the main photoreceptor implied in this response (dotted arrows), a function that is distinct from its role in entrainment of the circadian clock (solid arrows). Note that phytochrome (*SE5*) mediates perception of external coincidence in rice.

Table 1 Types of photoperiodic responses in plants

Short-day plants	Flower in response to light periods that are shorter than a critical photoperiod.
Long-day plants	Flower in response to light periods that are longer than a critical photoperiod.
Day-neutral plants	Flower at the same stage of development regardless of day-length.
Intermediate day-length plants	Flowering is inhibited by very long and very short photoperiods.
Ambiphotoperiodic plants	Flowering is delayed by intermediate photoperiods.
Dual day-length plants (long-day short-day and short-day long-day plants)	Require sequential exposure to two different inductive photoperiods.
Dark-dominant plants	Require long exposures to uninterrupted darkness. The inductive effect of long nights is inhibited by short exposures to red light. Broadly corresponds to the short-day plant category.
Light-dominant plants	Require long exposures to light. Flowering is promoted by a mixture of red and far-red light. Broadly corresponds to the long-day plant category.
Obligate responses	Where a particular day-length is required for flowering.
Quantitative responses	Where exposure to a favourable day-length accelerates flowering.

Specific examples for each category may be found in Ref. 12.

environmental conditions (solid arrow). Light-dark transitions set the phase of the clock, and thus determine the time of the day when floral responses can be induced. In *Arabidopsis*, this effect of light on the circadian clock is mediated by a broad range of photoreceptors, including phytochromes A, B, D, E, as well as cryptochromes 1 and 2.^[9] Another effect of light is to trigger the photoperiodic response when its presence coincides with the photo-responsive phase of the photoperiodic response rhythm (dotted arrow). The blue light photoreceptor cryptochrome 2 (CRY2) plays a major role in the perception of photoperiodic signals in *Arabidopsis*, and plants lacking CRY2 function do not exhibit FT induction under long-days.^[6] In contrast, the red/far red photoreceptor phytochrome appears to mediate perception of day-length in rice. As in *cry2* mutants of *Arabidopsis*, loss of phytochrome (SE5) function in rice abolished responses to long days. The *se5* mutant plants flowered as early under inhibitory long-days as wild-type under inductive short-day conditions.^[10]

CONCLUSIONS AND PERSPECTIVES

Many aspects of the day-length response remain to be investigated. The mechanism by which light regulates CO activity is not known. There is evidence that diurnal changes in CRY2 protein levels are required for appropriate perception of day-length in *Arabidopsis*,^[11] but the mechanism of these changes and their contribution to the photoperiodic response are not understood.

Comparison of patterns of *CO* and *FT* expression in a wider variety of plant species will determine whether rhythmic expression of these proteins may explain the range of day-length responses described in Table 1. The elucidation of photoperiodic timing mechanisms will enable the rational breeding and (or) engineering of crop varieties that are day-length insensitive. Alternatively it may be possible to alter the critical photoperiod for floral induction to allow growth of particular crops or ornamentals under latitudes that differ from their country of origin.

Photoreceptors and Associated Signaling I: Phytochromes

Karen J. Halliday

University of Bristol, Bristol, U.K.

INTRODUCTION

Plants rely on information from their surrounding environment to synchronize development to daily and seasonal changes. Many of these adaptive changes are mediated in response to alterations in day length and light quality. In higher plants, the need to sense and interpret these environmental cues in a meaningful way has led to the evolution of highly sophisticated light signaling networks. Controlling these networks are families of photoreceptors whose collective action shapes growth and development via a process that is referred to as photomorphogenesis. The phytochrome family of photoreceptors plays a pivotal role in this photosensory network controlling a diverse range of responses, from seed germination, de-etiolation, to cell elongation and flowering. In the model plant *Arabidopsis thaliana* there are five members of the phytochrome family: phyA, phyB, phyC, phyD, and phyE. These photoreceptors, which absorb mainly in the red (600–700 nm) and far-red (700–800 nm) regions of the electromagnetic spectrum, are able to monitor closely and respond to changes in the light environment. In recent years we have made significant inroads into defining roles for individual phytochromes; we have also begun to understand the nature of the signaling networks that they control.

ISOLATION AND CHARACTERIZATION OF PHYTOCHROME PHOTORECEPTOR MUTANTS

Analysis of mutants lacking one or more phytochromes has provided tremendous insights into the contribution of individual phytochromes and the interplay between phytochromes in the regulation of many developmental events. The phytochromes have an important role in de-etiolation and this was exploited to isolate the first phytochrome mutants. When grown in the dark *Arabidopsis* seedlings have elongated hypocotyls and small, folded, unexpanded, pale cotyledons. Exposure to the red, far-red, and blue components of white light triggers series of developmental changes that lead to de-etiolation: inhibition of hypocotyl elongation and opening, expansion, and greening

of the cotyledons. Genetic screens designed to select for mutants that were deficient in de-etiolation under specific wavelengths of light led to the identification of the *phyA* and *phyB* null mutants. Several *phyA* mutants were isolated in screens for long hypocotyl mutants under far-red light.^[1] Indeed, *phyA* mutants were shown to be completely insensitive to far-red light and they resembled dark-grown seedlings when grown under these conditions. This demonstrated that wild type *phyA* was important for mediating responses to de-etiolation in FR light.

PhyA has different properties from the other phytochromes. It accumulates to high levels in imbibed seeds, and dark-grown seedlings. Upon exposure to light PfrA is rapidly degraded; thus, *phyA* is light labile.^[2] Careful physiological analysis of mutants null for *phyA* demonstrated that this phytochrome operates via two modes of action: the Very Low Fluence Response mode (VLFR) and the High Irradiance Response mode (HIR).^[3] VLFRs are saturated with very low fluences of light, whilst HIRs require longer periods of far-red irradiation at higher fluence rates. Extensive analysis of *phyA* mutants has shown that *phyA* is not just important for de-etiolation, but also has an extensive role in controlling development throughout the plant's life. These roles include control of germination, photoperiod-dependent hypocotyl elongation, and the photoperiodic control of flowering.^[1]

Similar screens, but under white light, identified mutants that were null for *phyB*.^[1] Seedlings lacking *phyB* were shown to have a reduced sensitivity to red light and did not de-etiolate fully under those conditions. This indicated that *phyB* played a major role in controlling seedling de-etiolation under red light. In contrast to *phyA*, *phyB* does not degrade as rapidly when seedlings are exposed to light and so is more light stable. Indeed, *phyB* appears to be the most abundant of the phytochromes in light-grown seedlings.^[2] Responses demonstrated to be reversible by far-red light in the wild type were shown to be impaired in the *phyB* mutant.^[1] These experiments showed that red/far-red reversibility, the hallmark of phytochrome action, is a characteristic of *phyB* and other light stable phytochromes. This type of response is referred to as a Low Fluence Response or LFR. It is this property of phytochrome that enables the plant to monitor the proportion of red:far-red ratio accurately, a means of detecting neighboring plants and potential competition.

Such changes in light quality result from selective absorption by green vegetation, which enhances the proportion of far-red wavelengths in the reflected/scattered light. The consequent alteration in red:far-red ratio triggers a striking series of responses that include increased stem and petiole elongation and the acceleration of the transition to flowering. These responses, collectively known as the Shade Avoidance Response, appear to be an important survival strategy under unfavorable shade conditions.^[1] Mutants deficient in *phyB* strongly resemble wild type plants that have been exposed to low red:far-red ratio light suggesting a major role for *phyB* in this important suite of responses (Fig. 1).

The *phyD* mutation was discovered as a naturally occurring mutation in the *Arabidopsis* Wassilewskija accession.^[1] The *phyE* mutation was isolated in a genetic screen of mutagenised *phyA phyB* mutants that displayed a constitutively early flowering and elongated internode phenotype.^[1] The *phyD* mutant displayed a similar, but less marked seedling phenotype to *phyB* when grown under red light, suggesting a role for *phyD* in the control of de-etiolation. For many responses, when grown under standard laboratory conditions, the *phyD* and *phyE* monogenic mutants were similar to the wild type. However, analysis of mutants lacking *phyD* or *phyE* in addition to *phyB* revealed overlapping roles for these phytochromes with *phyB*. It has been demonstrated that the relative contributions of individual phytochromes varied according to the response.^[1,4,5] Indeed, the hierarchy of photoreceptor action appears to be modified by developmental or environmental changes. For example, under short photoperiods, *phyB* and *phyE* appear to have prominent roles in the inhibition of flowering.^[4] We have

Fig. 1 The *phyB* mutant phenotype: wild type (left) and *phyB* mutant grown under continuous white light (right). (This figure was kindly donated by Garry C. Whitelam, Leicester University, U.K.) (View this art in color at www.dekker.com.)

Fig. 2 The *phyB* mutant flowering phenotype is temperature-sensitive: flowering time, measured as rosette leaf number at bolting, in wild type plants and *phyB* mutants grown in 8 hour photoperiods at 22°C or 16°C. Bars represent the SE.

recently shown that the *phyB* mutant–early flowering phenotype is temperature conditional, and that *phyB* exerts a greater control on flowering at 22°C than at 16°C (Fig. 2). This reduced *phyB* action observed at cooler temperatures is balanced by a rise in activity of other phytochromes.^[4,5] This change in the relative contributions of individual phytochromes appears to be a means via which control of flowering is maintained in the natural environment where temperatures fluctuate. We have yet to determine a role for *phyC*, but, the recent isolation of *phyC* mutant alleles should enable us to do so.

The picture that is emerging from several elegant genetic studies is one where the phytochromes act not in isolation, but as an integrated network. This network extends beyond the phytochrome family to other photoreceptors: the cryptochromes and phototropins. Indeed, cross-talk between these different photoreceptor pathways is well documented.^[6,7] Such an interconnected network has two main functions: It ensures transitional developmental response and it provides a buffer for environmental (e.g., changes in ambient temperature) and genetic variation in the maintenance of the response.^[5,8]

PHYTOCHROMES ARE COMPLEX LIGHT-REGULATED CHROMOPROTEINS

Phytochrome was first purified from etiolated oat seedlings by Butler and coworkers over forty years ago.^[9] In the intervening period we have discovered much about the properties of this molecule. Phytochromes exist as soluble dimers that comprise two polypeptides of approximately 125 kDa. The phytochromes are unique among the

photoreceptors: They are photoreversible switches. Light induces interconversion between a red light-absorbing Pr form and a far-red light-absorbing Pfr form.^[9–11] These distinctive spectral properties are conferred by phytochromobilin, a linear tetrapyrrole chromophore that is covalently attached to the phytochrome apoprotein.^[9–11] Each phytochrome monomer can be subdivided into an amino-terminal sensor and a C-terminal output domain.^[9] It is the sensor domain that houses the chromophore, attached via the bilin lyase domain, also recognized as a GAF domain. Phytochrome GAF domains appear to belong to the bilin-lyase-specific subfamily of these ligand-binding domains. The regulatory or output region comprises two PAS-related domains (PRD) and a histidine-kinase-related domain (HKRD). PAS domains commonly bind small ligands and mediate protein–protein interactions. Similarities in the tertiary structure of PAS and GAF domains suggest there may be an evolutionary link between these two domains.^[7,10] The HKRD, which is similar to histidine kinase regions found in bacterial two-component sensor proteins, together with the PRDs, provide a means via which the phytochrome dimer can transduce its signals. Indeed, work from several laboratories has provided strong evidence that support this notion.^[7,11]

PHYTOCHROME SIGNAL TRANSDUCTION

In *Arabidopsis* seedlings light induces the radical change in gene expression required for the switch to skotomorphogenic to photomorphogenic development.^[1,7] This developmental switch is triggered largely by phytochrome and cryptochrome action. Following photoactivation the phytochromes translocate from the cytoplasm to the nucleus where they cluster in nuclear speckles, the putative site of action.^[3]

Defining the many phytochrome-controlled pathways is no small task. However, genetic screens and molecular techniques that detect protein–protein interactions have significantly enhanced our understanding of phytochrome signal transduction.^[1,7] These studies have identified multiple phytochrome signaling intermediates and revealed that the phytochromes interact directly with several of these components. One such interaction partner is PIF3, a basic helix-loop-helix class of transcription factor, which preferentially binds to phyB in its active form (Pfr).^[7] PIF3 also binds to the G-box DNA sequence motif common in the promoters of light-regulated genes. CCA1 and LHY, G-box containing genes and central components of the *Arabidopsis* circadian clock, were shown to be regulated by PIF3.^[7] The circadian clock regulates many cellular processes and developmental responses;

therefore, PIF3 may represent one mechanism via which light can interact to control these events.

Phytochromes display light-dependent Ser/Thr protein kinase activity.^[11] This provides a possible mechanism via which phytochrome signals can be transduced in response to light signals. NDPK2, cry1, cry2, and PKS1 have been shown to interact with phyA and/or phyB. Furthermore, *in vitro* kinase assays, coupled with red light-mediated *in vivo* phosphorylation assays (for NDPK2, cry1, and PKS1) indicate that these proteins may be targets for phytochrome kinase activity.^[7,11] The precise roles of NDPK2 and PKS1 in phytochrome signaling are not yet known. In contrast, physiological interactions between the cryptochromes and the phytochromes are well documented. It is, therefore, possible that some of these interactions result from modification of cryptochrome action via phytochrome-mediated phosphorylation.

CONCLUSION

Light cues that signal changes in the seasons or the immediate environment strongly influence growth strategy and the timing of development. The phytochromes detect these changes and act as an integrated signaling network to keep development in tune with the environment. Throughout development, it is equally important that responses are maintained under variable conditions. Indeed, the roles for individual photoreceptors and their hierarchy of action vary with developmental stage and environmental conditions.^[4–6] This flexibility in the signaling network means that environmental change can be accommodated. Although great strides have been made in recent years we are still at an early stage in our understanding of phytochrome signaling. A major challenge for the future is to understand how the light signaling network is integrated. A multidisciplinary approach, combining molecular genetics, biochemistry, bioinformatics, and mathematical modeling, is required if we are to achieve this goal.

Photoreceptors and Associated Signaling II: Cryptochromes

Chentao Lin

University of California, Los Angeles, California, U.S.A.

INTRODUCTION

Blue light affects many aspects of plant growth and development. The blue light responses of plants can be roughly divided into two large categories: photomovement responses and photomorphogenetic responses. Photomovement responses, including phototropic curvature, chloroplast relocation, and stomata opening, are mediated by phototropins. Plant photomorphogenetic responses, including inhibition of hypocotyl elongation, stimulation of cotyledon expansion, regulation of flowering time, entrainment of the circadian clock, and regulation of gene expression, are controlled by both phytochromes (in response to red/far-red light) and cryptochromes (in response to blue/UV-A light).

CRYPTOCHROME GENES AND PROTEINS

The term cryptochrome was coined in the late 1970s as a laboratory nickname for blue/UV-A light receptors that mediate plant blue light responses with the specific action spectra of a peak in the UV-A region (approximately 350–400 nm) and a peak with fine structures in the blue region (approximately 400–500 nm). The compound word is composed of -chrome for “pigment” (from the Greek *chroma* meaning color or pigment) and crypto- as in “cryptic” or “cryptogam.” This term was chosen because the molecular nature of blue light receptors remained hidden (cryptic) at the time in spite of extensive researches, and because the blue light responses are prevalent in cryptogams (plants without true flowers and seeds, such as ferns, mosses, algae, and fungi).^[1]

Cryptochrome now refers to proteins that share sequence similarity to DNA photolyase but lack the photolyase activity. The first cryptochrome gene was isolated from *Arabidopsis thaliana*, which is a small weed widely used in laboratories because of its easy handling and small genome. In 1980, a number of *Arabidopsis* photomorphogenesis mutants were reported, one of which, called *hy4*, showed long hypocotyls when grown in blue light.^[2] The gene corresponding to the *hy4*

mutation was isolated about a decade later, and it was found to encode a protein of 681 amino acids, for which the N-terminal sequence of approximately 500 amino acids was 30% identical to that of *E. coli* DNA photolyase.^[3] DNA photolyases catalyze the blue/UV-A light-dependent cleavage of cyclobutane pyrimidine dimers that is a major type of DNA damage caused by short-wavelength (<300 nm) UV light.^[4] To investigate whether the *HY4* gene indeed encoded a blue light receptor, a full-length recombinant *HY4* gene was expressed in insect cells and the recombinant protein purified.^[5] The recombinant *HY4* gene product is a yellow-colored soluble protein that bound noncovalently to flavin adenine dinucleotide (FAD). Cryptochromes may also contain a pterin as the second chromophore.^[4] The facts that the *HY4* gene product mediates a blue light response, shares sequence similarity to a blue light-dependent enzyme, and contains FAD, which absorbs both blue light and UV-A light, as a prosthetic group, indicated that it is a blue light receptor. The *HY4* gene was renamed *CRY1* (for cryptochrome 1) in 1995.^[5]

Cryptochromes have been found throughout the plant kingdom, including among the angiosperms, ferns, mosses, and algae, and in animals including fishes, frogs, flies, mice, and humans.^[1,4,6] Most plant species studied contain multiple members of the photolyase/cryptochrome gene family. For example, *Arabidopsis* has two cryptochrome genes, *CRY1* and *CRY2*, and two photolyase genes; tomato and barley each have at least 3 cryptochrome genes, *CRY1a*, *CRY1b*, and *CRY2*; ferns and mosses have five and at least two cryptochrome genes, respectively.^[1] The amino acid sequences of tomato *CRY1* (*CRY1a* or *CRY1b*) and *CRY2* are more similar to their *Arabidopsis* counterparts than to each other, indicating that the gene duplication event resulting in *CRY1* and *CRY2* occurred more than 100 million years ago at least, before the divergence of Brassicaceae (e.g., *Arabidopsis*) and Solanaceae (e.g., tomato).

Most plant cryptochromes have two domains, an N-terminal domain called PHR (for photolyase-related) that shares sequence homology with DNA photolyase, and a C-terminal domain called CCT (for cryptochrome C-

Fig. 1 Diagram depicting the structure of a plant cryptochrome. PHR: photolyase-related domain. CCT: Cryptochrome C-terminal domain. Motifs of the CCT domain are conserved in some plant cryptochromes, and the amino acids of these motifs are shown (X represents any amino acid). (View this art in color at www.dekker.com.)

terminus) that is unrelated to photolyase or any known proteins, although many plant cryptochromes contain conserved motifs in this domain (Fig. 1).^[1] The PHR domain of cryptochrome is evidently the chromophore-binding domain. The CCT domain is also required for the cryptochrome function. The reaction mechanism and 3-D structure of photolyases are well known,^[4] but neither has been extensively studied for cryptochromes. However, given the sequence similarity between cryptochrome and photolyase, at least some aspects of the cryptochrome structure and reaction mechanism may resemble that of a photolyase.

CRYPTOCHROMES MEDIATE VARIOUS PHOTOMORPHOGENETIC RESPONSES

Photomorphogenetic responses mediated by cryptochromes include blue light inhibition of stem elongation (Fig. 2), stimulation of leaf expansion, control of photoperiodic flowering, entrainment of the circadian clock, and regulation of gene expression.^[1,6] The functions of cryptochromes are conserved in different plants. It has been demonstrated that cryptochromes regulate hypocotyl inhibition in *Arabidopsis* and tomato. Different cryptochromes in the same plant can regulate the same light response. For example, in addition to CRY1, *Arabidopsis* CRY2 also contributes to the blue light inhibition of hypocotyl elongation response; and moss (*Physcomitrella patens*) CRY1a and CRY1b are both required for the blue light induction of side-branching on protonema. Different cryptochromes can also regulate distinct light responses. For instance, *Arabidopsis* CRY1 plays a more important role in hypocotyl inhibition, whereas *Arabidopsis* CRY2 is more involved in flowering-time control.

Although phytochromes are known to regulate photoperiodic flowering, it is now clear that cryptochromes also play significant roles in this response. The *Arabidopsis* laboratory strains Columbia (Col) and Landsberg *erecta* (*Ler*), both collected in the Northern Hemisphere, are nonobligate long-day plants that flower earlier in long days than in short days. The *cry2* mutants isolated from these strains flower later than the wild type in long days but not in short days, so these *cry2* mutants are late-flowering but more or less day-neutral.^[7] Another *Arabidopsis* ecotype, *Cvi*, collected from the tropical Cape Verde Islands, flowers earlier than many other *Arabidopsis* strains, and *Cvi* plants flower at about the same time in long days or in short days. The major QTL (quantitative trait locus) responsible for the day-neutral early flowering of the *Cvi* strain was determined to be the *CRY2* gene.^[8] A valine to methionine substitution (V367M) in the CRY2 protein of the *Cvi* strain was found to be responsible for its day-neutral early-flowering phenotype. A cryptochrome can act as a day-length sensor by changing its relative abundance in response to photoperiods. The abundance of *Arabidopsis cry2* protein shows a day-length-dependent diurnal rhythm. In short-day photoperiods, the level of CRY2 is lower in the day but higher in the night. In long-day photoperiods, such a diurnal rhythm of the CRY2 abundance is significantly diminished.^[1,8]

Fig. 2 *Arabidopsis* cryptochromes mediate blue light inhibition of hypocotyl elongation. *Arabidopsis* wild-type (*col4*) and *cry1cry2* double-mutant seedlings grown in continuous blue light for 5 days are shown. (View this art in color at www.dekker.com.)

Cryptochrome is a major photoreceptor regulating the circadian clock in both plants and animals. In animals, cryptochromes act redundantly with rhodopsins to regulate the circadian clock.^[4] In plants, the entrainment of the circadian clock is controlled by both phytochromes and cryptochromes.^[9] Although it has been shown that cryptochrome is a photoreceptor for the entrainment of the circadian clock in the fruit fly, whether cryptochromes also provide light entrainment to the circadian clock in mammals such as humans or mice is still being debated. Plant cryptochromes act mainly as photoreceptors rather than as critical components of the circadian clock; in contrast,^[9] mammalian cryptochromes are critical components of the central oscillator.^[4]

CRYPTOCHROME SIGNAL TRANSDUCTION

The initial photoreaction of cryptochrome remains unclear. Because electron transport is involved in the photolyase-catalyzed DNA repairing reaction, a redox reaction has been proposed to be likely involved in the cryptochrome photochemistry.^[6] It is also not clear what the signal transduction mechanism is underlying cryptochrome regulation of photomorphogenetic responses. It has been proposed that cryptochromes may act to change ion homeostasis in the cell, or that cryptochromes, which are often found in the nucleus, may regulate gene expression to alter developmental processes.^[11] And at least two types of biochemical reactions have been demonstrated in the cryptochrome function: protein–protein interactions and a blue light-induced cryptochrome phosphorylation.

Arabidopsis cryptochromes can interact with different proteins, including phytochrome B, COP1 (a putative subunit of E3 ubiquitin ligase complex known to be important for light-regulation of gene expression and hypocotyl inhibition), and ZTL (a PAS-domain-containing protein known to be important for the circadian clock and photoperiodic flowering).^[11] The functional significance of cry-COP1 interaction is demonstrated by the constitutive photomorphogenetic phenotype of *Arabidopsis* transgenic plants overexpressing CCT domain fusion proteins.^[10,11] The cry-phyB interaction may provide an explanation of why cry2 function is dependent on phyB.^[7,12] *Arabidopsis* cryptochromes have also been found to undergo a blue light-dependent phosphorylation, and the blue light-induced phosphorylation of *Arabidopsis* cry2 is important for its function and degradation.^[13] It has been proposed that cryptochromes are unphosphorylated and inactive in dark; blue light induces phosphorylation of cryptochromes by an unknown protein kinase; the phosphorylated cryptochrome becomes active in

triggering photomorphogenetic responses; and phosphorylation-induced cryptochrome degradation is a mechanism to desensitize the photoreceptor.^[13]

CONCLUSION

Cryptochromes are blue/UV-A light receptors regulating various photomorphogenetic responses of plants, but the detailed molecular mechanisms of signal transduction of cryptochromes is not clear at present. Investigation of the interaction among signaling processes of cryptochromes, phytochromes, and phytohormones will also be critical to our understanding of how plants regulate their developmental processes in response to light.

ACKNOWLEDGMENTS

Photoreceptors and Associated Signaling III: Phototropins

Bethany B. Stone
Emmanuel Liscum

University of Missouri, Columbia, Missouri, U.S.A.

INTRODUCTION

Plants have evolved a number of photoreceptor systems that mediate responses to a broad range of wavelengths from ultraviolet to near infrared. Several light-induced processes are specific to the blue (390–500 nm) and ultraviolet-A (320–390 nm) regions of the electromagnetic spectrum, including phototropism, regulation of stomatal aperture, and chloroplast position within mesophyll cells. Phototropism is the bending of a plant organ toward or away from a directional light stimulus. The phototropic response results from increased elongation of cells along one portion of the responding organ relative to cells in an opposing position. Stomata—small pores found along the surfaces of leaves and stems—are created between two guard cells fixed in position relative to each other at opposing ends. Because guard cells can swell or shrink in response to a variety of environmental signals (including light), stomatal pore size can change, allowing control of gas exchange and water release in leaves and stems. Mesophyll chloroplasts have the capacity to move within the cell to either maximize or minimize light capture. Although it has been known for some time that each of these responses is controlled by blue light, molecular studies have only recently identified the responsible blue-light photoreceptors, the phototropins.

ISOLATION AND CHARACTERIZATION OF THE PHOTOTROPIN 1 (PHOT1) MUTANTS

Two genes encoding proteins now classified as phototropins are found in the Arabidopsis genome.^[1] The first, *PHOTOTROPIN 1* (*PHOT1*) (formerly called *NPH1*, for *NON-PHOTOTROPIC HYPOCOTYL 1*), was not identified by genome sequencing but by classical genetics in a screen for *Arabidopsis* seedlings that failed to exhibit a hypocotyl phototropic response to low-intensity blue light.^[2] Not only are *phot1* mutants impaired in their positive hypocotyl phototropism (bending toward light), but also in their negative root phototropism (bending away from light) in low-light intensities. In high-intensity light, *phot1* mutants remained nonresponsive in the root, but

recovered phototropism in the hypocotyl, indicating the presence of a second blue-light photoreceptor acting at higher fluence rates.^[3]

ISOLATION AND CHARACTERIZATION OF PHOT2 MUTANTS

A second likely phototropin gene, *PHOT2* (originally designated *NPL1*, for *NPH1-like1*), was identified by genome sequence analysis by virtue of its 58% DNA sequence identity to *PHOT1*.^[4] A T-DNA insertion loss-of-function *phot2* mutant was subsequently shown to have normal phototropic responses under both low- and high-light conditions when a *phot1 phot2* double mutant exhibited essentially no phototropism under either light condition.^[5] Thus it appears that *phot1* is required for phototropism under low light, whereas *phot1* and *phot2* play redundant roles in high-fluence rates (Fig. 1).^[5]

Mutant analyses have also associated phototropins with blue-light-induced chloroplast movements. In low-fluence blue light, mesophyll chloroplasts align along the periclinal walls of cells to maximize light exposure (accumulation response). In contrast, high light causes chloroplasts to relocate to the anticlinal walls in order to minimize light capture and thus avoid photodamage (avoidance response).^[6] Kagawa and colleagues^[7] identified *phot2* mutants (initially designated as *cav1*, for *chloroplast avoidance 1*) in a screen for plants that failed to exhibit the chloroplast avoidance response. A similar lack of chloroplast avoidance response was found in reverse genetic analyses of *phot2* T-DNA mutants.^[5,8] The singular role of *phot2* in this high-light response differs from that observed with phototropism, where both *phot1* and *phot2* are responsible for photoperception in high light (Fig. 1). However, it appears that both *phot1* and *phot2* can signal the chloroplast accumulation response.^[5,7,8] Interestingly, the control of stomatal aperture also requires the activities of *phot1* and *phot2*, but in yet another way. Unlike phototropism (in which the two photoreceptors signal the same response but at two different fluence rates) and unlike chloroplast movement (in which the two photoreceptors trigger two different responses), stomatal opening requires both *phot1* and *phot2* at all light intensities (Fig. 1).^[9]

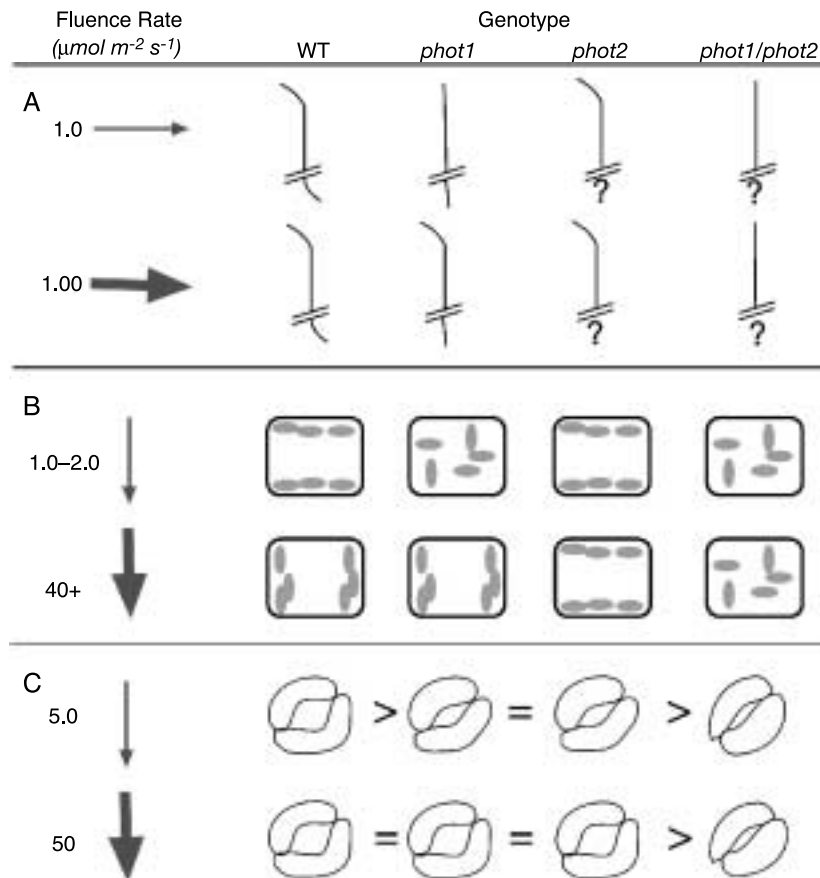

Fig. 1 The effect of fluence rate on wild type, *phot1* mutants, *phot2* mutants, and *phot1/phot2* double mutants with respect to (A) phototropism in the hypocotyl^[5] and root;^[4] (B) chloroplast movement;^[5] and (C) stomatal opening. (View this art in color at www.dekker.com.)

PHOTOTROPIN PROTEINS ARE FLAVIN-BINDING LIGHT-ACTIVATED SERINE/THREONINE PROTEIN KINASES

A decade ago, Reymond and associates reported light-induced phosphorylation of a approximately 120-kilo-delta(kDa) membrane-associated protein with the phototropic response,^[10] and early work with the *phot1* mutants demonstrated that they lacked this light-induced phosphorylation response.^[2] When *PHOT1* was cloned by positional cloning it was found to encode a 120 kDa protein with a carboxyl-terminal serine/threonine kinase domain, making it likely that the phosphorylation response was in fact an autophosphorylation response.^[11] Christie and colleagues found that *phot1* expressed heterologously in insect cells was autophosphorylated in response to blue light, indicating that all components necessary for the light-induced autophosphorylation—photoreceptor, kinase, and substrate—are present in *phot1* itself.^[12]

The *PHOT1* gene also includes two similar amino-terminal domains with 43% sequence identity to each other and similarity to a class of domains found in

signaling proteins of various species.^[11] These domains are a subset of the PER-ARNT-SIM (PAS) domain superfamily, known to mediate protein-protein interactions and cofactor binding. Because proteins containing this subclass of PAS domains are responsive to light, oxygen, or voltage, these domains have been designated LOV1 and LOV2.^[11] In work by Christie and colleagues it has been found that the blue-light sensitivity described above is dependent upon binding of one flavin mononucleotide (FMN) molecule to each LOV domain, providing support for the hypothesis that a dual-chromophoric flavoprotein photoreceptor regulates phototropism in low-fluence blue light.^[2,12] *Phot2*, like *phot1*, is autophosphorylated in response to blue light and each of its LOV domains binds one FMN molecule.^[5]

A number of studies have examined the photochemical and photophysical properties of the LOV domains for phototropin proteins. Both optical and NMR spectroscopy have been used to demonstrate that *phot1* LOV domains in solution undergo a dark-reversible photocycle that involves the formation of a C(4a) cysteinyl adduct between the FMN and the *phot1* polypeptide.^[13,14] The formation

of the reversible covalent linkage between phot1 LOV domains and the FMN chromophore has been confirmed by X-ray crystallography at a 2.6Å resolution.^[15] The structural changes associated with this light-driven molecular switch presumably lead to activation of the carboxyl-terminal protein kinase domain.^[14,15]

PHOTOTROPINS FROM SPECIES OTHER THAN *ARABIDOPSIS*

Phototropins have been identified in several plant species besides *Arabidopsis*, including oat (*Avena sativa*),^[16] pea (*Pisum sativum*; accession number U83281), rice (*Oryza sativa*),^[16] and maize (*Zea mays*; accession number AF033263). Phototropins are not limited to higher plants, as a phototropin has also been found in the unicellular alga *Chlamydomonas reinhardtii*^[13] as well as the nonphotosynthetic bacterium *Bacillus subtilis*.^[17] The finding that apparent phototropins (based on similar sequence and predicted structure) exist in diverse taxa from prokaryotes to photosynthetic eukaryotes begs the question: Can we classify these proteins as either phot1 or phot2 and thus predict functions? The simple answer at present is maybe.

The *PHOT* genes in the various taxa can be classified as either *PHOT1* or *PHOT2* based on their sequence similarities to the *Arabidopsis* sequences.^[16] Moreover, in higher plants the phototropins can be classed as phot1 or phot2 based on mRNA expression patterns. For example, *PHOT1* and *PHOT2* also have very different gene expression patterns, with *PHOT2* induced by blue light^[7,8,18] and *PHOT1* gene expression reduced by blue light. These expression pattern differences fit nicely with the observed differences in physiological functions of *phot1* and *phot2* mutants in *Arabidopsis* under different light conditions. Kasahara and colleagues have recently suggested that phototropins can also be classified as either phot1 or phot2 based on discrete photochemical properties of the LOV domains in each, such as differences between LOV photoproduct formation and dark recovery. How the biochemical differences between the phototropin proteins relate back to differences in gene sequence has not yet been determined. Time will tell whether these generalizations hold true as more functional studies are done.

SIGNALING DOWNSTREAM OF PHOTOTROPINS

Other nonphototropic hypocotyl (*nph*) mutants were isolated in the same screen that identified *phot1*. One of these, *nph3*, was phenotypically similar to *phot1*, suggesting that NPH3 function occurs early in the phototropism

signaling pathway, possibly close to photoperception.^[19] Whereas there are no transmembrane domains in the NPH3 protein, it localizes to the plasma membrane,^[20] like *phot1*.^[2,21] Motchoulski and Liscum reported a physical interaction between *phot1* and NPH3 by both a yeast two-hybrid and in vitro pull-down assays. NPH3 may function as a scaffolding protein to bring the photoreceptor, *phot1*, in contact with other downstream phototropism signaling components.^[20] The *NPH3* homologue, *RPT2* (for ROOT PHOTOTROPISM 2),^[3] may perform a similar function with *phot2* under high light conditions.^[22] It is tempting to speculate that other members of the NPH3/RPT2 family may scaffold early signaling components for other physiological response that the phototropins regulate, such as chloroplast relocation and stomatal control.

Electrophysiological studies are also providing additional insight for signaling events that occur downstream of phototropin activation. First, Baum and associates reported that high-intensity blue light causes transient increase in cytoplasmic Ca^{2+} within 20 seconds of the “lights on” signal.^[23] When *phot1* mutants were exposed to blue light, the Ca^{2+} increase did not occur, suggesting that *phot1* is the photoreceptor responsible for the increase in cytosolic (Ca^{2+}), and that this transient increase in (Ca^{2+}) may be part of some signaling pathway regulated by *phot1*. Calcium transients are coincident with increased proton pump activity in guard cells that leads to blue-light-induced stomatal opening.^[24] Kinoshita and colleagues have demonstrated that blue-light activation of the plasma membrane H^+ -ATPase does not occur in *phot1 phot2* double mutants,^[9] providing a potential connection between the observed Ca^{2+} transients and responses controlled by phototropins.

CONCLUSION

Therefore, phototropins are involved in the regulation of multicellular (phototropism), cellular (stomatal opening), and even subcellular (chloroplast movement) responses in a semiredundant fashion. Each of these responses uses a unique combination of the two phototropins to respond to low- and high-intensity light. Clearly one of the challenges for the next decade is to identify downstream elements of phototropin-signaling pathways in both plant and non-plant species.

Photoreceptors and Associated Signaling IV: UV Receptors

T. H. Attridge

University of East London, Stratford, U.K.

N. M. Cooley

CSIRO (Plant Industry), Victoria, Australia

INTRODUCTION

Interest in the perception of ultraviolet began many years ago with physiological evidence for a putative UV-A/blue photoreceptor. As techniques have improved various receptors can be demonstrated to be operating in this region of the electromagnetic spectrum. In this article we examine what is known of these receptors, their response pathways and the interaction of these pathways.

THE RECEPTORS

It is now known that plants contain at least ten photoreceptors. These are five phytochromes (phy A–E), two cryptochromes, two phototropins, and a photoreceptor with properties akin to both phytochrome and phototropin and dubbed superchrome.

The major developmental photoreceptors, cryptochrome and phytochrome are capable of absorbing radiation in the UV part of the spectrum. The UV absorption spectra of Pfr and Pr are very similar and only small changes in Pfr/Ptot can be achieved. No ecological or physiological function has been ascribed to these changes. There is no evidence to date to indicate that the five species of phytochrome differ in their UV absorption although differences have been demonstrated in the visible part of the spectrum.

In recent years it has been revealed that there are two types of cryptochrome, CRY1, which can be stimulated by blue and UV-A radiation, and CRY2, which is stimulated by blue. The presence of this UV-A/blue receptor does not preclude the existence of other specific UV-A receptors that act independently, in association with each other, or in association with known photoreceptors.

Phototropins mediate phototropic responses with blue light, green light, and UV-A radiation. Identification has occurred in a number of species and is reviewed by Briggs et al.^[1] Phototropins are proteins that have two LOV domains in the N-terminal region, which binds FNM as a chromophore.

UV-B radiation causes damage to DNA but there is also a good deal of evidence that indicates plants possess receptors to UV-B that cause developmental changes. The UV-B receptor has not yet been isolated and little is known of its signaling pathway. Evidence from current research could be assembled to suggest that a major function of UV receptors is to damp down the perception of the signal by the production of UV-absorbing metabolites. This could be of particular importance in reducing UV-B induced DNA damage. Much of what we know about UV-A and UV-B signaling has come from recent studies of UV-regulated gene expression in *Arabidopsis*. What is known^[2–4] of the UV induction of chalcone synthase (CHS) in *Arabidopsis* is shown in Fig. 1. CHS appears to be controlled by a number of different photoreceptors and radiation conditions. Experimental evidence has suggested that CRY2 is regulated in the blue while CRY1 is regulated in the UV-A/blue. Using single and double *phyA* and *phyB* mutants, this group^[4] is able to show that phytochrome is a positive regulator of the CRY1 inductive pathway with no preference for phyA or phyB and that there is interaction between CRY1 and phyB. UV-B can also control CHS. When this is so, neither CRY1 or CRY2 appear to be involved, nor is the synergy between blue and UV-A pathways involved with the UV-B response. PhyB is a negative regulator of the UV-B inductive pathway and since phyB acts upstream on the UV-B pathway from the points of synergism with blue and UV-A, it has been proposed that the flux through the UV-B and CRY1 pathways might be controlled by phyB.

UV-A RECEPTION

The study of the putative blue/UV-A has led to our present understanding of the cryptochrome and these photoreceptors are dealt with elsewhere in this volume. However, any understanding of the integration of the signals received by the plant from the electromagnetic spectrum must take into account that in the presence of UV-A, CRY1 can be stimulated and cause developmental

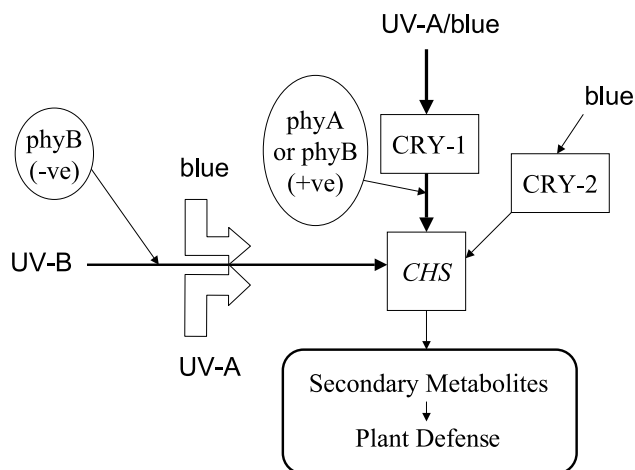

Fig. 1 Summary of the control of CHS gene expression in *Arabidopsis thaliana* showing the interactions of the various pathways and pigments. Nothing is known of the exact points of interaction. (Adapted from Ref. 2 with information from Ref. 4.)

responses. The dual action maxima of CRY1 invites the question “Do plants have specific UV-A receptors?” A certain amount of evidence suggests that this may be so.

In an ecological study of a number of meadow species,^[5] various growth parameters responded to elevated UV-A under outdoor conditions. These responses were further investigated with action spectra that were produced by growing *Cynosurus cristatus*, a common meadow grass, under polychromatic sources of UV, each with a different λ_{central} . In the action spectrum shown

(Fig. 2), there is a sharp peak on the UV-B/UV-A border and a broad maximum throughout the UV-A. Under outdoor conditions, absorption of blue radiation by cryptochrome would be close to saturation and it is difficult to see, in terms of reciprocity, how the addition of so little energy could cause such significant responses unless UV-A was being received by a specific receptor with its own transduction pathway. Further, in a review of the growth responses of various *Arabidopsis* ecotypes to UV-A and UV-B+A, numerous responses were found to UV-A.^[6] One ecotype in particular, Aa-0, was more sensitive to UV-A than UV-B.

UV-B RECEPTORS

UV-B radiation beyond the tolerance of a species will result in damage primarily due to the absorption of UV-B quanta by DNA resulting in dimerization. A secondary cause is the production of reactive oxygen species (ROS), which subsequently cause damage to DNA. However, besides damage, a pivotal role has been suggested for ROS (see below).

Responses to UV-B that are nondamaging or beneficial to the plant may include de-etiolation, flavonoid biosynthesis, leaf and hypocotyl development, regulation of leaf number, and branching frequency.^[7] Evidence that these and other plant responses are under the control of a specific UV-B receptor come from a number of action spectra that have an action maximum between 290 and 300 nm.

Fine profile definition of the receptor cannot be expected at these wavelengths since a large number of

Fig. 2 Polychromatic action spectra for inhibition of leaf area of *Cynosurus cristatus* action spectra showing action maxima in both UV-B and UV-A where * $P < 0.05$. (Adapted from Ref. 5.)

Fig. 3 The % inhibition of dry weight accumulation by supplementary UV-B+A expressed in terms of the accumulation of dry weight by the same ecotypes of *Arabidopsis thaliana* under ambient conditions. (From Ref. 5.)

molecules present in the plant tissues exhibit large changes in absorption and scattering in the UV region and can distort the shape of the action spectra. However, the unassailable argument is that if any of these responses were directly or indirectly linked to DNA damage, then wavelength efficiency would continue to rise with decreasing wavelength rather than form a maximum. Although phytochrome and flavins absorb in the UV there is no coincidence with the 290–300 nm maxima of the action spectra. The absorption of known photoreceptors is poor in the UV spectrum compared to the visible and it is difficult to see how the lesser absorption of these receptors in the UV at lower natural energies could influence their activity via the same induction pathway(s).

A study of responses of various ecotypes of *Arabidopsis* to UV-B^[6] demonstrated a straight-line relationship between the growth rate of the control cohort and the level of inhibition induced in the UV-B treatment (see Fig. 3). This relationship indicates that the faster a plant grows the more susceptible it is to UV-B. Higher growth rates infer higher rates of cell division and it has been suggested that there might be a link between UV-B and inhibition of cell division.

Work with the *Arabidopsis* mutants *hy 42.23N*^[3] also supports the concept of a specific UV-B receptor in that normal levels of CHS can be generated under UV-B for which there is no other explanation.

TRANSDUCTION

Pharmacological experiments designed to investigate the involvement of calcium in the signal transduction from

UV receptors used cell suspensions of *Arabidopsis*, in which CHS was controlled in the same manner as in mature leaves.^[3] Using nifedipine, ruthenium red, lanthanum, an ionophore, and the calmodulin antagonist W7 with UV-B and UV-A/blue irradiation, it is argued that calcium at a specific cellular location passes through calcium channels and causes a localised increase in calcium concentration. The calmodulin antagonist W7 strongly inhibits the UV-B induction but not the UV-A/blue induction of CHS transcript. This is in agreement with the genetic evidence that these signals are perceived by separate systems.

As mentioned above, irradiation of plants with UV-B can result in the generation of intracellular ROS (see Ref. 8), which can cause serious damage to membranes. However it has also been suggested that ROS can act as signaling intermediates and are involved in UV-B induced transcript increases in a number of photosynthetic proteins in various plants.^[8] ROS may also function as secondary messengers acting up stream in a number of pathways including the synthesis of salicylic acid, jasmonic acid, and ethylene.^[8]

SIGNAL DAMPING

CHS is a controlling enzyme in the production of flavonoids and phenylpropanoids. If these compounds are produced in the epidermal layers of the plant, they can efficiently absorb UV radiation while also allowing transmission of PAR. The study of *Arabidopsis* mutants deficient in various aspects of flavonoid and lignin synthesis has led to detailed knowledge of the regulation of the phenylpropanoid pathway and its role in plant defense against UV-B.^[9] Mutants capable of tolerating high fluences of UV-B have been shown to be able to accumulate high levels of sinapate and flavonoids.^[10]

Many of the nondamage plant strategies turned on by UV radiation would include reduction of leaf area, reduction in plant height, branching, and leaf number. These may all be interpreted as strategies that would reduce interception of radiation. Thus stimulation of receptors of UV may well function to produce screens and other developmental changes that would lead to reduced reception of harmful radiation.

Photosynthate Partitioning and Transport

María Fabiana Drincovich

Rosario National University, Rosario, Argentina

INTRODUCTION

Triose phosphates produced by the Calvin cycle in the chloroplasts may be converted to starch or exported to the cytosol, where they synthesize sucrose to be transported to other parts of the plant. In this way, the pathways for sucrose and starch synthesis are separated in the cytosol and plastids and are fed by different hexose phosphate pools. The activity of the triose phosphate translocator (TPT)—located in the chloroplast inner membrane—is central in communicating the hexose phosphate pools of both compartments by exchanging the three carbon intermediates dihydroxyacetone phosphate (DHAP) and 3-phospho glycerate (3PGA) for inorganic phosphate (Pi).

SUCROSE SYNTHESIS OCCURS IN THE CYTOSOL

Sucrose is a major product of photosynthesis and serves as the long-distance transport compound in most plants. Triose phosphates synthesized in the chloroplasts by the Calvin cycle are transported to the cytosol by the TPT where they produce hexoses and subsequent synthesis of sucrose.

Once in the cytosol, the combined action of triose-phosphate isomerase and fructose 1,6-aldolase converts triose phosphates to fructose 1,6-bisphosphate (F1,6BP). The interconversion of F1,6-BP and fructose 6-phosphate (F6P) involves the regulatory metabolite fructose 2,6-bisphosphate (F2,6BP) and three enzymes: ATP-dependent phosphofruktokinase (PFK; $F6P + ATP \rightarrow F1,6BP + ADP$), pyrophosphate-dependent phosphofruktokinase (PFP; $F6P + PPi \leftrightarrow F1,6BP + Pi$), and fructose 1,6-bisphosphatase (F1,6BPase; $F1,6BP + H_2O \rightarrow F6P + Pi$).^[1] PFK and F1,6Base are found in both the cytosolic and plastidic compartments in leaves but PFP occurs exclusively in the cytosol. PFP catalyses a reversible reaction and is activated by F2,6BP in the direction of F1,6BP formation, although its direct role in controlling F1,6BP synthesis and degradation *in vivo* in leaves is still under discussion. PFK is inhibited by PEP and by other metabolites of the last part of the glycolytic pathway. In this way, this pathway is negative-feedback regulated, involving the function of the TPT, which means that if DHAP is supplied by the

chloroplast, there is no need to generate F1,6BP through glycolysis (Fig. 1). Cytosolic F1,6BPase regulates the flow of carbon from the triose phosphate to the hexose phosphate pool. This enzyme is strongly inhibited by the metabolite F2,6BP, which is synthesized from F6P by fructose 6-phosphate 2-kinase and converted back to F6P by fructose 2,6-bisphosphatase (Fig. 1). Fructose 6-phosphate 2-kinase is activated by Pi and F6P and inhibited by triose phosphates, in contrast to fructose 2,6-bisphosphatase, which is inhibited by Pi and F6P. Hence, the concentration of F2,6BP is related to the activity of the TPT, which determines the concentration of triose phosphates and Pi in the cytosol. As the concentration of F2,6BP is controlled by the status of the triose phosphate pool, F1,6BPase is active only when carbon is supplied by the chloroplast (Fig. 1).

After converting triose phosphates to hexose phosphates, the principal route of sucrose synthesis combines the reactions of sucrose-phosphate synthase (SPS, $UDP\text{-glucose} + \text{fructose } 6\text{-P} \leftrightarrow \text{sucrose } 6\text{-P} + UDP$) and sucrose-phosphate phosphatase, which has a large negative free energy change ($\text{sucrose } 6\text{-P} \rightarrow \text{sucrose} + Pi$).^[2] The synthesis of UDP-glucose involves the action of the enzyme UDP-glucose pyrophosphorylase ($G1P + UTP \leftrightarrow UDP\text{-glucose} + PPi$). In the absence of a cytosolic pyrophosphatase, the reaction is readily reversible. A second enzyme—sucrose synthase ($UDP\text{-glucose} + \text{Fructose} \leftrightarrow \text{sucrose} + UDP$)—is capable of catalyzing both sucrose synthesis and degradation. Nevertheless, this enzyme predominates in sucrose-utilizing tissues and is more involved in sucrose degradation. SPS is regulated by both covalent modification and allosteric modulation. Glucose 6-phosphate (G6P) directly activates the enzyme and also inhibits a kinase that phosphorylates and down-regulates the activity of SPS, while Pi inhibits SPS and a phosphatase that up-regulates the activity of SPS (Fig. 1).

STARCH SYNTHESIS OCCURS IN PLASTIDS

When the synthesis of sucrose exceeds the capacity of the leaf to export it, synthesis of starch is used as an overflow mechanism to store carbohydrate. Triose phosphates in the chloroplast are converted to hexose phosphates, which form ADP-glucose to incorporate glucose to starch. The

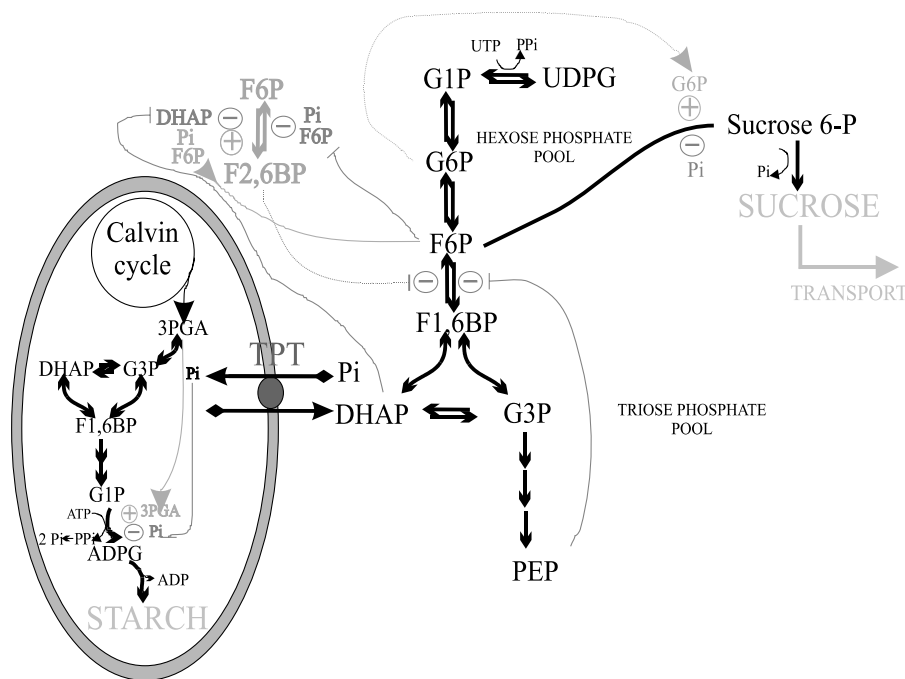

Fig. 1 Regulation of starch and sucrose synthesis. (View this art in color at www.dekker.com.)

enzyme that synthesizes ADP-glucose—ADP glucose pyrophosphorylase (Glucose 1-P+ATP \leftrightarrow ADP-glucose+PPi)—is the regulatory enzyme in starch biosynthesis.^[3] A plastid-specific pyrophosphatase cleaves pyrophosphate (PPi) driving ADP-glucose synthesis. In turn, starch synthase incorporates glucose from ADP-glucose to the nonreducing end of amylose or amylopectin chain, while a starch-branching enzyme produces 1 \rightarrow 6 α linkages. When chloroplastic 3PGA is abundant, ADP glucose pyrophosphorylase is activated. In contrast, when Pi concentration increases, the enzyme is inhibited (Fig. 1). Pi concentration can rise not only when photosynthesis slows, but also when the TPT is active in exchanging triose phosphate from the Calvin cycle by cytosolic Pi.

INTEGRATED CONTROL OF SUCROSE AND STARCH SYNTHESIS INVOLVES TWO CELL COMPARTMENTS

Different processes tightly regulate the balance between sucrose and starch synthesis, which are both related with a constant sensing of metabolite levels in both the chloroplast and the cytosol. The balance between sucrose and starch synthesis varies during the day in re-

sponse to different environmental conditions that regulate the rate of carbon assimilation and photosynthesis and sucrose transport.

At the beginning of the light period, the Calvin cycle becomes operational and triose phosphates accumulate in the chloroplast. This accumulation triggers the TPT to exchange triose phosphates by Pi, increasing cytosolic concentration of triose phosphates with a consequent decrease in Pi concentration. In turn, F2,6BP concentration decreases, relieving the inhibition of F1,6BPase. This allows the flow of carbon into the hexose phosphate pool (Fig. 1). The increase in G6P and decrease in Pi concentrations activate SPS, allowing the synthesis of sucrose to proceed. Meanwhile, starch synthesis is inhibited by high Pi and low PGA concentration in the chloroplast. Sucrose export is active in this condition (Fig. 2A).

When the increase in photosynthate exceeds the ability of the cell to export sucrose—which may occur at midday at high light conditions—starch begins to be synthesized from excess carbon. Concurrently, sucrose accumulation inhibits its own synthesis, hexose phosphates accumulate, and F6P induces F2,6BP synthesis (Fig. 1). The increase in this metabolite inhibits F1,6BPase, producing an accumulation of triose phosphates in the cytosol that slows the export from the chloroplast. 3PGA accumulates in the chloroplasts, activating ADP-glucose

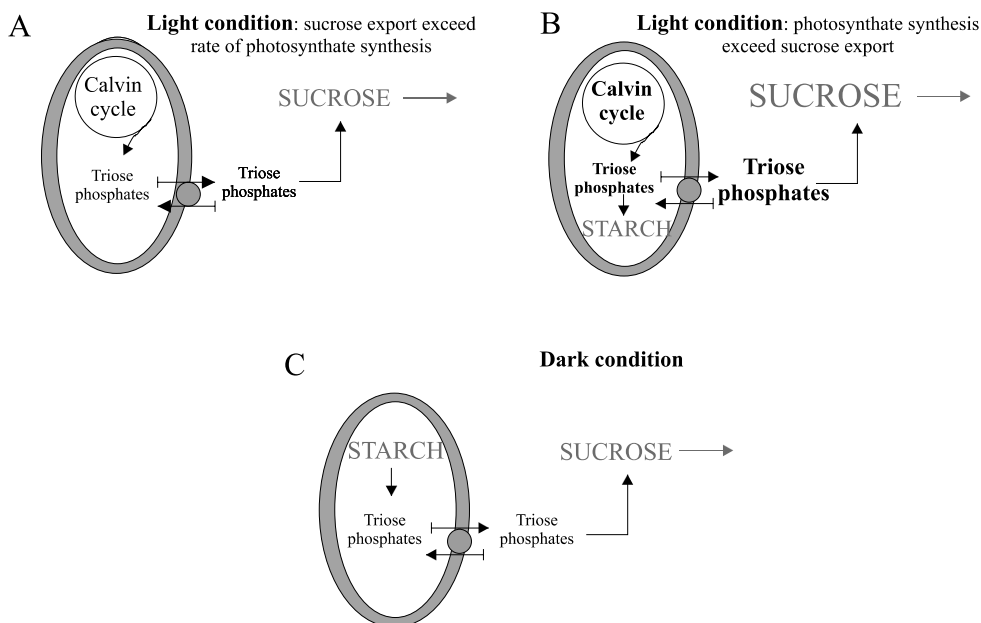

Fig. 2 Three conditions with different balance between starch and sucrose synthesis are shown. A and B: Light condition with different rates of photosynthate synthesis; C: Dark condition in which starch degradation provides triose phosphates for sucrose synthesis. TPT: triose phosphate translocator. (View this art in color at www.dekker.com.)

pyrophosphorylase and promoting starch synthesis (Fig. 1). Pi concentration in the cytosol increases as a result of decreased import into the chloroplast, which contributes to the inhibition of SPS and the increase in F2,6BP concentration. Hence, carbon flow is derived from sucrose to starch (Fig. 2B).

When light declines, the rate of photosynthesis slows, and with it the rate of sucrose synthesis. The decrease in 3PGA concentration in the chloroplasts no longer activates ADP-glucose pyrophosphorylase, which, in combination with Pi accumulation, induces the stop of starch biosynthesis. At this time, amylolytic and/or phosphorolytic starch breakdown is triggered. Triose phosphates are transported to the cytosol and F2,6BP decreases the amount of carbon (and hence, sucrose) allowed to flow into the hexose phosphate pool. Sucrose is then transported to other parts of the plant. In this condition, sucrose export exceeds the rate of synthesis (Fig. 2C).

TRANSGENIC PLANTS WITH ALTERED SUCROSE OR STARCH LEVELS

Transgenic plants with altered expression of the TPT have been developed. Potato plants with lower TPT activity presented increased starch levels, indicating a central role of the TPT in the flux of carbon into sucrose and starch.^[4] Later, antisense TPT tobacco lines showed that the decrease in TPT levels could be compensated by high

turnover of starch and subsequent glucose export from the chloroplast to the cytosol.^[5] Recently, transgenic tobacco plants with antisense repression or overexpression of the TPT^[6] were used to calculate control coefficients of the TPT on carbon partitioning and photosynthesis.^[7] Under high CO₂, tobacco plants with decreased or increased TPT activity presented, respectively, higher or lower carbon incorporation into starch.^[6,7] Transgenic plants with altered amounts of F2,6BP have also been developed.^[8,9] These plants have directly demonstrated the importance of this regulatory compound in the integration of cytosolic and chloroplastic metabolism during photosynthesis. Elevated F2,6BP levels reduced the rate of sucrose synthesis at the start of the light period, whereas a decreased content of F2,6BP promoted the partitioning of photosynthates into sucrose relative to starch, with a decline in the rate of carbon assimilation. In this way, decisive evidence was provided of the crucial role of F2,6BP in coordinating sucrose synthesis with the rate of carbon fixation and in regulating photosynthate partitioning between sucrose and starch.

APOPLASTIC OR SYMPLASTIC PHLOEM LOADING IN LEAVES DEPENDS ON THE SPECIES

Sucrose synthesized in leaves is transported to the site of consumption and storage via the phloem. Phloem loading

in leaves may occur apoplastically or symplastically depending on the species.^[10] Anatomical features have been used to categorize plant species based on their mechanism of phloem loading. The symplastic path occurs via the plasmodesmata, which connects mesophyll cells and the conducting elements of the phloem. In the apoplastic route, sucrose is first exported into the apoplast and then is taken up by the phloem by an energy-dependent transport system.^[10]

Photosynthesis and Stress

Barbara Demmig-Adams

Volker Ebbert

William W. Adams III

University of Colorado, Boulder, Colorado, U.S.A.

INTRODUCTION

The impact of stress on photosynthesis can be viewed as the response of photosynthesis to environmental conditions outside the favorable range. For example, although differing greatly in their origin, the stresses of freezing temperatures, low water availability, and high salinity have a common impact in that they all result in low water availability to the plant. In response to this, stomates close to varying degrees and net carbon uptake declines. But what happens behind closed stomates? In some species, the decline of carbon uptake is due merely to a transient closure of stomates—with a full maintenance of internal maximal photosynthetic capacity. In other species, stomatal closure is accompanied by a downregulation of the internal maximal capacity of photosynthesis, including, e.g., the capacity of photosynthetic electron transport. In evergreens, this downregulation of electron transport capacity is typically accompanied by a phenomenon referred to as photoinhibition of photosynthesis.

PHOTOSYNTHESIS BEHIND CLOSED STOMATES

Whereas some species maintain their intrinsic photosynthetic capacity when stomates close under unfavorable environmental conditions, others downregulate it. Those species that maintain electron transport capacity use electrons in processes other than carbon fixation (such as photorespiration or oxygen reduction in the Mehler-peroxidase pathway).^[1] This offers the advantage that solar energy can still be used to provide some adenosine triphosphate (ATP) and reducing equivalents—even when there is little or no net carbon gain.

Other species suspend all photosynthetic activity when net carbon uptake ceases and strongly downregulate photosynthetic electron transport capacity. This strategy precludes any utilization of solar energy, but offers the advantage of effectively suppressing the transfer of electrons to potentially toxic superoxide (Fig. 1). This latter strategy necessitates an efficient dissipation of excess absorbed solar energy no longer used in photochemistry as harmless thermal energy (Fig. 2). In many

evergreens, the utilization of solar energy in photosynthesis is strongly downregulated under environmental stress, yet the light-harvesting chlorophyll is preserved.^[2] This poses a potentially lethal danger in the form of energy transfer from chlorophyll to toxic singlet excited oxygen (Fig. 2).^[1,3] Such a transfer of energy from chlorophyll to singlet oxygen can be suppressed effectively by the harmless dissipation of this energy as thermal energy. The syndrome of persistently low utilization of absorbed solar energy in photosynthesis and highly efficient thermal dissipation is a key feature of the photoinhibition of photosynthesis under stress (Fig. 2).^[4]

PHOTOINHIBITION OF PHOTOSYNTHESIS

Photoinhibition of photosynthesis can occur in response to exposure to a wide variety of environmental stresses or to sudden increases in growth light intensity. The hallmark of photoinhibition is a combination of two features. First, a decrease in maximal electron transport capacity, resulting from inactivation and subsequent degradation of photosystem II centers. This is accompanied by a second feature—a switch to continuously high levels of harmless dissipation of a potentially lethal excess of light absorbed in the largely preserved light-harvesting antennae of photosystem II (Fig. 2). Whereas these features are generally accepted, current interpretations vary and range from viewing photoinhibition as reflecting damage to photosystem II centers on one hand^[5] versus downregulation of photochemistry in response to a low demand for photosynthate on the other.^[2,6] Some consequently predict an increase in photosynthetic productivity under stress if photoinhibition could be eliminated. It must be noted that those species exhibiting the strongest photoinhibition in the field are those that possess the highest levels of stress tolerance.^[2,4]

PERSISTENT AND FLEXIBLE FORMS OF PHOTOPROTECTION

In evergreens, the switch from utilizing solar energy in photosynthesis to dissipating it as heat can persist for an

Fig. 1 Schematic depiction of photosynthetic reactions in leaves, including the absorption of solar energy and photosynthetic electron transport, formation of NADPH and ATP, and uptake of carbon dioxide and its conversion to sugars. O_2^- is superoxide, formed by transfer of an electron (e^-) to oxygen. (View this art in color at www.dekker.com.)

entire unfavorable season. All species, however, utilize a flexible version of this process. All sun-exposed leaves reroute excess absorbed solar energy to thermal dissipation during peak exposure to direct sunlight, and return to efficient harvesting of solar energy for photosynthesis when light levels decline again.^[7] The importance of this process is illustrated by the fact that mutants deficient in thermal dissipation have a reduced reproductive fitness.^[8] The fraction of absorbed light allocated to thermal dissipation typically increases under a variety of environmental stresses.^[7] Thermal dissipation is thus a key photoprotective mechanism in plants and counteracts the formation of toxic reactive oxygen when the utilization of solar energy in photosynthesis declines (Fig. 2).^[1,3,9] In addition, all species also possess back-up mechanisms to detoxify reactive oxygen species once formed.^[9]

CONTRASTING ACCLIMATION PATTERNS IN SPECIES WITH DIFFERENT GROWTH FORMS AND LIFESPAN

What are the reasons for species-dependent differences in stress response? The answer may lie in the degree to which growth processes and utilization of carbon are affected by environmental extremes in a given species. A key factor regulating maximal photosynthetic capacity is the demand for photosynthate at the whole plant level.^[10] As long as photosynthate continues to be consumed in growth processes (i.e., sinks; Fig. 1), a high photosynthetic capacity is maintained. When unfavorable environmental conditions lead to a cessation of growth and carbon utilization, photosynthetic capacity is downregulated.

Different species vary in how strongly growth and carbon utilization respond to environmental change.

Freezing Temperatures

In seasonally cold climates, overwintering annual and biennial species exhibit different responses than overwintering long-lived evergreens. (Figs. 3–5). All of these species likely suspend net carbon uptake on subfreezing days. Annuals or biennials, on one hand, maintain intermittent growth as well as maximal photosynthetic capacity (Fig. 3, *Malva neglecta*; Fig. 4), and rapidly resume photosynthesis on milder winter days.^[2] Some evergreens, on the other hand, cease growth for the duration of the winter, downregulate their maximal photosynthetic capacity (Fig. 3, Douglas fir; Fig. 5), exhibit strong photoinhibition, and remain photosynthetically inactive even on milder days.^[2]

Why don't all species exercise the same flexibility as the annuals and biennials? The acclimation patterns are apparently associated with lifespan. Species with a shorter lifespan tend to invest in maintaining growth and maximal photosynthetic capacities, whereas many species with a longer lifespan simply abandon growth and downregulate maximal photosynthetic capacity during unfavorable seasons. What might be the advantage of the latter strategy? The downregulating evergreens clearly possess a very high level of stress tolerance. Only species employing this latter strategy are found in extreme environments, such as above 3000 m in subalpine forests where soil water remains frozen throughout the winter.

Fig. 2 Schematic depiction of principal fates of solar energy absorbed by light-harvesting chlorophyll. This energy can be utilized in photochemistry, resulting in photosynthetic electron transport. When this utilization via photochemistry is either downregulated or does not occur fast enough to match the rate of light absorption, dangerous transfer of energy to oxygen (leading to the formation of toxic singlet oxygen) is suppressed by harmless dissipation of the excess energy as thermal energy (heat). (View this art in color at www.dekker.com.)

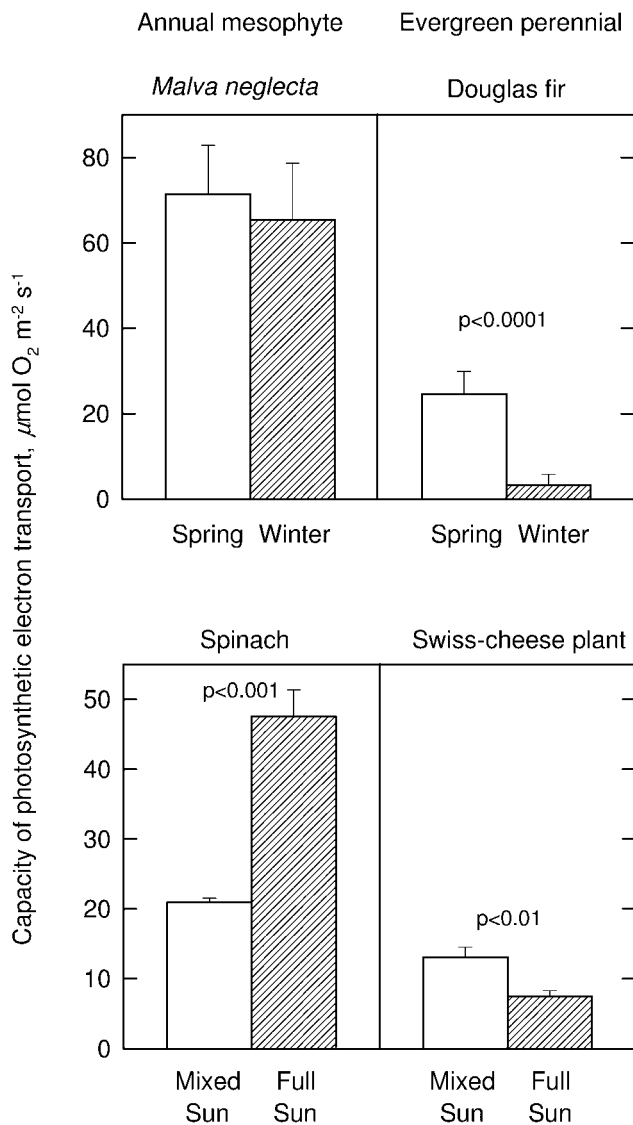

Fig. 3 Response of maximal capacities of photosynthetic electron transport to environmental extremes in different species. The seasonal response of naturally growing populations of the biennial herb *Malva neglecta* (see also Fig. 4) is compared with that of the conifer Douglas fir (*Pseudotsuga menziesii*; see also Fig. 5), both growing at 1700–2000 m near Boulder, Colorado, U.S.A. (data from Ref. 2). The acclimation to different growth light environments in a naturally lit greenhouse of the crop plant spinach is compared with that of the evergreen perennial *Monstera deliciosa* (Swiss-cheese plant; see also Fig. 8; V. Ebbert and D. L. Mellman, unpublished data). Plants were grown with ample water and nutrient supply.

Low Water Availability and Salinity

Contrasting strategies have also been observed under stress conditions other than freezing temperatures, such as low water availability at moderate temperatures. For species adapted to arid (dry) habitats, several principal

Fig. 4 Photograph of *Malva neglecta*, growing during the winter in Boulder, Colorado, U.S.A. (1700 m). (View this art in color at www.dekker.com.)

response types have been described. Some species accumulate osmotically active substances to maintain water uptake from the soil (i.e., perform osmotic adjustment), and it is often thought that crop yield under drought may be increased by enhancing solute accumulation.^[11] However, osmotic adjustment may be beneficial only in combination with enhanced root development to allow access to water deeper in the soil.^[11] An important group of species (phreatophytes) native to arid environments use

Fig. 5 Photograph of Douglas fir, on the south-facing slope of Gregory Canyon west of Boulder, Colorado, U.S.A. (View this art in color at www.dekker.com.)

Fig. 6 Photograph of *Mesembryanthemum crystallinum*, growing along the Pacific coast of Baja Norte, Mexico, in late December. (View this art in color at www.dekker.com.)

this strategy. But there are also cases where neither osmotic adjustment nor turgor maintenance takes place and strong photosynthetic downregulation and photoinhibition occur, such as in *Nerium oleander* that is native to seasonally dry environments. Salinity is another environmental factor leading to low water availability to the plant. Among species adapted to high levels of salinity (halophytes), different strategies can once again be observed. An example of a species with an extremely flexible strategy is *Mesembryanthemum crystallinum* (Fig. 6) that switches from C3 photosynthesis and rapid growth under more favorable conditions to slowed growth, enhanced succulence, and Crassulacean acid metabolism (CAM) under low water availability/high salinity. Other species, such as mangroves (Fig. 7), instead maintain low growth rates over a wide range of salinities and thermally

Fig. 7 Photograph of the mangrove *Rhizophora stylosa*, growing along the pacific coast of Queensland, Australia. (Photograph by Otto L. Lange.) (View this art in color at www.dekker.com.)

Fig. 8 Photograph of 12-week-old spinach plants grown from seed in a sunlit greenhouse and watered with low-nitrate (0.25 mmol/L) (left) versus ample-nitrate (10 mmol/L) (right) nutrient solution. (View this art in color at www.dekker.com.)

dissipate a large fraction of the light they absorb when sun-exposed.

Low Nitrogen Availability

Photosynthetic response to low nitrogen availability has been studied extensively in annual species such as spinach.^[12] Nitrogen deficiency affects the growing points most severely and leads to stunted overall growth (Fig. 8). This results in severe sink limitation (cf. Fig. 1), and carbon accumulates in the photosynthesizing source leaves. This induces photosynthetic downregulation and favors remobilization of nitrogen from older source leaves to the growing points. Because the downregulation of photosynthesis affects both the capacity of light harvesting and electron transport, and the absorption of light thus decreases along with its utilization, photoinhibition typically does not occur in this species.

Although not studied in mechanistic detail, evergreens adapted to low-nutrient environments tend to exhibit less visible effects and can apparently remain green.

Fig. 9 Photograph of *Monstera deliciosa*, growing in full sun exposure in a greenhouse. (View this art in color at www.dekker.com.)

Exposure to High Light Levels

Annuals typically increase photosynthetic capacity with increasing growth light intensity, as long as other factors such as nitrogen availability are not limiting (Fig. 3, spinach). Evergreens tend to show less pronounced increases, even under favorable conditions (Fig. 3, Swiss-cheese plant; Fig. 9), and instead exhibit strong increases in thermal dissipation of excess absorbed light and sometimes strong photoinhibition of photosynthesis.^[4] The maximal photosynthetic capacities of the evergreens shown in Fig. 3 are much lower than those of the annuals and biennials. It appears that the life span of leaves is inversely related to maximal photosynthesis rate but positively related to the propensity for photoinhibition.

PHOTOSYNTHETIC PATHWAY AND STRESS RESPONSE OF PHOTOSYNTHESIS

As mentioned earlier, exposure to low water availability triggers a switch to CAM in *M. crystallinum*. Both C₄ photosynthesis and CAM are characterized by a higher water-use efficiency and nitrogen-use efficiency than C₃ photosynthesis, thus offering advantages when these factors are limiting.^[13] In addition, both pathways confer a higher tolerance of high temperatures as a result of minimal photorespiration rates and, in the case of some CAM plants, a higher intrinsic high temperature tolerance.

CONCLUSION

The response of photosynthesis to environmental stress clearly depends on species. Two contrasting examples are long-lived species that endure entire unfavorable seasons in a state of suspended growth and photosynthesis versus short-lived species that continuously maintain growth and photosynthesis but are limited to less extreme environments. Suspension of intrinsic photosynthetic capacity during adverse seasons is dependent on the downregulation of photochemical conversion of solar energy into high-energy electrons and the upregulation of photoprotective thermal dissipation of the absorbed solar energy.

Photosynthetic Pathways: Scarcity-Driven Evolution

Stan R. Szarek

Arizona State University, Tempe, Arizona, U.S.A.

INTRODUCTION

An important adaptation to CO₂-limited photosynthesis was development of metabolic mechanisms to concentrate the substrate. CO₂-concentrating mechanisms (CCM) occur in cyanobacteria, algae, and land plants. Crassulacean acid metabolism (CAM) occurs within select land plants (e.g., orchids and cacti) in at least six different metabolic variations. A 40-fold increase in the CO₂ concentration within the cell containing ribulose biphosphate carboxylase/oxygenase (RUBISCO) has been reported. Another CCM, dependent on activity of phosphoenolpyruvate carboxylase (PEPC), is C₄-type photosynthesis. This pathway, which includes four metabolic variations, occurs frequently within the grasses and sedges and achieves a 10-fold increase in the intracellular CO₂ concentration. Although most of the world's crops lack a CCM, it may be possible to express the genes for CCMs in them and improve their photosynthetic efficiency.

ATMOSPHERIC CO₂

The raw materials for photosynthesis are radiant energy from the sun, water from the soil, and atmospheric CO₂. The first two are abundant relative to molecules of CO₂. Over the last 120 million years, the estimated concentration of atmospheric CO₂ has decreased from 0.3% (or 3000 μmol/mol) to 0.04% about 65 million years BP. Analyses of ice cores indicate that an even lower level, near 0.018%, occurred about 10⁵ years BP. The current scarcity of this gas, in addition to its physical features, makes CO₂ a limiting factor for photosynthesis. It has relatively low solubility in water, being about 15 μM at 15°C, and its solubility decreases with increasing temperature to about 9 μM at 35°C. This feature especially limits photosynthesis in high-temperature environments.

CO₂ ASSIMILATING ENZYME

Ribulose biphosphate carboxylase/oxygenase (RUBISCO) functions as the fundamental enzyme for assimilating CO₂ in all organisms that perform oxygenic

photosynthesis. The enzyme in chloroplasts is a 16-subunit protein that possesses novel features. Its affinity for CO₂, over that for O₂, has changed during the course of its evolution, being 8-fold higher in plants than in cyanobacteria. This differential affinity decreases as temperature increases. In addition, the current form of this carboxylase in plants has a relatively low kinetic efficiency (K_m about 25 μM; $k_{cat}=3 \text{ sec}^{-1}$ when fully activated) in relation to the concentration of dissolved, gaseous CO₂ in water 15 μM or less. Perhaps as a compensatory mechanism, this protein may constitute up to one-half of the leaf's total soluble protein. Many researchers have reported that the rate of apparent photosynthesis by a C₃-type (see below) leaf correlates strongly with the amount of RUBISCO in that leaf.

PHOTOSYNTHESIS IN CYANOBACTERIA AND ALGAE

An important adaptation to CO₂-limited photosynthesis in cyanobacterial and algal ancestors of plants was development of a CO₂-concentrating mechanism (CCM). In recent years, multiple forms of CCMs have been reported. The cyanobacteria have acquired two different CO₂ transporters and two types of HCO₃⁻ transporters.^[1] Transcription for one of the latter transport systems is induced under low CO₂ conditions. The cyanobacteria also possess carboxysomes, the site for CO₂ assimilation within the cell and the location for carbonic anhydrase. This enzyme regulates the CO₂/HCO₃⁻ interconversion for efficient photosynthesis. It is estimated that inorganic carbon concentrations at the site of RUBISCO approach 50 mM, about 100-fold more carbon than occurs in air-equilibrated water.

PHOTOSYNTHESIS IN LAND PLANTS

The photosynthetic mechanism common to the relatives of the mosses, ferns, conifers, and 85% of the world's angiosperm flora is C₃-type photosynthesis. The occurrence of CCMs in this biochemical group is rare. Higher relative rates of CO₂ assimilation occur in a few C₃-type plants, such as cultivated sunflowers with high carbonic

anhydrase activity and some annual life-cycle plants from warm deserts that have large amounts of RUBISCO in their ephemeral leaves.

CO₂-CONCENTRATING MECHANISMS IN LAND PLANTS

Crassulacean Acid Metabolism

The diel change in the acid content within leaves of succulent plants was recognized more than 150 years ago. Subsequent microbiological research with propionic acid bacteria suggested a metabolic system that might be similar to the one operating in succulent plants that accounted for the nocturnal acidification. Pulse-chase studies with leaves exposed to ¹⁴CO₂ in the dark provided evidence, in 1958, that ¹⁴C was incorporated into malic acid. Much research has since confirmed and clarified the nature of this CCM specifically known as Crassulacean acid metabolism (CAM). Characteristics diagnostic for the occurrence of CAM include: stomata primarily open at night and closed during the day; metabolism occurring in large (200–500 μm in diameter) chlorenchyma cells; a massive nocturnal accumulation of malic acid; and net CO₂ assimilation during the nighttime.^[2,3]

The nature of this CCM centers upon a cytosolic form for phosphoenolpyruvate carboxylase (PEPC). An inverse pattern of starch degradation and acid accumulation occurs during the nighttime. Starch degradation provides the carbon skeletons for PEP. With nocturnal opening of stomata, atmospheric CO₂ diffuses into the leaf (or stem). Some remains as dissolved CO₂, but the majority is transformed to HCO₃⁻, the latter being the substrate for PEPC. Carboxylation of PEP results in the synthesis of malic acid which is transported into the vacuole as malic acid or malate²⁻.

Membrane transport studies suggest an ATPase at the tonoplast, pumping protons into the vacuole. A malate/H⁺ exchange, using a transmembrane protein in the tonoplast of CAM cells, may be coupled (directly or indirectly) to this proton pump. The existence of a K⁺/H⁺ symporter might also play a role in net malate influx. The accumulation of acid in the vacuole, a compartment that may constitute >95% of the cytoplasmic volume, approaches 500 mmol H⁺/m² of leaf (or stem) surface area. Malate accumulation continues until dawn when exposure to light triggers an acid efflux from the vacuole. The cytoplasmic compartment is then flooded with the organic acid, which acts as a “feedback inhibitor” of PEPC. There is also evidence that the K_i and K_m components of PEPC change on a diel basis, independent of malate exposure. Decarboxylation releases CO₂ from malic acid and, with daytime closure of stomata,

intercellular CO₂ concentrations increase to levels >1%. By comparison, the internal CO₂ concentration in photosynthesizing leaves of C₃ plants has been estimated at 0.02–0.025% (or 200–250 μmol/mol).

Crassulacean acid metabolism represents a *temporal* separation for the carboxylation of atmospheric CO₂ (nighttime) and net carbon assimilation (daytime). The biochemical events occurring during the daytime are C₃-type: carboxylation of ribulose 1,5-bisphosphate (RuBP), via RUBISCO, to two trioses; reduction of 3-phosphoglyceric acid; and the regeneration of RuBP by the Calvin cycle. Some of the trioses are diverted for starch synthesis which increases in concentration during the daytime period.

The CAM pathway exhibits an extraordinary range of metabolic plasticity governed by environmental, developmental, tissue-specific, hormonal, and circadian cues.^[3] In one subgroup, including *Opuntia* species when water-stressed, plants close their stomata for the entire 24-hr period. This condition persists until the next effective rain event, which may be a months-long period. There is a dampened level of acid accumulation but no net assimilation of atmospheric CO₂. This alternative to typical CAM has been called *CAM-idling*. The plants stay alive, and perhaps reduce photooxidative damage,^[4] by recycling the internally generated CO₂.

A second subgroup—those known as *CAM-cycling* plants—functions as C₃-type photosynthetic plants when there is ample water in the soil. When water becomes limiting for absorption and tissue water potentials decrease, stomata close throughout the diel period and CAM-idling ensues. This photosynthetic flexibility occurs in leaf succulent plants, e.g., *Pereskia*, *Talinum*, and *Cissus*.^[5]

A third subgroup is based on evidence for a *morphological partitioning* of CAM and C₃-type metabolism within a single species. During the wet season, a plant may produce ephemeral leaves which demonstrate only C₃-type features. The stem, in both dry and wet periods, functions as CAM only. This phenomenon has been reported in *Frerea*, *Euphorbia*, and *Pachypodium*. In rare cases, e.g., *Portulaca* species, C₄ and CAM-cycling co-occur in leaves, but CAM-idling can be induced in stems.^[6]

A fourth subgroup demonstrates an *anatomical partitioning* of CAM and C₃-type metabolism within a single leaf. The middle mesophyll cell layer of *Peperomia* leaves expresses the gene for RUBISCO, has light-dependent CO₂ assimilation, and has no diel flux of acidity. In contrast, the mesophyll cells at the lower (adaxial) surface of the leaf solely express the gene for PEPC, demonstrate nocturnal CO₂ assimilation, and have a significant diel flux of acidity.

An additional subgroup includes those CAM plants that change the type of photosynthetic metabolism during the *ontogeny* of a single individual. Early in plant

development, young cacti and *Peperomia* spp. function as C₃-type plants. As the plants age, the entire specimen shifts to a CAM mode of growth.

Photoperiodism has a regulatory role in short-day plants of *Kalanchoe*, inducing a circadian rhythm in the activity of PEPC.

With all this metabolic flexibility in expressing CAM, it is not surprising that a polyphyletic origin has been proposed for CAM. This type of CCM has been reported in four different taxonomic orders, including the Lycopsidea (isoetes), Filicopsida (ferns), Gnetopsida (welwitschia), and Anthophyta (flowering plants). Among the latter group, there are at least 21 dicot families as well as 8 monocot families. One study suggests that at least 25,000 species possess this CCM. The four plant families having the largest number of probable CAM plants are the orchids (epiphytic), the cacti, the crassulaceous plants, and the bromeliads (epiphytes), in a decreasing order for number of taxa. Agronomically important CAM plants include *Agave* spp., pineapple, and the opuntias.

C₄-Type Photosynthesis

A second CCM, revealed by pulse-chase studies with ¹⁴CO₂, also produces a 4-carbon, initial product during daytime CO₂ assimilation. The molecule is either malic acid or aspartic acid (hence its description as C₄-type photosynthesis). The initial carboxylation of atmospheric carbon (as HCO₃⁻) is also catalyzed by cytosolic PEPC in a chloroplast-containing mesophyll cell (MC). The 4-carbon molecule then diffuses into an adjacent bundle sheath cell (BSC), wherein a decarboxylase reaction releases CO₂, with a turnover time for ¹⁴C-malate near 2 sec. The ancestral carboxylase RUBISCO, localized exclusively in the chloroplast of BSC, then initiates a C₃-type photosynthetic carbon reduction.

The C₄ isoform for PEPC may have evolved from one of two C₃-type isoforms.^[7] The first is a light-activated, cytosolic enzyme with greater tolerance toward malate. PEPC is more nearly saturated with its substrate (HCO₃⁻) than RUBISCO. Although its K_m is near 25 μM, the dissolved bicarbonate concentration (equilibrated with air at cellular pH) is near 460 μM. As such, the CO₂ delivered to the BSC approaches concentrations about 10-fold greater than the CO₂ concentrations at the site of carboxylation in C₃-type plants. The elevated levels of CO₂ in BSC increase the proportion of carboxylase to oxygenase activity by RUBISCO.^[8] The specific localization of PEPC in the MC,^[9] which surround the BSC, decreases CO₂ efflux from the leaf that would result from any photorespiration occurring in the BSC. These features promote a higher rate of net CO₂ assimilation in the leaves of C₄-type plants, relative to that in C₃-type plants. This is especially true in high-temperature environments as the

affinity of PEPC for its substrate is less affected by temperature than is RUBISCO. This CCM is also advantageous when carbon acquisition is limited by drought and salinity^[10] and when nitrogen is limiting.^[11]

Characteristics diagnostic for C₄-type photosynthesis include: presence of chlorenchymatic Kranz anatomy in the leaf; a *spatial* separation of carboxylation (in the MC) and net carbon assimilation (in the BSC); >95% of the initial ¹⁴C-label in a 4-carbon molecule; and close vein spacing. Various subgroups within C₄-type photosynthesis have been reported, including those defined by or containing the following:

1. The type of decarboxylase enzyme for processing malate (or aspartate) in BSC
2. Lacking *Kranz anatomy* but having C₄ biochemical features, e.g., *Salsola kali* and some *Orcuttia* grasses^[12]
3. C₃-C₄ intermediates defined either by anatomy and/or biochemistry, e.g., many *Flaveria* spp.
4. C₄-type photosynthesis through spatial compartmentation of photosynthetic enzymes by separation of two types of chloroplasts and other organelles with the cytoplasm of a single chlorenchyma cell^[10]

Paleobotanical evidence points toward the origin of the angiosperms at about 130 million years BP. Evidence from fossil anatomical, paleopalynological, and paleocarbonate studies suggest an origin for C₄-type photosynthesis about 5–7 million years BP. Molecular sequence comparisons push the origin back another 10–13 million years. The origin of C₄ from C₃^[13] is also polyphyletic as eight taxonomic orders contain C₄ plants. The estimated number of individual plant species in this group may be 8000–10,000. The taxonomic families with the highest number of C₄ species are the grass, sedge, and chenopod taxa.

Agronomically important C₄-type plants include corn, sorghum, sugarcane, millets, and various pasture grasses. Many of the worst weedy species are C₄-type plants, including Bermuda grass, purple nutsedge, jungle rice, and barnyard grass. Although most agronomically important crops are C₃-type plants, research has been initiated to express corn genes in transgenic rice with the goal of increasing the photosynthetic efficiency of C₃-type plants.^[14]

A comprehensive review of C₄ photosynthesis is the work by Sage and Monson.^[15]

Photosystems I and II Structures

Andrew N. Webber

Arizona State University, Tempe, Arizona, U.S.A.

INTRODUCTION

The most fundamental recent advances in our understanding of the molecular mechanism of photosynthesis come from the application of X-ray crystallography and electron microscopy to develop detailed three-dimensional models of many of the photosynthetic membrane protein complexes. Photosystem II (PSII) and Photosystem I (PSI) are reaction center complexes found in chloroplasts that capture light energy and initiate photosynthetic electron transfer. Although many biochemical aspects of the mechanism of action of each complex have been worked out by careful experimental analysis, there are still many questions as to how these complexes are organized such that they can perform complex biochemical tasks. In this section, the most recent information on the structure of PSII and PSI will be overviewed.

PSII

The structure of the PSII complex isolated from the thermophilic cyanobacterium *Synechococcus elongatus* has been solved to a resolution of 3.8 Å.^[1,2] This PSII complex is composed of at least 17 subunits, which include 14 intrinsic membrane proteins and three extrinsic subunits located on the luminal side. The membrane intrinsic part of PSII consists of 36 transmembrane α -helices, of which 22 are assigned to D1, D2, CP43, and CP47, and are arranged with a local pseudo-twofold symmetry (Fig. 1).

Two groups of five transmembranes spanning α -helices, arranged as interlocking semicircles and assigned to α -helices A–E of the D1 and D2 subunits, form the reaction center heterodimer. This arrangement of the D1 and D2 subunits resembles that of the L and M subunits of the purple bacterial reaction center, and also the five C-terminal α -helices of the PsaA and PsaB proteins of PSI.

Each of the CP43 and CP47 subunits, which are “core” antenna chlorophyll–protein complexes, consists of six transmembrane α -helices and flanks both sides of the D1/D2 subunits (Fig. 1). The structure of CP43 and CP47 is similar to the arrangement of the six N-terminal helices of the PsaA and PsaB subunits of PSI. CP43 has

been assigned to the subunit closest to D1, and CP47 has been assigned to the subunit closest to D2, based on earlier chemical cross-linking studies. CP43 and CP47 make up the internal antenna comprised of 12 and 14 chlorophyll *a* molecules, respectively. The chlorophyll *a* molecules form two layers close to the luminal and stromal sides of the membrane.

The electron transfer chain cofactors form two branches on either side of the pseudo-C2 axis and are assigned to the D1 and D2 subunits by analogy to the purple bacterial reaction center. Toward the luminal side, two chlorophylls with a Mg–Mg distance of 10 Å may represent the reaction center primary donor P_{680} . This distance is quite large compared to other reaction centers, and suggests that excitonic coupling is relatively small and that each chlorophyll may be considered as a monomer. Two chlorophylls further toward the stromal side of PSII and located 9.8 and 10 Å from the primary donor chlorophylls are analogous to the accessory chlorophylls of the purple bacterial reaction center. They are followed by two pheophytin molecules, PheoD1 and PheoD2. The final electron acceptor, the tightly bound Q_A , is located 12 Å from PheoD1. The putative binding site of the mobile Q_B is unoccupied in the crystals. Two additional chlorophylls associated with the D1 and D2 subunits are assigned to ChlZD1 and ChlZD2.

The redox-active tyrosine, Tyr 161 of D1, bridges electron transfer between the manganese cluster and P_{680}^+ . A protrusion of the electron density in the last turn of the luminal side of helix C in D1 may represent Tyr 161 at a distance of 7 Å from the manganese cluster.^[1] The manganese cluster itself is located on the luminal side and is about 15 Å off of the C2 axis. A detailed understanding of the manganese cluster must await a higher-resolution structure. In addition, the presence of Ca^{2+} ions, which are important for water oxidation, was not observed.

PSI

The structure of the trimeric PSI complex from *S. elongatus* has been solved at 2.5 Å.^[3] In the electron density map, 11 subunits could be identified. Ten of these were identified with known amino acid sequences.

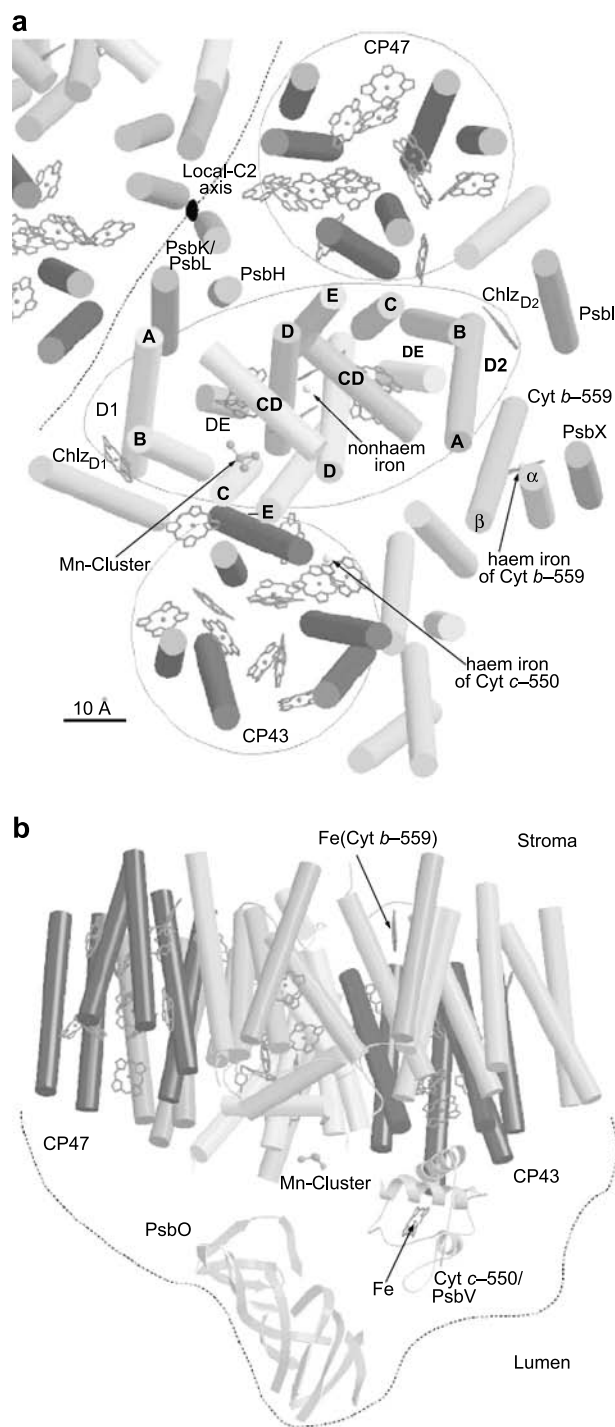

Fig. 1 Structure of PSII. (a) Arrangement of transmembrane α -helices and cofactors in PSII. The view direction is from the lumen side, perpendicular to the membrane plane. (b) Side view of the monomer looking down the long axis of the D1 and D2 subunits. (From Ref. [1].) (View this art in color at www.dekker.com.)

However, the PsaK subunit was not well resolved, and the 12th subunit matched the amino acid sequence of

PsaX, a subunit only identified in a few PSI preparations. Together with the 12 protein subunits, PSI also contained 127 cofactors comprising 96 chlorophylls, 2 phylloquinones, 3 Fe₄S₄ clusters, 22 carotenoids, 4 lipids, and 1 putative Ca²⁺ (Fig. 2).

The PsaA and PsaB subunits each contains 11 transmembrane α -helices that are divided into an amino terminal domain of six α -helices (A/B-a to A/B-f) and a carboxy-terminal domain of five α -helices (A/B-g to A/B-k). The carboxy-terminal domains enclose the cofactors of the electron transfer chain and are organized in a manner very similar to D1 and D2. The amino terminal domain α -helices are organized in a fashion similar to CP43 and CP47.

On the stromal side of PSI, the interhelical loops connecting the transmembrane α -helices partly constitute the binding site for the PsaC, PsaD, and PsaE subunits. The electron transfer chain of PSI is comprised of six chlorophylls, two phylloquinones and an Fe₄S₄ cluster. The chlorophylls and the phylloquinone are arranged in two branches related by a pseudo-C2 symmetry and coordinated by the five carboxy-terminal helices of PsaA and PsaB (Fig. 3). The cofactors forming either the A branch or the B branch are not exclusively bound by PsaA or PsaB because the A side accessory chlorophyll is bound by the B subunit and vice versa.

The primary electron donor P_{700} is formed by the excitonically coupled chlorophyll pair eC-A1/eC-B1. The two chlorin rings overlap, are separated by an interplanar average distance of 3.6 ± 0.1 Å, and are orientated perpendicular to the membrane plane. P_{700} is, in fact, a heterodimer, with eC-B1 being a chlorophyll *a* and eC-A1 being a chlorophyll *a'*—the C13² epimer of chlorophyll *a*. Chlorophyll *a'* also participates in hydrogen bonds from amino acid side chains and water^[3-5] (Fig. 4). The 13¹-keto carbonyl oxygen at ring E is the acceptor of a hydrogen bond from Thr (A743). The phytol ester carbonyl oxygen is a hydrogen bond partner of Tyr A735. In addition, the carboxy “ether” oxygen of the 13²-carboxymethoxy group is hydrogen-bonded by water. Three amino acids [Tyr(A603), Ser(A607), and Thr(A743)] are also putative hydrogen bond partners with this water molecule, but they cannot be assigned for certain because the H-bonds are not observable by X-ray diffraction. The H-bond to the 13²-carboxymethyl group may be one of the factors that stabilizes the incorporation of chlorophyll *a'* into the PsaA site.^[4] The hydrogen-bonding partners in PsaA are not conserved in PsaB. Furthermore, there are no H-bonds to chlorophyll *a* eC-B1. This H-bonding pattern has important implications for the electronic structure of P_{700}^+ as the electron spin density should be located preferentially toward the non-H-bonded chlorophyll eC-B1, in agreement with electron paramagnetic resonance spectra and electron nuclear double resonance studies

Fig. 2 Structure of the PSI trimer from *S. elongatus* viewed normal to the membrane from the stromal side. Stromal subunits have been omitted for clarity. Different structure elements are viewed in each of the three monomers (I, II, III). (I) Arrangement of the transmembrane spanning α -helices. (II) Includes also the interconnecting stromal and luminal loops. (III) Includes the cofactors associated with the intrinsic membrane proteins. The chlorophylls and quinones of the electron transfer chain are shown in blue, and the iron–sulfur centers are shown as orange and yellow spheres. (From Ref. [3].) (View this art in color at www.dekker.com.)

indicating that at least 80% of the spin density is located on the chlorophyll ligated by PsaB.^[4]

Toward the stromal side, a second pair of chlorophylls may be analogous to the accessory chlorophylls of the purple bacterial reaction center. The central Mg of these chlorophylls is ligated by water molecules hydrogen-bonded to an Asn of PsaA or PsaB.

The third pair of chlorophylls, eC-A3 and eC-B3, probably represents the electron acceptor A_0 . These chlorophylls are coordinated by sulfur atoms provided by Met A688 and Met B668. Such coordination of a hard acid such as Mg^{2+} by a soft base such as S is unusual and could contribute to the unusually low redox potential of this chlorophyll.^[5] This possibility is supported by the fact that site-directed mutations that change the axial ligand to one that should better coordinate the chlorophyll, such as His, block forward electron transfer from A_0 to the phylloquinone.

One or both of the phylloquinones Qk-A and Qk-B may correspond to the electron acceptor A_1 . The issue of whether one or both quinones are reduced and pass electrons to the iron–sulfur center F_x is still an area of considerable controversy and has functional implications as to whether either or both branches are involved in electron transfer. Kinetic measurements indicate that

Fig. 3 The cofactors of the PSI electron transfer chain. The pairs of chlorophylls and phylloquinones are arranged in two branches (A or B) and are labeled with the letter A or B, indicating whether they are coordinated by the PsaA or the PsaB subunit. The center-to-center distances between the cofactors are given in angstroms. (From Ref. [3].) (View this art in color at www.dekker.com.)

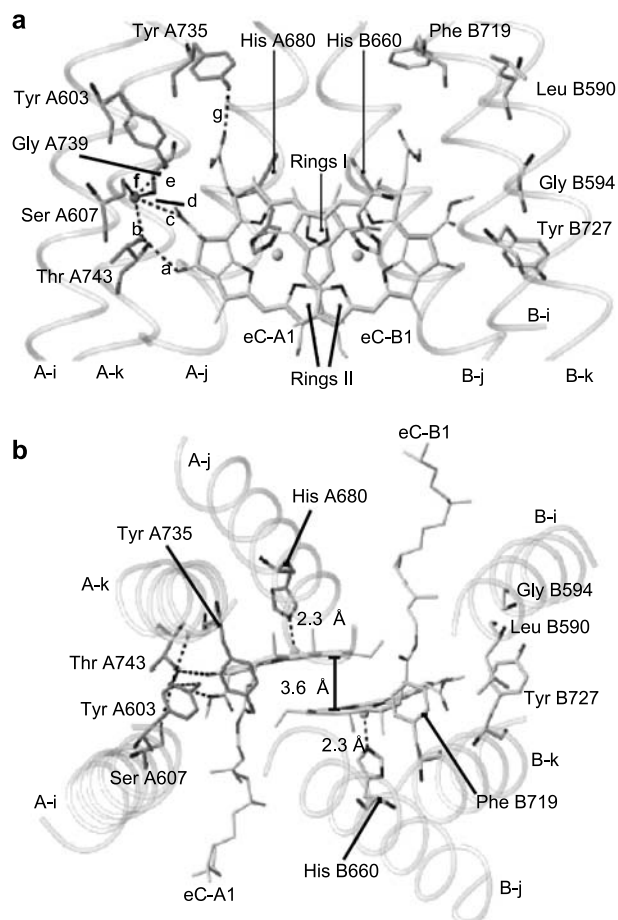

Fig. 4 (a) The environment of the primary donor chlorophylls P_{700} of PSI. The view is perpendicular to the chlorin planes. All of the possible hydrogen bonds to the eC-A1 chlorophyll are shown as dashed lines. There are no potential hydrogen bond partners with eC-B1. (b) Same as (a), but the view is along the pseudo-C2 axis. (From Ref. [3].) (View this art in color at www.dekker.com.)

electron transfer across the B branch is nearly 10 times more rapid than across the A branch.

CONCLUSION

The structures of PSI and PSII have provided detailed information on the way that light harvesting and electron

transfer cofactors are organized. Improved structural resolution of the PSII complex will lead to a more complete view of the water-oxidizing complex that should answer many questions about its mechanism. The future challenge lies in attempting to understand the way in which the protein environment modifies the properties of the different cofactors so that they are able to perform their specific tasks. In particular, questions pertaining to redox properties of specific chlorophylls and quinones, and questions relating to what factors determine the directionality of electron transfer, can now be addressed based on the detailed structural information.

Photosystems: Electron Flow Through

Arlene Haffa

Arizona State University, Tempe, Arizona, U.S.A.

INTRODUCTION

The capture of photons and their conversion into an energy form that can be stored and utilized later is the purpose of photosynthesis. Photosynthesis requires electron transfer reactions through photosystems to transduce photon energy to a charge-separated state, the power of which drives the synthesis of organic compounds useful for further chemistry. This transduction requires that the process be fast enough and the involved sites sufficiently spatially separated to prevent charge-separated states from recombining back into charge-neutral states before they are utilized. The segregation of charge is accomplished via a series of oxidation-reduction reactions through several pigment-protein complexes. In plant chloroplasts, electrons are transferred through two pathways: a linear noncyclic series of electron carriers that connect the beginning and the end of the system, and a cyclic pathway that operates around the second half of the system.

ELECTRON TRANSFER REACTIONS

Electron transfer involves an oxidation/reduction reaction (redox for short). One molecule yields an electron and is called the donor (D). A different molecule receives the electron and is called the acceptor (A). D becomes electron deficient, i.e., is oxidized and becomes a cation. A is reduced and becomes an anion. D has a more negative redox potential, i.e., it gives up an electron more readily than A. In photosynthesis, energy for the first reaction, which excites the donor with the most negative redox potential, is provided by photon energy and is called a photochemical reaction. Electrons are then transferred to a series of compounds with increasingly more positive (i.e., more easily reduced) redox potentials. This process is energetically downhill and does not require additional light but, along with the first reaction, is collectively called the light reactions. Good photon absorbers typically have conjugated double bonds, i.e., alternating single and double carbon-carbon bonds. A single photon that has the proper energy to excite an electron can move the electron from a lower to a higher energy orbital. If electron transfer occurs before the excited molecule relaxes to the ground state, then the

excited molecule (D*) gives the electron to an acceptor (A). This can be written as:

D is the primary donor. If conditions are energetically favorable, A can transfer its electron to another nearby molecule. A is referred to as the primary acceptor and the next molecule to receive the electron is a secondary acceptor.

ELECTRON TRANSFER REACTIONS IN PLANTS

Primary electron transfer in photosystems occurs in pigment-protein complexes called reaction centers. The proteins hold the pigments at proper distances and orientations for these reactions and also create electrostatic fields that make the reactions energetically possible. Exitoic energy arrives at the reaction center via an antenna complex where it excites two closely positioned chlorophyll *a* molecules, an arrangement referred to as the special pair (P, or the dimer). Plants have two types of reaction centers called Photosystem I (PSI) and Photosystem II (PSII). The special pairs of these photosystems are called P700 and P680, respectively, based on the wavelength of light necessary to excite them. Both P700 and P680 are on the luminal side of the thylakoid membranes of higher plants, which is important for creating charge-separated states and proton-motive forces. The entire photosynthetic electron transfer chain also includes a cytochrome *b₆f* complex, which does not directly require a photon to initiate the electron transfer process. Many types of bacteria are capable of performing photosynthesis with only one photosystem.^[1]

NONCYCLIC OR LINEAR ELECTRON TRANSFER

Electron flow through both systems is called noncyclic, or linear, because it is a one-way flow via the three major complexes of the photosynthetic chain: PSII, the cytochrome *b₆f* complex, and PSI (Fig. 1). Plastoquinone (PQ)

Fig. 1 Linear electron flow from water to NADP⁺ and the creation of a proton-motive force. Abbreviations are given in the article. (Created using information from Refs. 2–4 and 8–10.)

and plastocyanin (PC) act as shuttles between the first and second and the second and third complexes, respectively.

When PSII donates an electron to the electron transport chain that connects the photosystems, it regains electrons by oxidizing water to produce oxygen. PSI donates electrons to NADP⁺ to produce NADPH, and regains its electrons from the electron transport carrier plastocyanin.

The first electron transfer within the reaction center of PSII is from P680 to a pheophytin (a chlorophyll molecule lacking the central Mg atom), which occurs in several picoseconds.^[5] Electrons are subsequently transferred to quinone acceptors (first Q_A then Q_B) over longer time scales (hundreds of picoseconds and then microseconds) toward the stromal side of the membrane. Q_B is

Fig. 2 Z-scheme depicting electron flow in plant photosynthesis from water to NADP⁺, showing relative energies of pigments along the transfer pathway that make the process thermodynamically favorable. (From Ref. 2.)

not permanently fixed in PSII and is generally called plastoquinone (PQ) when it is not associated with PSII. For simplicity only PQ is used in Fig. 2. Each PQ molecule requires two electrons and two protons to become reduced, which is therefore a two-photon process. Before the second photon can excite P680, the reaction center is brought from an oxidized state back to the ground state by an electron from water via an oxygen-evolving complex (OEC), and a tyrosine residue (Tyr) on one of the protein subunits. After full reduction ($\text{PQ} + 2\text{e}^- + 2\text{H}^+ \rightarrow \text{PQH}_2$), PQH_2 leaves PSII, and the binding site is refilled by an unreduced PQ from the plastoquinone pool in the membrane. PQH_2 transfers its electrons to a cytochrome b_6f complex. One electron is transferred to a cytochrome b (b_L for low then b_H for high energy) through the Q cycle and the other is transferred to a Rieske Fe-S center that participates in the linear electron transport. Electron transfer from PQH_2 to the cytochrome complex is accompanied by proton release. The protons, which were taken from the stromal side of the thylakoid membrane, are released on the luminal side, forming a proton-motive force. The potential energy in the proton-motive force is used to drive conversion of ADP to ATP by ATP synthase. The electron on the Rieske center is transferred from an iron (Fe) atom in the iron-sulfur complex to plastocyanin, located on the luminal side of the complex. Plastocyanin leaves the complex and docks on PSI where it transfers an electron to P700^+ , reducing it to P700.

Electron transfer through PSI is similarly initiated by a photon.^[2] P700 transfers an electron to A_0 (a chlorophyll a molecule), which then transfers it to A_1 (a phylloquinone). A_0 and A_1 designate the primary and secondary electron acceptors. The electron is then passed through bound iron-sulfur centers (F_X to F_A to F_B) to a ferredoxin (Fd), which is soluble. Ferredoxin then transfers the electron to an NADP^+ reductase, which completes the electron flow by reducing NADP^+ to NADPH.

The Z-scheme (for zigzag) is a description of electron flow in photosynthesis from water to NADP^+ (Fig. 2).^[3,4] It provides information about the energetics of the pigments in the electron transfer chain.

CYCLIC ELECTRON TRANSFER

Ferredoxin is also capable of performing electron transfer directly back to the electron transfer chain instead of to NADP^+ . Electrons are then passed to PQ, through the cytochrome b_6f complex to plastocyanin and back to P700^+ . This process produces a proton gradient (and thus ATP) but not NADPH.

REACTION CENTER STRUCTURE/FUNCTION

The fundamental cores of PSI and PSII consist of symmetrically arranged cofactors imbedded in a dimer of protein subunits. Although there is symmetry in the arrangement of the photosynthetic cofactors, experiments suggest that electron transfer occurs primarily down one side of the reaction center. The symmetry is broken by differences in amino acids in the protein subunits. These differences alter the redox properties of the cofactors and dictate the directionality of the electron transfer reactions.

A detailed understanding of the exact electron transfer mechanisms in PSII has not been elucidated.^[5] Evidence for electron transfer occurring down one side of PSII has traditionally been extrapolated from bacterial reaction centers of purple nonsulfur bacteria.^[1] In the bacterial reaction center, the sides are called A and B, but the basic overall structure—although simplified and incapable of oxidizing water—possesses homology to PSII. Numerous spectroscopic experiments on the femtosecond timescale have been performed.^[6] Although the structure is symmetrical, only the A side is observed as active under normal physiological conditions. One exception is the high energy excitation that results (lifetime <15 ps) in B-side charge separation using the B-side accessory bacteriochlorophyll as the primary donor.^[7] Advances in the purification of PSII and experimentation on these pigment/protein complexes leads to the same conclusion in this photosystem (i.e., there is an active and an inactive branch).^[8] The spectral properties of PSII differ from those of the bacterial reaction center, however, and the mechanism of electron transfer may be different.^[5]

PSI also possesses an approximate symmetry.^[2] Experiments on PSI have not led to a clear conclusion as to whether one or both of the electron transfer pathways is used. Data suggest that electron transfer may occur on both sides, but one side seems to be kinetically much faster. Electron transfer on the slower branch cannot be observed without somehow impairing the faster branch.

CONCLUSION

The study of electron flow through photosystems has revealed that plants are capable of utilizing either linear or cyclic electron transfer pathways to convert light into stored energy forms. The two systems allow plants to adapt to a variety of environmental conditions. Primary charge separation reactions occur in symmetric pigment/protein complexes called reaction centers. Further study is needed to determine how the symmetric structure of the reaction center relates to its function.

Phyllosphere Microbial Diversity

Mark J. Bailey

Ian P. Thompson

Tracey M. Timms-Wilson

Centre for Ecology and Hydrology, Oxford, U.K.

INTRODUCTION

The phyllosphere is an exposed habitat prone to physical and chemical extremes that impose considerable selective pressures on resident communities, resulting in fluctuations in both the diversity and density of microbial populations. This variable and unbuffered nature makes the study of plant surface microbial ecology particularly challenging. Not least as airborne and water splash deposition of microorganisms on plant surfaces confuses the differentiation between true phyllosphere colonists and airborne surface contaminants. Nutrients, including amino acids, carbohydrates, or organic acids, and water can be limiting on the leaf surface. However, additional nutrients can diffuse via the waxy cuticle particularly after damage following infection or ageing. In addition, temperature, ultraviolet (UV), and infrared radiation fluctuate diurnally and directly affect the biota on the upper (adaxial) surface of the leaf. These biotic and abiotic factors all expose microbial communities to extreme stress that require resistance or tolerance mechanisms to aid survival. It is therefore apparent that bacteria, yeast, and fungi, which colonize aerial plant surfaces, must be specialists that have adapted to life at the edge. In the following sections there follows a brief synopsis of the approaches that are available to determine the diversity of phyllosphere microbiota and the molecular basis of their adaptation to life at the leaf.

THE PHYLLOSPHERE

The surface and interior of aerial parts of plants are defined as the phyllosphere, which represents the habitat for many microbial communities. Bacteria are by far the most abundant colonizers, typically with community densities of 10^7 cells per cm^2 of leaf surface.^[1] Leaves and flowers often form very complex shapes forming what is probably the largest biotic surface area on the planet on which microbial colonization can occur. These “epiphytic” microorganisms utilize exudates from the leaves and other aerial parts of the plant. Although many phyllosphere microbes form an apparently commensal relation-

ship with the plant leaves, numerous interactions are mutualistic and/or parasitic.

METHODS TO MEASURE MICROBIAL DIVERSITY

Table 1 shows a list of typical bacterial species recorded in the phyllosphere. Many approaches have been employed to examine phyllosphere microbial community composition. In general, abundant species are often detected easily, whereas those with small population sizes are more difficult to detect; thus the appropriateness of detection methods is important. While cultivation-based methods have provided a great deal of knowledge concerning the distribution and physiology of microorganisms, their general usefulness may be limited because of bias, incompleteness, and time constraints. Some of these limitations have been overcome in recent decades by adopting nucleic acid-based techniques. However, all techniques have their own advantages and limitations, and the use of complementary approaches will undoubtedly provide a more complete picture of microbial community dynamics than any single technique alone.

Culture-Based Methods

This approach is based on the isolation and growth of microorganisms in the laboratory. Individual colonies are isolated on solid agars containing nutrients; the choice is operator dependent. Media have been developed that enable selective growth of specific populations either by modifying nutrient composition, by inclusion of inhibitors, or by incubation conditions. For enumeration it is assumed that each colony is formed from a single cell. All culture conditions are selective for those microorganisms that are able to grow under the specific artificial environment provided. Thus one can increase the coverage of plate count techniques by using several media, each of which selects for a separate fraction of the community. However, it is estimated that only 1% to 10% of the total microbial community^[2] can be grown using contemporary methods of isolation. The plate count

Table 1 Species identified in the phyllosphere of some studied plants

Molecular: identified by molecular methods such as 16S rDNA DGGE followed by sequencing. Culturable: identified by methods requiring cultures of the strain for identification.

Source: From Refs. [2–7] and unpublished data.

technique depends on the cultivation of the microorganisms on the media used, and selectivity therefore depends on the composition of the medium. Less selective media can be used for “total viable and culturable” counts, e.g., Luria–Bertani (LB) medium.^[8] Miller et al.^[9] showed that the highest number and largest diversity of soil bacteria were found when using a relatively nutrient-poor medium such as R2A (Difco, Oxoid). Once pure cultures have been obtained, a number of methods are available to identify the species diversity represented. Metabolic and molecular techniques have been employed including BIOLOG, restriction digestion or sequencing of 16S rRNA genes, enterobacterial repetitive intergenic consensus sequence–PCR (ERIC-PCR),^[10] random amplified polymorphic DNA (RAPD),^[11] fatty acid methyl esters (FAME) analysis,^[3] multilocus enzyme electrophoresis (MLEE),^[12] fluorescence in situ hybridization (FISH),^[13] rDNA intergenic spacer analysis (RISA),^[14] and length heterogeneity PCR (LH-PCR).^[15]

Culture-Independent Methods

Molecular techniques have revolutionized our ability to describe the diversity of communities, predominantly on the basis of 16S ribosomal RNA gene phylogeny. An advantage of molecular techniques is that they can be developed to analyze the total nucleic acid fraction (DNA and/or RNA) extracted directly from the environment. Methods include reverse array hybridization and clone library screening, PCR-based community profiling techniques such as denaturing gradient gel electrophoresis (DGGE) and temperature gradient gel electrophoresis (TGGE),^[16] and single-strand conformation polymorphism (SSCP).^[17,18] Other methods based on PCR include amplified ribosomal DNA restriction analysis (ARDRA), terminal restriction fragment length polymorphism (T-RFLP), and LH-PCR, which are based on enzymatic digestion of PCR-derived amplicons with restriction endonuclease enzymes.^[19,20] In one of the first applications

of its kind,^[4] DGGE-16S rRNA gene analysis was applied to describe the total diversity of phyllosphere communities. Related studies^[5] confirmed their findings that many previously described bacterial genera are abundant and that few novel taxa were detected. As seen in rhizosphere studies, phyllosphere diversity varies between plant species and time of sampling,^[21] but leaf-associated communities are less complex.

POPULATION DYNAMICS

The size and nature of the phyllosphere microbial community are not only a reflection of the host plant physiology and local environmental conditions, but also the phenotypic and genotypic plasticity of local microbial populations and how they adapt to change.^[22] If a population cannot adapt it will be outcompeted by succeeding groups, this event may be dynamic, and diurnal cycles as well as seasonal cycles of succession have been observed. In a study of the seasonal changes seen in the phyllosphere of sugar beet,^[3] the greatest microbial numbers were detected on senescing primary leaves, and fluctuations in numbers of filamentous fungi, yeast, and bacteria were similar on senescent primary, mature, and immature leaves. This study also showed that the phyllosphere is a highly selective habitat for microorganisms, with as few as 13 bacterial species on each leaf type throughout a growing season, and the bacterial community on any given leaf type on a given day was usually numerically dominated by one or five other species. Bacterial community diversity was at its lowest mid season correlating with the warmest driest weather, and at its highest near the end of the season when rainfall was high and temperature low. Other studies on sugar beet have shown bacterial proliferation and recolonization from season to season, emphasizing the point that phyllosphere colonists are specialists.^[23] These observations have led to more detailed molecular investigations to establish whether bacteria colonizing aerial plant surfaces carry novel genes specific to that habitat, and how bacteria perceive the habitat and regulate adventitious gene expression.

Reporter Genes and IVET to Identify Cellular Activity and Novel Traits In Situ

In vivo expression technology (IVET)^[24] is a gene fusion technology where ecologically significant genes can be identified on the basis of their positive contribution toward a specific phenotype. In vivo expression technology has been used to study environmentally significant genes expressed in the phytosphere by nonpathogenic-plant-associated bacteria such as *Pseudomonas fluorescens* SBW25.^[25] SBW25 has been shown to carry genes

that are induced only in the phyllosphere.^[26] In related activities, phyllosphere bacteria have been genetically modified to carry reporter genes (*lacZY*, *lux*, *gfp*) that are either constitutively expressed or placed under the control of inducible promoters, to facilitate the monitoring of bacterial colonization and activity.^[27] They have also been used as bioreporters to determine the presence of specific carbon sources or effectors including fructose and sucrose^[13] and Fe⁺³^[28] in pseudomonads. Other systems have also been adopted to study the rate of gene transfer on leaf surfaces. These include the work of Bjorkof et al.^[29] and Normander et al.^[30] who monitored plasmid transfer between introduced inocula and the work of Lilley and Bailey^[31] who recorded seasonal influences on the initiation of plasmid transfer between natural populations and the fitness advantage plasmids provide to their host.

CONCLUSION

The phyllosphere is a complex and challenging environment to study microbiology. However, as molecular methods improve and our understanding of microbial genomics advances, we become better equipped to understand how the diversity of individuals contributes to the population ecology of the overall community. It will be intriguing to resolve what specific traits are needed for survival in the phyllosphere; already, we are developing our knowledge of the mode of action of a number of phytopathogens. These data will be of immediate value in diagnosis and disease prevention, but hopefully they will help to drive the development of suitable and effective biocontrol agents.^[1,32]

Physiology of Crop Yield

Gustavo A. Slafer

Roxana Savin

Department of Crop and Forest Sciences, University of Lleida, Centre UdL-IRTA, Lleida, Spain

Abstract

Improving yield is generally a major criterion when designing strategies for both breeding and management of major grain crops. In this chapter, we discuss firstly the two main approaches to understand grain yield in major crops (illustrated with examples from wheat); i.e. dividing grain yield into simpler numerical components, and understanding it as the consequence of growth and partitioning. Then a more mechanistic approach, combining the main and more functional elements of both models is proposed, identifying a critical growth period. As yield per unit land area must be limited by the source, an additional model is offered indicating when source-strength may actually regulate yield most strongly in agreement with the mechanistic model.

INTRODUCTION

Crop yield is normally the attribute which breeding programs and management decisions are mainly focused on. In the case of grain crops, it is the final outcome of crop growth and development processes, and is strongly regulated by genetic factors, environmental conditions, and genetic and environmental interactions throughout a growing season. A major aim of most crop physiologists is to identify processes that determine differences in yield because of genetic and environmental factors. In this article we have briefly reviewed the state of the art in this field, illustrating the case of wheat, one of the major crops whose yield physiology has been most comprehensively studied.

TRADITIONAL APPROACHES TO YIELD PHYSIOLOGY IN GRAIN CROPS

Yield is the proportion of the total biomass of the crop allocated to the harvestable organs. In the case of cereals and other grain crops, it is biomass allocated to grains. Traditionally it has been analyzed with two different, complementary approaches: the analysis of yield components and the analysis of dry matter accumulation and partitioning (Fig. 1).

Yield Components

The yield component approach has been the most popularly used one: It is simple and relatively easy.

In this approach, yield is simply dissected into single numerical components (i.e., plants per unit land area, spikes per plant, spikelets per spike, grains per spikelet, resulting in the number of grains per m^2 , and average individual grain weight; right part of Fig. 1). The approach has, however, a major drawback in that the components are not independent; in fact, they are consistently negatively related among themselves.

The negative relationships between the subcomponents of the number of grains per unit land area could be attributed to feedback processes.^[1] In the case of the two major yield components, the number of grains per unit land area and their averaged individual weight at harvest, whose generation is only minimally overlapped in time, the negative relationship may not be because of feedback processes. In fact, and regardless of what is often assumed, the negative relationship between the number and average weight of wheat grains seems to be largely independent of a strong competition for assimilates.^[2] The lack of a strong (or any) competition among grains during their active growth, after the number of grains has been fixed, indicates that in most conditions the wheat canopy during postanthesis can provide assimilates in excess to the demands of the growing grains.^[3,4] However, even recognizing a physiologically sound relationship between yield and grain number per m^2 , based on the fact that wheat grains hardly compete for assimilates during their active growth, it is a small step toward understanding yield physiology: grain number per unit land area is as complex as, and harder to assess than, yield itself.

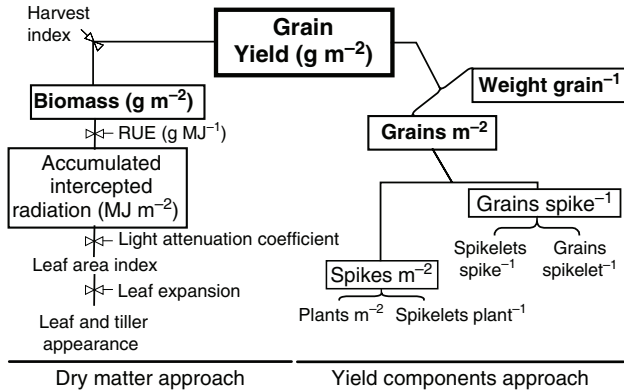

Fig. 1 Representation of two different and complementary approaches for analyzing grain yield. The yield component approach (right panel) consists in dissecting grain yield into single numerical components. The dry matter approach (left panel) is based on dry matter accumulation (strongly dependent upon the ability of the crop canopy to intercept incoming radiation) and partitioning. RUE is radiation use efficiency.

Dry Matter Accumulation and Partitioning

The approach based on dry matter accumulation and partitioning is far more mechanistic (Fig. 1, left panel). Understanding the determination of biomass requires crop assessment analyses and interpretations made at different times during the growing season. However, the approach is still quite straightforward: The only source of energy for crop growth is solar radiation and, therefore, the amount of accumulated growth depends proportionally on the amount of accumulated intercepted radiation, transformed into dry matter with certain efficiency (in the case of wheat and other C_3 cereals, in general between 1.0 and 1.5 g/MJ, or approximately twice those values if referring to photosynthetically active radiation; e.g., Ref.^[5]). The main organs in charge of intercepting (and absorbing) solar radiation are leaves, and the main property of the leaves related to crop radiation interception is the area. Then leaf area index (LAI) (area of leaves per unit land area) is considered the main attribute of the crop canopy responsible for intercepting incoming solar radiation and in turn providing resources for crop growth and biomass accumulation. The capacity of a certain LAI to intercept incoming radiation depends on the properties of the leaves in the canopy. It is mathematically described as the light attenuation coefficient, and the higher the proportion of solar radiation absorbed by each unit of LAI (e.g., more planophile canopies) the higher the light attenuation coefficient of the canopy.^[6] Although more mechanistically explaining yield than yield components, this approach has also a drawback: It assumes that

increasing radiation interception and biomass accumulation would result in increasing yield irrespective of when the increased biomass was achieved. In other words, it assumes that yield is equally sensitive to changes in biomass at any time during crop growth. Although, perhaps, logical, this assumption does not fit the reality. For instance, experiments showing responses of yield to nitrogen fertilization disregarding whether the fertilizer was applied before sowing, in very early developmental stages or during late tillering,^[7] demonstrate that yield is not only sensitive to changes in biomass accumulation but also when growth takes place. Another example may be provided by the fact that the optimum plant density for maximizing grain yield is far lower than that required for maximizing vegetative growth.^[8]

WHAT IS ACTUALLY CRITICAL FOR DETERMINING CROP YIELD?

Defining What Stages Are Critical

From the pioneering work by Fischer,^[9] it was clearly established, mainly from experiments in which wheat

Fig. 2 Mechanistic model for understanding the physiological bases of grain yield. This model takes into account the phases in which yield have been found to be most responsive to environmental and genetic changes. Briefly, if critical LAI maximizing radiation interception is reached by the timing of the onset of stem elongation, then the maximum biomass accumulation during this period could be achieved for that particular environment. Then a proportion of biomass accumulated by the crop during that phase (of approximately 3–4 weeks) immediately preceding anthesis is partitioned into the spike allowing a particular level of spike dry matter at anthesis, largely determining grain number and yield.

Fig. 3 Schematic diagram of wheat development showing the yield sensitivity to source strength at different stages throughout the growing season (main, thick line). The diagram also shows in the background other curves representing the total number of shoots per m^2 ending the curve with the number of spikes per m^2 just before anthesis (dashed line), the total number of floret primordia per spike ending the curve with the number of those primordia developing to fertile florets (dotted line), and grain weight (dashed and dotted line). Below the abscissa two boxes stand for the length of the period of stem and spike growth. Stages indicated in abscissas are sowing (Sw), seedling emergence (Em), floral initiation (FI), double ridge (DR), heading (Hd), anthesis (At), beginning of grain filling period (BGF), physiological maturity (PM), and harvest (Hv).

plants were subjected to brief but intense shading periods at different timings, that wheat yield is far more sensitive to changes in growth during the relatively short period from approximately three few weeks before to few days after anthesis than during any other timing (provided the crop has been adequately established soon after sowing). This relatively short “window” of phenological time coincides with the timing when the stems and spikes are competitively growing. Then final crop yield seems to be particularly sensitive to changes in resource accumulation and allocation in that period, determining the spike dry matter of the spikes per unit land area at anthesis. Precisely, the number of grains per m^2 , whose subcomponents in the “yield component approach” are being produced throughout the whole period from sowing to anthesis,^[1] seems to be virtually exclusively sensitive to growth and partitioning during the “window” of phenological time when stems and spikes grow actively. The result is the universal positive relationship between the number of grains per m^2 that the crop has at maturity and the dry matter per m^2 allocated into spikes at around anthesis.^[10] The word “universal” is used herein to express that only exceptionally this relationship has not been highly significant. For instance, disregarding where, in which conditions and with what cultivars the classic shading experiments were made, the relationship has always being confirmed. In addition, when less artificial treatments were applied (e.g., comparing yield physiology between high-yielding

modern cultivars and their low-yielding predecessors; or between nitrogen-deficient crops and those well fertilized, between untreated controls and plots subjected to extended photoperiods reducing the length of the stem elongation phase, and so on) the relationship always explained much of the physiological bases of yield.^[10]

A Modified Model Recognizing a Critical Phase

Redefining the two most well known, general models to make them fit the empirical evidence, a new physiological model may be revealed. This model would accept that grain number is a major driving for yield in a crop in which final grain weight is largely independent of availability of resources during the effective period of grain growth. This does not mean at all that individual grain weight is invariable, but that genetic–environmental factors altering grain weight are largely direct effects on the capacity of the grains to grow rather than a resource-mediated process during the effective grain filling. As the subcomponents of grain number per m^2 cannot be used reliably to understand it physiologically, the mechanistic bases of grain number have to be found with a resource accumulation and allocation model. Using such a model requires focusing on growth/partitioning during the window of phenological time when yield has been found to be most responsive to

environmental changes: in the case of wheat the stem elongation phase (Fig. 2). In this model, yield is maximized if LAI reaches its critical value by the onset of stem elongation, and both crop growth rate and partitioning to the growing spikes between stem elongation and anthesis are maximal. Both factors contribute to a large spike dry weight per m^2 at anthesis, largely determining the grain number per m^2 that a posteriori will be filled.

When Does Source Strength Drive Yield?

The model illustrated in Fig. 2 implies that although crop yield per unit land area is essentially a source-driven process,^a it is only during a rather short “window” of phenological time (say from 3 to 4 weeks before to 5 to 10 days after anthesis) that the crop sensitivity to source strength is critical for yield (Fig. 3). This window of time coincides with the timing when a very large number of potential sites that could produce a grain (tillers that might bear a spike, and floret primordia that might develop to a fertile floret and then fertilize to produce a grain) drops dramatically. The level will be determined by the particular genotype and environmental conditions, as reflected by the spike dry weight at anthesis, which in turn depends on the total crop growth during stem elongation and the partitioning of that growth between the stems and the spikes. To further increase the number of grains per m^2 , which is critical for increasing productivity in a crop whose final yield is largely sink limited during the grain growth period, breeding and management must then be focused to further enlarge the spike dry weight per unit land area at anthesis, by either improving resource use, resource use efficiency, and/or partitioning toward reproductive growth during this particular window of phenological time.

CONCLUSIONS

Physiological analysis of yield determination in wheat suggests that the crop only responds significantly to changes in resource use and partitioning during a brief period of few weeks before to a few days after anthesis, when the number of grains largely determining yield (in a crop sink limited during grain growth) is established. The final number of grains is determined in

relation to the dry weight per m^2 that the spikes reach at anthesis, which itself is a function of total crop growth during the stem elongation phase and the proportion of that biomass allocated into reproductive growth. For the sake of brevity, we have confined the analysis to wheat. However, with minor differences, the same kind of analysis fits well to other major grain crops.^[11]

^aYield must be source limited by definition, as the “unit land area” (m^2 in an experimental plot and acre or hectare in real production) essentially represents a certain availability of resources in that area for a particular site \times year \times agronomic condition (the more the resources that can be used the higher the yield of the crop).

Physiology of Herbivorous Insects

Cedric Gillott

University of Saskatchewan, Saskatoon, Canada

INTRODUCTION

The long duration of insect–plant coevolution, especially the coevolution of insects and angiosperms since the Cretaceous (150 million years b.p.), has been a major contributor to the diversity of species seen in modern Insecta. Of the approximately 1 million extant insect species identified, more than 80% feed on plant material at some stage in their life. This high proportion, plus the enormous numbers of individuals in populations of a species that occur under appropriate conditions (e.g., up to 10^{10} locusts in a swarm), means that herbivorous insects play a major role in the flow of energy from primary producers to upper-level consumers. All parts of a plant may be used as food: leaves, stems, roots, sap, pollen, nectar, seeds, fruits, and nuts. In many species, but especially Lepidoptera and many Diptera and Hymenoptera, the diet may change from the juvenile to the adult stage. Further, insects may live on or within plants, some species (e.g., gall formers) triggering changes in the structure and physiology of the host for their benefit. To take advantage of the availability of plants as sources of food and shelter, an insect's structure and physiology, especially in respect to feeding and reproduction, have taken on special adaptations.

EXTERNAL FEATURES

Body Form

In most adult insects and juvenile exopterygotes (insects with external wing development, such as grasshoppers, termites, true bugs, and thrips), the division of the body into three major regions (head, thorax, and abdomen) is readily visible (Fig. 1A). However, in many juvenile endopterygotes (insects with a pupal stage, such as ants, bees and wasps, beetles, butterflies and moths, and true flies), the separation of the regions may be indistinct (Fig. 1B, C). Each region comprises a number of segments, each of which primitively possessed a pair of appendages. In modern insects, these appendages may have disappeared; further, new nonsegmental structures may have arisen.

Head

The head is the major sensory center, typically bearing a pair of segmental antennae, which are the principal location of sense organs for touch, taste, and smell, and nonsegmental eyes. Adult insects and juvenile exopterygotes have paired compound eyes, typically having several thousand photosensitive units. Compound eyes are capable of limited form perception, color vision, and in some species, for example the honeybee, perception of polarized light that can be used in navigation and orientation. Simple eyes (up to six pairs) found in juvenile endopterygotes and many adult insects each comprise fewer photosensitive units than compound eyes. In caterpillars and beetle larvae they appear to function like compound eyes. In adults they may measure light intensity, be involved in maintenance of diurnal rhythms, and help to maintain stability during horizontal flight. The mouthparts are derived from ancestral segmental appendages. In herbivorous insects they may be adapted for chewing (as in grasshoppers and beetles), piercing and sucking (aphids), or sucking only (butterflies and moths). In chewing mouthparts the well-developed mandibles typically have both cutting and grinding surfaces (Fig. 2A), while the labrum (upper lip), labium (lower lip), and maxillae taste and manipulate the food. In sucking species, the mandibles and maxillae generally form elongate stylets that pierce tissue. The maxillae are interlocked to form the salivary and food canals, and the labium is developed as a protective tube (Fig. 2B).

Thorax

The thorax is the locomotory center of the insect. Typically, it bears three pairs of legs and, in adults only, the wings (Fig. 1A). Legs are secondarily absent in larvae of Diptera (Fig. 1C) and many Coleoptera and Hymenoptera. Though normally used for walking and running, legs may be modified for other functions, such as jumping (Fig. 1A), sound production, digging (Fig. 3A), and pollen collection (Fig. 3B). The legs of many insects, notably Diptera and Lepidoptera, have many chemosensilla as well allowing these insects to taste the substrate as they walk over it!

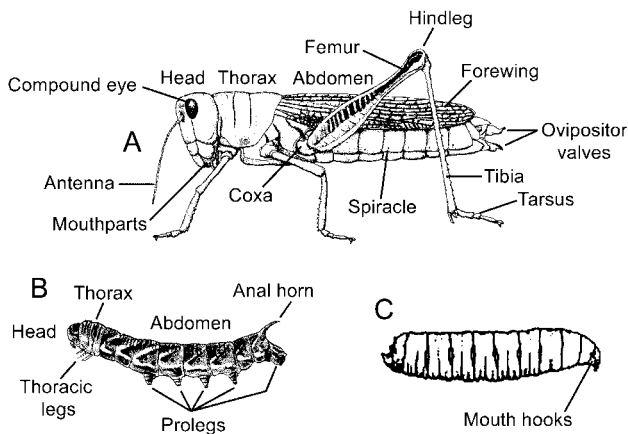

Fig. 1 Insect external features: (A) Grasshopper, (B) hornworm caterpillar, (C) cabbage root maggot. In the grasshopper the three body divisions—head, thorax, and abdomen—are readily seen. Though the caterpillar’s head is obvious, the junction between the thorax and abdomen is indistinct; the thorax is recognized by the presence of the three pairs of true legs. In the maggot the only sign of the head are the paired hooks, believed to be remnants of the maxillae. *Note:* The insects are not drawn to scale. (Fig. 1A from Pfadt, R.E. *Field Guide to the Common Western Grasshoppers*; USDA APHIS, Wyoming Agriculture Experiment Station, Bulletin 912, 1988.)

The evolution of wings and flight was a key factor in the success of insects. In the short term, flight facilitates escape from predators as well as dispersal, which is especially useful for species whose food sources and breeding sites are sparsely distributed. In the long term, dispersal leads to colonization of new habitats, geographic isolation, and, ultimately, speciation. Wings, generally two pairs, may be modified for both flight-related and other functions. Reduction to a single pair, or linking of the fore- and hindwings on each side, improves aerodynamic efficiency. In Diptera the greatly reduced hindwings (halteres) function as gyroscopic organs. The hardened forewings (elytra) of beetles provide protection. In crickets and grasshoppers the forewings are used in sound production. In Lepidoptera the wings may be colored and patterned for camouflage or to warn would-be predators that the insect is toxic. Occasionally, a nontoxic species (e.g., the viceroy butterfly) avoids being eaten by having wings that mimic those of a toxic species (e.g., the monarch butterfly).

Abdomen

The abdomen is the metabolic and reproductive center of the insect. The ancestral segmental appendages are lost on most segments, but at the posterior tip they remain as the external genitalia. In males they serve as clasping and

intromittent organs, while in females they typically form the ovipositor whose structure reflects the site of egg laying. Thus, in grasshoppers that lay eggs in soil, the short and heavy ovipositor is used to dig a hole; in cicadas it is a hard tubelike structure that places the eggs in plant tissues; and in many Hymenoptera it is variously modified for sawing, piercing, boring, and stinging.

Integument

Covering the entire surface of the insect’s body—including the sense organs—as well as lining the foregut, hindgut, tracheal system, and parts of the reproductive system, is an inert, acellular layer called the cuticle. The cuticle may comprise, from inside to outside, the procuticle and a very thin, multilayered epicuticle. Where strength and rigidity are required, as for muscle attachment and general protection, the procuticle may be relatively thick. However, in regions of the body where flexibility or sensitivity is paramount, as at leg joints and over sense organs, only epicuticle is found. The outer layer of the epicuticle is a monolayer of wax molecules which, by reducing water loss from the body, has been another factor contributing to the success of insects as terrestrial organisms. The wax may also be important in preventing entry of microorganisms and in chemical communication where it serves as a pheromone or kairomone (see “[Coordinating Systems](#),” following). Color production is also a function of the cuticle. Pigmentary colors result from the occurrence of specific pigments in the cuticle, including carotenoids, pteridines, and ommochromes. Iridescent colors result from the scattering of light due to the laminated nature of the procuticle.

PHYSIOLOGY

Maintenance Systems

Several insect maintenance systems differ markedly from those of vertebrates. For example, the gas-exchange system of insects comprises a tubular air-filled system with segmental openings to the exterior (spiracles) along each side of the body (Figs. 1A, 4). The tubes (tracheae and tracheoles) carry oxygen to and carbon dioxide from the core of tissues, making gas exchange highly efficient. Thus, the blood of insects has no role in gas exchange. Blood in insects does not travel within vessels as in vertebrates. Instead, the simple tubular heart, aided by various undulating membranes, pushes blood sluggishly past the internal organs and through the appendages. Excretion and salt–water balance are achieved via a series of fine Malpighian tubules (Fig. 5A) that filter ions, small organic molecules (including uric acid, the normal form of

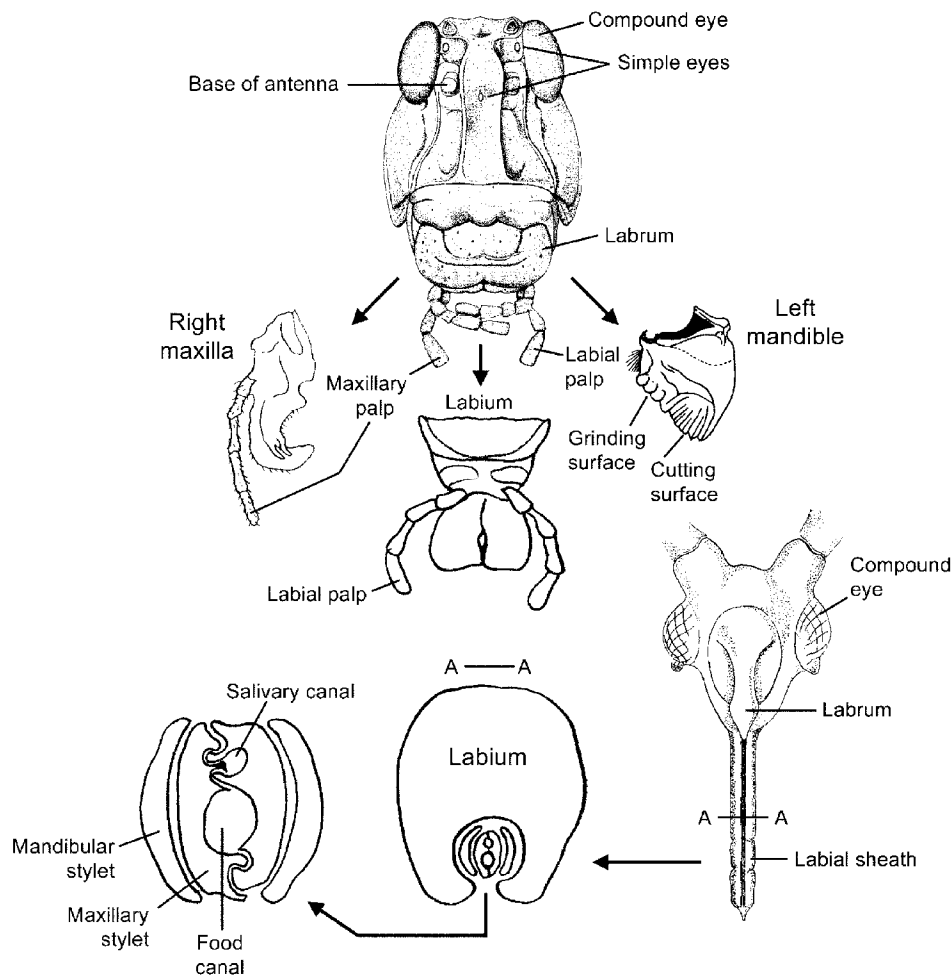

Fig. 2 Head and mouthparts: (A) Grasshopper (cutting and grinding mouthparts); (B) homopteran (piercing and sucking mouthparts). In the grasshopper the mandibles have both shearing and grinding surfaces. The maxillae, labrum (upper lip), and labium (lower lip) are used to test the texture and taste of the food, as well as to manipulate it. In Homoptera the labium serves as a protective sheath for the delicate stylets, which are highly modified mandibles and maxillae. The maxillae interlock to form the salivary and food canals. (Fig. 2A in part redrawn from Pfadt, R.E. *Field Guide to the Common Western Grasshoppers*; USDA APHIS, Wyoming Agriculture Experiment Station, Bulletin 912, 1988. Fig. 2B in part redrawn from Dixon, A.F.G. *Biology of Aphids*; Edward Arnold, London, 1973. Reproduced by permission of Hodder/Arnold Publishers.)

nitrogenous waste), and water from the blood and release these into the hindgut. In the hindgut, resorption of useful materials occurs, and the remaining materials form urine.

Coordinating Systems

Like vertebrates, insects coordinate physiological activity by means of nervous and endocrine systems. The nervous system is relatively simple in both structure and function; much activity is the result of simple reflex pathways, and insects possess very limited ability to learn and memorize. By contrast, insect hormonal systems have roles comparable to those of vertebrates—for example, in reproduction, growth, excretion, and blood–sugar regulation—and

appear to be equally complex. Communication and coordination of behavior among insects may include visual, tactile, and auditory stimuli, but chemical signals are usually of greater importance. They include pheromones, allomones, and kairomones, which are chemicals released from the body of one insect to induce a behavioral or physiological response in other insects. Pheromones act intraspecifically and are used by numerous species, but especially Lepidoptera and Coleoptera, to attract mates. Indeed, synthetic sex attractants are widely used in integrated pest management (IPM). Other pheromones regulate sexual maturation and caste differentiation in social insects; mark trails to and from food and indicate its quality and quantity; stimulate aggregation or

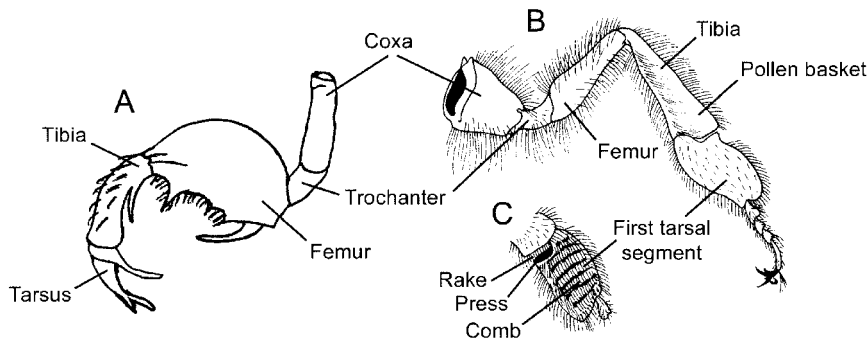

Fig. 3 Insect leg adaptations: (A) Foreleg of cicada (digging and tunneling); (B), (C) hindleg of honey bee (pollen collection). In the cicada the coxa is lengthened to provide increased rotation, the femur is spadelike for moving soil loosened by the tibia and tarsus, which are equipped with spines. On the bee's hindleg, rows of hairs (comb) on the inner side of the first tarsal segment (C) scrape pollen off the abdomen. The rake, a row of hairs at the distal end of the tibia, collects pollen from the comb of the opposite leg and transfers it to the pollen press. The compacted pollen is then moved into the pollen basket (B) where it is stored until the bee returns to the nest.

dispersion; and warn of impending danger. Allomones are used to repel would-be predators, as in the release of formic acid by some ants. Kairomones are chemical signals (including some pheromones) released by one species and detected by another. For example, the aggregation pheromone of bark beetles is used by hymenopteran parasites to locate their hosts!

Food Acquisition and Utilization

The feeding habits of herbivorous insects have special significance for humans from an opposite perspective. Some insects cause enormous damage to crops and stored plant products, whereas others are of massive benefit as pollinators. Generally, olfactory stimuli trigger the initial orientation to a potential food source. Phagostimulants or deterrents on or within the food then determine whether

feeding continues. The alimentary canal comprises three regions: foregut, midgut, and hindgut (Fig. 5A). In insects that feed on solid matter, the canal is generally fairly short. By contrast, in most sap feeders, which must both

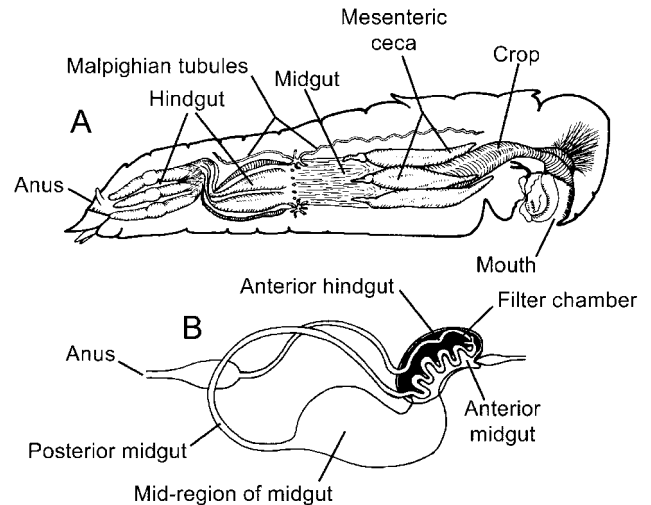

Fig. 5 Insect alimentary canal: (A) Grasshopper, (B) froghopper. The gut of a grasshopper is relatively short and straight. It includes a crop where food is stored and further ground up; the midgut and its diverticula (mesenteric ceca), where digestion and absorption take place; and the hindgut, where feces are produced. By contrast, in the sap-feeding froghopper the gut is very long and coils back on itself, so that the anterior midgut and anterior hindgut are closely adjacent within the filter chamber. This enables excess water in the sap to be rapidly translocated into the hindgut, thereby concentrating the food for digestion and avoiding harmful dilution of the blood. (Fig. 5A redrawn from Hodge, C. The anatomy and histology of the alimentary tract of *Locusta migratoria* L. (Orthoptera: Acrididae). *J. Morphol.* **1939**, *64*, 375–399. Fig. 4 Grasshopper tracheal system. This is a network of gas-filled tubes that open to the exterior via paired segmental spiracles. The tubes branch and spread as increasingly finer tracheoles to all parts of the body. In larger insects sections of the tubes may be dilated, forming air sacs that increase the volume of air that can be exchanged during ventilation.

concentrate the food prior to digestion and prevent the excess water from diluting the blood, the canal is long and coiled back upon itself, and it passes through a filter chamber (Fig. 5B). Here, the anterior midgut and hindgut are closely adjacent, allowing water to pass from the former to the latter and thus to be excreted without entering the body cavity. Generally, the foregut is where food is stored. The midgut, lined with a peritrophic matrix that protects this region from physical damage and entry of microorganisms, is where digestion and absorption occur. The hindgut processes undigested material into feces, though in many herbivores, especially those that feed on woody materials, this region may have special sections that house symbiotic bacteria or protozoa to facilitate digestion. Only a few insects manufacture enzymes capable of splitting cellulose and hemicellulose. The hindgut symbionts degrade such compounds into glucose and organic acids, which are then absorbed through the hindgut wall.

Following their absorption across the gut wall, products of digestion are metabolized in the fat body, a tissue analogous in function to the vertebrate liver. Here, they are converted into appropriate energy-supplying or growth-promoting molecules, or are stored. The fat body is also the principal site for detoxification of insecticides and plant-produced toxins.

Reproduction

Generally, insects have a high reproductive capacity and a short generation time. By facilitating rapid adaptation to changing environmental conditions, including development of insecticide resistance, these factors have also been important in the success of insects. Most insects reproduce sexually and lay eggs. Males locate females using visual, auditory, or chemical cues, especially sex attractants. The latter may be active over distances of several kilometers. Among herbivorous insects, gravid females determine which are suitable host plants by chemical or visual cues. Eggs may be laid in soil, or on or within plant tissues.

Embryogenesis, larval development, and metamorphosis are usually rapid, enabling several generations to occur each year. However, in cold climates there may be only one generation annually, with most species overwintering in the egg or pupal stage.

Though most species are bisexual and lay eggs, others—including many pestiferous Homoptera—include parthenogenesis (which produces female-only generations) and sometimes also viviparity in their reproductive repertoire. These unusual strategies lead to massive population increases, hence the insects' ability to exploit a temporary abundance in their food supply and their prominence as major vectors of plant diseases.

Phytochemical Diversity of Secondary Metabolites

Michael Wink

Universität Heidelberg, Heidelberg, Germany

INTRODUCTION

Plants produce a wide variety of secondary metabolites that have evolved as defense compounds against herbivores and microbes. Some secondary metabolites attract pollinating insects or fruit-dispersing animals; others serve as UV protection or as signal compounds. Secondary metabolites can be divided into two main groups—those without nitrogen and those with nitrogen in their structures. Nitrogen-containing compounds include alkaloids, amines, nonprotein amino acids, cyanogenic glycosides, glucosinolates, protease inhibitors, and lectins. Nitrogen-free compounds are various terpenoids (mono-, sesqui-, di-, tri-, and tetraterpenes; saponines; and cardiac glycosides), polyketides (anthraquinones), phenolics (flavonoids, anthocyanins, galloyl and catechol tannins, phenolic acids, lignans, and lignins), and polyacetylenes. The modes of action of these compounds are briefly discussed.

WHAT ARE SECONDARY METABOLITES?

A chemical analysis of low molecular-weight substances present in a plant reveals the usual inorganic ions, amino acids, sugars, organic acids, fatty acids, and some other compounds that are needed for primary metabolism or development. In addition, all higher plants produce one or several representatives of the so-called secondary metabolites (SMs), which are also low molecular-weight compounds. In contrast to primary metabolites, SMs are not essential for a plant in terms of primary metabolism; i.e., a plant can usually survive without a particular SMs, especially when grown under protection in a greenhouse.^[1–9]

SMs can have ecological functions in that they serve to protect against herbivores, microbes, or competing plants. Some SMs also function as signal compounds to attract pollinating or seed-dispersing animals. SMs usually occur in complex mixtures that also differ among plant organs and developmental stages; e.g., seeds have SMs profiles that often differ from those of leaves and roots. In general, a particular group of plants produces two to three main types of SMs concomitantly, such as phenolics, terpenoids, or alkaloids. Often, a basic structure is present that

is varied by several substitutions, such as additional OH-groups, methyl-groups, or double bonds. SMs are dynamic compounds showing turnover, and their biosynthesis can be enhanced upon attack by microbes or herbivores.^[1,6–9] Jasmonic and salicylic acid are important signal molecules in this context.^[10]

Some SMs occur in phylogenetically related taxa (e.g., glucosinolates in families of the Capparales), whereas others have a broader distribution (often a major radiation in a particular tribe or family and outliers in several others). Considering the whole plant kingdom (including algae, mosses, horsetails, and ferns), an impressive diversity of SMs exists. Fig. 1 gives an estimate of the numbers of known secondary metabolites and illustrates a few representative structures. Three major groups of SMs can be recognized: nitrogen-containing substances, terpenes, and phenolics.

PHYTOCHEMICAL DIVERSITY

Nitrogen-Containing Secondary Metabolites

Over 14,000 nitrogen-containing SMs have been described so far: Alkaloids, amines, nonprotein amino acids, cyanogenic glycosides, and glucosinolates are the main compounds in this group. A few SMs of high molecular weight should also be considered in this context: Some plants accumulate peptides and proteins (protease inhibitors, amylase inhibitors) that play a role in antimicrobial and antiherbivore defense. Their biosynthesis can be induced upon wounding or microbial attack.

Nonprotein amino acids (NPAA)

In addition to the 20 common L-amino acids, more than 400 other amino acids that are not building blocks of proteins exist in plants.^[1–9] NPAAs often figure as antinutrients or antimetabolites, i.e., they may interfere with the metabolism of microorganisms or herbivores. Many nonprotein amino acids resemble protein amino acids and can be considered to be their structural analogues. For example, 3-cyanoalanine is an analogue to L-alanine, S-aminoethylcysteine to L-lysine, L-azetidine-2-carboxylic acid to L-proline, and L-canavanine or

Fig. 1 A number of known secondary metabolites.

L-indsopicine to L-arginine. Because NPAAAs are often (at least partly) remobilized during germination, they function as N-storage compounds in addition to performing their role as defense chemicals.

Amines

Aliphatic mono- and diamines, polyamines, aromatic amines, and amine conjugates are the main SMs in this group.^[1–9] Aliphatic monoamines and diamines are widely distributed SMs in plants, and occur as independent products in their own right or as intermediates in the biosynthesis of alkaloids (as precursors for several groups of alkaloids, such as pyrrolizidine, nicotine, tropane, quinolizidine, *Lycopodium*, and *Sedum* alkaloids). Simple amines serve as attractants in some flowers (e.g., *Arum maculatum*) or as defense compounds in many other plants. Aromatic amines derive from tryptamine and tyra-

mine. Because several tryptamine and tyramine derivatives are structurally identical or similar to those of the neurotransmitters serotonin, dopamine, or noradrenaline they may interfere with the corresponding receptors. Hallucinogenic or stimulating effects have been reported for bufotenine, psilocybin, psilocin, *N,N*-dimethyltryptamine, mescaline, ephedrine, or ergot alkaloids.^[11–14]

Cyanogenic glycosides

Cyanogens are derivatives of 2-hydroxynitriles that form glucosides with β -D-glucose.^[2–9] More than 60 different cyanogenic glycosides have been described from 2600 plants (mainly Rosaceae, Fabaceae, Gramineae, and Araceae). When plants are wounded by herbivores or other organisms, the cellular compartmentation breaks down and cyanogenic glycosides are hydrolyzed by β -glucosidase and nitrilase to the corresponding aldehyde

or ketone and hydroprussic acid (HCN).^[15] HCN is highly toxic for animals or microorganisms because it inhibits electron transfer components of the respiratory chain and binds to other enzymes with metal ions. Foods that contain cyanogens, such as manihot (*Cassava esculenta*) and sorghum, have repeatedly caused intoxication and even death in humans and animals.

Glucosinolates

Glucosinolates contain sulfur as an additional element (thioglucosides). When hydrolyzed, glucosinolates liberate D-glucose, sulfate, and an unstable aglycone, which normally converts to isothiocyanate (common name, mustard oil) as the main product.^[2-9,15] Isothiocyanates are responsible for the distinctive, pungent flavor and odor of mustards and horseradish. More than 80 different glucosinolates have been found in the Capparales (families Capparidaceae, Brassicaceae, Resedaceae, Moringaceae, and Tropaeolaceae).

Alkaloids

Alkaloids represent a large and diverse class of SMs with a heterocyclic nitrogen that can react as a base.^[1-9,11-16] Alkaloids have been detected in about 15% of plants, bacteria, fungi, and even animals. Within the plant kingdom, they occur in primitive groups such as *Lycopodium* or *Equisetum*, in gymnosperms, and most abundantly in angiosperms. Alkaloids often exhibit toxicity toward animals and humans. Their main targets are elements of the neuronal signal transduction system.^[13,14] Alkaloids certainly evolved as defense chemicals against herbivores, but also inhibit microorganisms and other plants. In addition, some plants employ them as degradable N-transport and N-storage compounds.^[5]

Secondary Metabolites Without Nitrogen

Over 20,000 nitrogen-free SMs have been described so far. Terpenoids, phenylpropanoids, flavonoids, polyketides, and polyacetylenes, are the main compounds in this group.^[1-9]

Terpenoids

Main terpenoids include monoterpenes (with 10 C atoms), sesquiterpenes (15 C), diterpenes (20 C), triterpenes (30 C), steroids (27 C), tetraterpenes (40 C), and polyterpenes. Although their main building blocks are simple, most terpenes represent complex structures because of various substituents and secondary ring formations.^[1-9]

Mono- and sesquiterpenes are often volatile and can be isolated as essential oils. These compounds are usually lipophilic and are stored in specialized oil cells, trichomes, resin channels, or other dead cells.^[15] They are especially abundant in Asteraceae, Apiaceae, Lamiaceae, Rutaceae, Lauraceae, Cupressaceae, Pinaceae, Myrtaceae, and Zingiberaceae. An intriguing number of complex ring structures can be found in sesquiterpenes. Some of them are highly reactive compounds, such as ptaquiloside in the fern (bracken) *Pteridium aquilinum* or the sesquiterpene lactone helenaline of *Arnica* species, which can alkylate DNA and proteins. Bracken is known to cause bladder cancer in humans and live-stock. Some sesquiterpenes from gymnosperms mimic the insect juvenile growth hormone (a terpenoid with 17 or 18 C). In general, mono- and sesquiterpenes function as chemical defense compounds against herbivores and microbes, but the volatile terpenes also serve to attract pollinating insects.

Among diterpenes we find extremely complex ring structures, some of which, such as phorbol esters of Euphorbiaceae and Thymelaeaceae, are infamous for their toxicity (they activate protein kinase C and can act as tumor promoters). The plant hormone gibberellic acid belongs to the class of diterpenes, as does forskolin, a potent activator of adenyl cyclase. Another diterpene, taxol A (paclitaxel, taxol[®]), can be isolated from several yew species and has been used for almost 10 years with great success in the chemotherapy of various tumors.^[7,13,14]

Triterpenes and steroids can occur as aglycons but more often occur as saponins. Whereas free triterpenes and steroids are lipophilic compounds, the saponins are water soluble and amphiphilic molecules that can make biomembranes leaky. They therefore show characteristics of broad antimicrobial and antiherbivore activity. Saponins are widely distributed in the plant kingdom; approximately 70% of all plants produce them. A special case of steroidal saponins is cardiac glycosides that inhibit Na⁺,K⁺-ATPase and are therefore strong toxins (but are useful in heart medication). Cardiac glycosides can be divided into two classes: cardenolides and bufadienolides.^[1-9] Another class of bioactive steroids is the phytoecdysons, which have been isolated from ferns and several higher plants. They mimic the insect moulting hormone ecdysone and are therefore insecticidal.

Carotinoids represent the most important members of tetraterpenes. Carotinoids are the precursors for vitamin A in animals, used to produce retinal and retinoic acid (retinoids bind to nuclear receptors and are local mediators of vertebrate development).

Polyterpenes, consisting of 100 to 10,000 isoprene units, are prominent in latex of Euphorbiaceae and other families; they are used commercially in rubber (from *Hevea brasiliensis*) or gutta-percha.

Phenolic compounds: Phenylpropanoids, coumarins, flavonoids and tannins

Phenylpropanoids can occur as simple compounds (as phenylacrylic acids, aldehydes, or alcohols) that differ by their degree of hydroxylation and methoxylation. Phenylpropanoids can also be conjugated with a second phenylpropanoid, such as rosmarinic acid (an abundant tannin of Lamiaceae) or with amines, such as coumaroyl-putrescine.^[1–9]

Coumarins and furocoumarins are common in certain genera of the Apiaceae, Fabaceae, and Rutaceae. Furocoumarins with a third furane ring form linear psoralen or angular angelicin types. Furocoumarins can intercalate DNA, and upon illumination with UV light can form cross-links with DNA bases and also with proteins.^[7] They are therefore mutagenic and possibly carcinogenic. In plants they serve as defense compounds against herbivores and pathogens.

Phenylpropanoids can condense with a polyketide moiety to flavonoids, chalcones, catechins, and anthocyanins. These compounds are characterized by two aromatic rings that carry several phenolic hydroxy, methoxy, and sugar groups. Many of the flavonoids, chalcones, and anthocyanins are widely distributed in higher plants and show colors under visual and UV light and are typical SMs of flowers and fruits. The color of anthocyanins depends on the degree of glycosylation, hydrogen ion concentration, and the presence of certain metals (e.g., aluminium ions) in the vacuole. These SMs function to attract pollinating insects or fruit-dispersing animals. The phenolic hydroxyl groups can interact with proteins to form hydrogen and ionic bonds and can therefore interfere with a multitude of molecular targets.

Isoflavones are common SMs in legumes. They exhibit estrogenic properties and inhibit tyrosine kinases. Therefore, they are often regarded as useful compounds that might play a role in the prevention of certain cancers. Such ingredients are called nutraceuticals (in analogy to phytopharmaceuticals). Other isoflavones, such as rotenone, have potent insecticidal properties and have been used as biorational pesticides for plant protection.

Catechins, which often dimerize or even polymerize to procyanidins and oligomeric procyanidins, form a special class of phenolics. These nonhydrolyzable tannins are characterized by a large number of hydroxyl groups that can interact with proteins to form hydrogen, ionic, and possibly even covalent bonds. These compounds serve as defense chemicals against invading pathogens and herbivores. Another important group of tannins comprises esters of gallic acid with sugars. These hydrolyzable gallotannins are widely distributed in plants, often in bark, leaves, fruits, and galls. Gallotannins contain a large

number of phenolic hydroxyl groups, so can form stable protein-tannin complexes and thus interact with a wide variety of protein targets in microbes and animals.^[1,5,7]

Polyketides

Important polyketides are anthraquinones, quinones, and flavonoids. SMs with an anthracene skeleton can be present as anthrones, anthraquinones, anthranols, dianthrones, naphthodianthrones, dianthranols, and corresponding mono- or diglycosides.^[1–9] Anthracene derivatives are common in certain genera of the Polygonaceae, Rhamnaceae, Fabaceae, Rubiaceae, Hypericaceae, and Aloes.

Glycosylated monomeric anthrones exhibit a strong laxative activity in vertebrates and can be regarded as potent defense chemicals. They have also been used in medicine as laxatives for several thousand years.

Carbohydrates

Several carbohydrates (such as glucose, galactose, or fructose) form glycosides with SMs and are thus participants in both primary and secondary metabolism.^[1–9] Other carbohydrates appear to be allelochemicals in their own right: An example is phytic acid (a myoinositol esterified with up to six phosphate groups) that can complex Ca^{++} and Mg^{++} ions and thus functions as an antinutritive substance. Several di-, tri-, and oligosaccharides—such as stachyose and raffinose, typically found in seeds and roots—produce substantial flatulence in herbivores and thus come closer to typical SMs in being regarded as defense compounds against herbivores.

CONCLUSION

SMs show an impressive structural diversity that can be understood from an ecological and evolutionary perspective. Many SMs have evolved as bioactive compounds that interfere with nucleic acids or proteins (known as evolutionary molecular modelling) and show antimicrobial or insecticidal and pharmacological properties. SMs are therefore of interest in medicine as therapeutics and in agriculture as biorational pesticides. Several SMs have antioxidative, radical scavenging, or estrogenic properties; food and crops containing these nutraceuticals will play an increasingly important role in nutrition.^[6,7]

Many crop and food plants originally produced SMs before domestication. During plant breeding, many of the traits leading to SMs have been eliminated because

corresponding SMs were toxic, bitter, or unpalatable.^[5] Unfortunately, this strategy also removed the natural resistance of many cultivars with the consequence that human-made synthetic plant protectives must replace the natural defense compounds formerly present.

In light of the novel strategies of genetic engineering and food processing, SMs should not be regarded as useless compounds. On the contrary, SMs represent valuable traits that might be used to improve viability, resistance, and the nutritional quality of crop and food plants.

Phytochrome and Cryptochrome Functions in Crop Plants

Jim Weller

University of Tasmania, Hobart, Tasmania, Australia

INTRODUCTION

Light has profound effects on plant development. Variation in the quality and irradiance of light can influence processes throughout the plant life-cycle, including seed germination, stem elongation, leaf expansion, bud dormancy, synthesis of photosynthetic and photoprotective pigments, and the initiation of flowering. Light is perceived and its developmental effects mediated by two important families of photoreceptor proteins: the phytochromes, which predominantly absorb red (R) and far-red light (FR), and the cryptochromes, which primarily absorb blue light (B). Most recent progress in understanding the roles of these photoreceptors in plant development has come from studies in *Arabidopsis thaliana*, although phytochrome and cryptochrome functions are also being explored by a genetic approach in other model species including tomato, pea, and rice. In most cases, photoreceptor functions in these species have been found to be broadly consistent with their roles in *Arabidopsis*. However, the fact that these species differ in growth habit, physiology, and photoreceptor complement means that they offer a broader perspective on photoreceptor function and how genes controlling photoreceptor function might be useful for modifying specific traits in a diverse range of crop plants.

PHOTORECEPTOR GENE FAMILIES

The phytochrome and cryptochrome photoreceptors are encoded by small gene families in most species so far examined. The full extent of these gene families is known in only a few species, but even so it is clear that they can be somewhat variable in size. For example, different lineages within the phytochrome and cryptochrome families may have undergone independent duplications. The best illustration of this is the existence of phyB-type gene pairs in *Arabidopsis* (phyB and phyD) and tomato (phyB1 and phyB2), where members of each pair are more closely related to each other than to either of the corresponding genes from the other species.^[1] There is also evidence for recent duplications within the crypto-

chrome gene family. Whereas *Arabidopsis* has only two cryptochromes (cry1 and cry2), both tomato and barley have three expressed *CRY* genes, including two *CRY1*-like genes.^[2] It is likely that as more species are examined more such instances will be identified. A substantial difference in phytochrome gene complement is also seen in monocots. In contrast to the five found in *Arabidopsis*, rice and sorghum have only three phytochromes, corresponding to phyA, phyB, and phyC lineages, suggesting that monocots may not have undergone the expansion within the phyB lineage that is seen in dicots.

Despite the differences in photoreceptor gene complement, the basic features of specific photoreceptors seem to be generally conserved. For example, where examined, phyB-type phytochromes have generally been found to be relatively stable, whereas phytochrome A is degraded in the light and *PHYA* expression is strongly down-regulated.

STUDYING BASIC PHOTORECEPTOR FUNCTIONS IN CROP PLANTS

Photoreceptor functions in a wide range of crop species have been studied for many years by means of indirect physiological approaches involving irradiation with monochromatic light. However, direct information about photoreceptor functions relies on the use of mutants or transgenic lines with altered photoreceptor levels. Table 1 lists the photoreceptor mutants that have been isolated in *Arabidopsis* and a range of other higher plant species. In general, far less is presently known about cryptochrome function than about phytochrome function, and whereas many phytochrome-deficient mutants are known in crop species, the only known cryptochrome mutant is the *cry1* mutant of tomato.

De-etiolation

As germinating seedlings emerge from the soil, or after dark-grown seedlings are transferred to white light, they display a developmental response called de-etiolation, which includes the co-ordinated inhibition of hypocotyl/

Table 1 Photoreceptor mutants in higher plants

cucumber		<i>lh</i>				

epicotyl/coleoptile elongation, promotion of leaf expansion, and synthesis of chlorophyll and anthocyanin. The basic features of photoreceptor function appear relatively well conserved between *Arabidopsis* and other species that have been examined to date. Analyses of photoreceptor mutants in tomato and pea have shown that phyA is the only receptor mediating de-etiolation responses to the light in the FR region of the spectrum. PhyA is present at high level in dark-grown seedlings and can mediate de-etiolation responses to low irradiance R and B. As a result it is important during the initial phase of the dark-to-light transition. Under high irradiances, the level and influence of phyA decline rapidly, and phyB and cry1 become the predominant photoreceptors, mediating responses to R and B, respectively.^[3,4] A deficiency in either one of these photoreceptors enhances elongation growth and impairs leaf development. This may be quite dramatic (e.g., *lh* in cucumber, *ein* in Brassica) or relatively mild (e.g., *phyB1* in tomato). The difference may have to do with the existence in some species of multiple phyB with overlapping functions.

In contrast, phyA deficiency has little overall effect on seedling morphology in pea, tomato, or rice grown under high irradiance white light, presumably because the effects of phyA are masked by phyB and cry1 under these conditions. However, in the absence of these photoreceptors or under low irradiances of light, a clear phenotype for *phyA* mutants does become evident. The relative contribution of phyA to de-etiolation also differs in different species. In tomato, phyA has a small role in R regardless of which other photoreceptors are present, but in pea, it plays a substantial role in the absence of phyB.^[3,4] This may be related to differences in stability of the phyA protein. Also, phyA can interfere with phyB function, an interaction best illustrated in tomato, where

phyA mutants show a phyB-dependent enhancement of anthocyanin synthesis under R and W.^[5]

Shade-Avoidance

Growth of fully de-etiolated plants is also significantly affected by light, in particular by the amount of light and the proportion of FR, in a syndrome termed the shade-avoidance response. In terms of photoreceptor function, the shade-avoidance response actually consists of two distinct photoresponses. PhyB-type phytochromes induce leaf expansion and inhibit stem elongation in response to R. FR activates phyA to induce a similar set of responses, but inactivates phyB phytochromes by converting them to their Pr form. Most phyB mutants thus show a partial shade-avoiding phenotype. Like the seedling response to R, strength of this phenotype varies with species, possibly depending on the number of phyB-like phytochromes present. For example, the *phyA phyB1 phyB2* triple mutant of tomato shows a strong shade-avoidance response, whereas in pea, the *phyA phyB* double mutant is completely unresponsive.^[4,5] The activity of phyA may also be an important factor determining the overall strength of the shade-avoidance response in any given species. For example, tomato has a strong shade-avoidance response that is not much influenced by the loss of phyA. In contrast, pea shows a weak shade-avoidance response that is dramatically enhanced in plants lacking phyA.^[4,5] This interference of phyA with shade-avoidance has also been examined with a view to practical applications. Studies in several species have shown that elevated levels of phyA can enhance the response to the FR present in canopy shade, thus suppressing the shade-avoidance response and even causing proximity dependent dwarfing.^[6]

Flowering and Photoperiodism

The tendency to flower early is often seen as part of the shade-avoidance syndrome. Consistent with the important role for phyB-type phytochromes in shade-avoidance responses, phyB-deficient plants in several species show early flowering. The early-flowering phenotype of phyB-deficient plants is seen under both long and short photoperiod conditions, and in both short-day plants (SDP; e.g., sorghum, rice) and long-day plants (LDP; e.g., *Arabidopsis*, pea). For this reason phyB is not thought to be involved with detection of daylength as such. Instead, the primary function of phyB-type phytochromes may be to detect noncompetitive conditions (high R:FR ratio) and delay flowering. As the FR content increases, these phytochromes are inactivated and plants flower early as a result. One exception is seen in *Nicotiana plumbaginifolia*, in which flowering is promoted by low R:FR, but is delayed in the phyB-deficient *hlg* mutant.^[7] In tomato, *phyB* mutations have little effect on flowering, although it is not clear whether this is due to the compensating action of another phytochrome or the possibility that flowering is not responsive to R:FR in this species.

In contrast to phyB, a clear role for phyA has been identified only in LDP. In rice, the only SDP for which *phyA* mutants have been isolated, the loss of phyA does not have any discernable effect on flowering, suggesting that it may not be important for flowering or photoperiodic responses in SDP.^[8] In the LDP pea, *phyA* deficient mutants are late flowering in LD, and show pleiotropic characteristics of plants grown in SD.^[9] Delayed flowering is also seen in *phyA* mutants of *Arabidopsis* under some long day conditions. PhyA thus appears to have an important role in the promotion of flowering in response to day extensions, and thus acts antagonistically to phyB. Transgenic potato plants with reduced phyA levels failed to inhibit tuberization under long photoperiods,^[10] whereas transgenic aspen overexpressing phyA failed to enter dormancy under short photoperiods.^[11] Taken together, these results suggest that the level of phyA may determine the critical day length for long-day responses and that phyA acts to promote the transition from growth strategies appropriate to winter (slow vegetative growth, production of vegetative storage organs, dormancy) to those appropriate for summer (rapid vegetative growth and induction of flowering).

Other Responses

There are many other documented responses to light in crop plants that have yet to be investigated from a genetic perspective. Phytochrome has a well known role in germination of many small-seeded species, and there is some limited genetic evidence for the role of phytochromes in tomato seed germination,^[12] but pea and rice

are large-seeded and show no substantial light effects on germination. There is also evidence from tomato that phytochrome regulates competence for shoot regeneration and specific aspects of fruit ripening.^[13,14] Apical dominance is another trait that is clearly modified by photoreceptor action. Activation of the shade-avoidance response results in greater elongation growth and reduced branching or tillering.^[15] In contrast, phyA in pea acts to suppress lateral branching, although this can be explained through its effects on the photoperiodic response.^[9] In addition, both phyA- and phyB-type phytochromes are likely to influence many other important traits and processes that are responsive to photoperiod, including root development, tuberization, fruit set and development, and partitioning of dry matter between stem and leaf.

CONCLUSION

It is clear that the phytochrome and cryptochrome photoreceptors affect several different responses of applied interest. Modification of photoreceptor activity, either through classical breeding or transgenic manipulation, may offer some prospects for improvement of specific light-responsive traits. A better understanding of light responses may help to modify seedling growth in dense propagation systems, through selection and development of light sources and transparent sheeting materials used in glasshouses and growth. Selection strategies including a consideration of shade-avoidance responses may lead to improved harvest index, increased growth of storage organs, and reduced lodging, features which may in turn allow higher cropping densities and more efficient harvesting. Conversely, in some fiber crops constitutive shade-avoidance may have desirable effects on fiber properties. Modification of photoreceptor activity may help to control photoperiod responsiveness, making it possible to accelerate, delay, or prevent flowering and bolting, and help in the development of crop varieties better suited to a given location or cropping regime. Fruit-specific regulation of photoreceptor activity may provide a means to modify fruit properties. There is no doubt that continuing to expand our knowledge of photoreceptor functions in a broader range of crop plants will offer further useful insights and applications.

Phytoremediation

Clayton L. Rugh

Michigan State University, East Lansing, Michigan, U.S.A.

INTRODUCTION

Phytoremediation is defined as the use of plants for degradation, removal, and detoxification of chemical pollutants from contaminated soils, sediments, or waters. Phytoremediation is considered a subcategory of bioremediation, or the use of biological organisms, processes, or products for environmental detoxification and typically implies microbes, such as bacteria and fungi. The term phytoremediation is formed from the Greek “*phyton*”, for “plant” and the Latin “*remedium*” for “to heal again.” Phytotechnologies have garnered increasing scientific and commercial interest as a more environmentally compatible and less expensive method of site remediation relative to engineering-based methods, such as excavation, soil washing, or soil incineration. Planted systems may provide numerous accessory functions in addition to contaminant removal such as pollutant containment via high-volume water use and erosion mitigation by soil and sediment stabilization against wind and rain. Important ecological benefits of phytoremediation include soil enrichment with root-released materials and decomposed plant litter, soil aeration, and micro- and macrofauna habitat development. Agricultural-scale costs of phytoremediation may be considerably less expensive than intensively engineered approaches. The reduced cost and ecologically restorative qualities of phytoremediation have advanced this technology as a viable and attractive option for environmental cleanup. The majority of phytoremediation laboratory research and field application has occurred with naturally occurring plants upon empirical discovery of their exceptional abilities for such applications. This has led to a growing body of scientific literature and wider acceptance for plants in many aspects of environmental rehabilitation. Further characterization of plant physiological, biochemical, and molecular genetic mechanisms in response to target contaminants is critical for optimization and advancement of the field of phytoremediation. Subsequently, biotechnological plant improvement is being pursued to enhance the utility of plants as an aggressive and effective method of environmental decontamination.

PHYTOREMEDIATION TECHNOLOGIES

Laboratory and greenhouse experimentation have given rise to phytoremediation treatment methodologies for a wide range of environmental contaminants, including heavy metals, petroleum and its manufacturing byproducts, solvents and degreasers; agricultural chemicals such as fertilizers, pesticides and herbicides, explosives, and radioisotopes. The general field of phytoremediation is subclassified into more specific areas of application, dependent upon the contaminant chemical class and treatment site conditions. Phytoextraction describes the use of metal-tolerant plants, or hyperaccumulators, to acquire elevated levels of inorganic contaminants in their aboveground tissues with subsequent harvest, recovery and disposal or recycling of the metals. Phytodegradation is the use of plants capable of enzymatic breakdown of organic, or carbon-containing, compounds to simpler and less toxic chemicals either alone or in combination with soil microbes, the latter process also known as phytostimulation or rhizosphere-assisted bioremediation. Phytostabilization refers to the use of plants to immobilize contaminants within the soil profile to minimize pollutant escape or biological exposure. Rhizofiltration describes the use of plant root systems to intercept or degrade waterborne contaminants.

Phytoextraction

The initial proposal for the use of plants as an applied technology for the treatment of polluted habitats grew out of the discovery of plants that could grow on metal-rich, nutrient poor soils and “hyperaccumulate” elevated levels of these otherwise toxic metals in their leaves and stems. In their native habitats, these metal hyperaccumulating plants had been utilized by local indigenous populations as indicators of useful metal deposits. Researchers proposed that these species could be used to revegetate mining- or smelter-impacted, barren soils with subsequent soil regeneration by plant extraction and harvest of the toxic metal pollutants.^[1] In addition to beneficial minerals, other plant species have been observed to accumulate elevated levels of nonnutrient,

Fig. 1 Experimental phytoremediation installation 1 year after planting at an industrial brownfield site impacted with polyaromatic hydrocarbons (PAHs) (taken August 2003). Approximately 20,000 regional native plants of 22 species are planted in 12 separate plots (each 40 × 90 ft) with distinct plant combinations and habitats (e.g., upland or wetland). The installation covers a 1.6-acre area and will be monitored for 3–5 years for in situ treatment of nearly 4100 cubic yards of contaminated soil in addition to the study of plant community dynamics during the site restoration process.

hazardous elements such as thallium, cadmium, and arsenic. To accelerate the phytoextraction process, chemical amendments such as synthetic chelators, e.g., ethylene diaminetetraacetic acid (EDTA), or weak acids, e.g., citrate, have been used to enhance soil-pollutant desorption and plant uptake rates. Hyperaccumulating species are being intensively researched for better understanding of their physiological and biochemical mechanisms to allow optimization and genetic engineering of these novel processes in larger biomass, agronomically compatible crops.

Phytodegradation

Plants have been demonstrated to enzymatically degrade a variety of carbon-based, or organic, pollutants, including the degreaser solvent trichlorethylene (TCE) and explosive chemicals, such as trinitrotoluene (TNT).^[2] Phytodegradation of organic pollutants may occur by secretion of enzymes into the surrounding soil matrix or uptake and metabolism within root cells or in aerial plant tissues. Contaminant uptake may be limited to relatively hydrophilic chemicals, with an octanol–water partitioning coefficient ($\log K_{ow}$) less than 3. In addition to breakdown of water-soluble pollutants, large biomass plants, partic-

ularly trees, can contain the contaminants within or extract them from the rhizosphere during periods of intensive water uptake and transpiration.

Phytostimulation

For most organic pollutant phytoremediation, soil microbes are expected to play a significant and possibly essential role for effective contaminant degradation. Phytostimulation describes the reciprocal benefits achieved for pollutant biodegradation in planted soils, where plant roots supply nutrients, enzymes, and aeration, and microbes, including fungi and bacteria, contribute enhanced soil colonization and complementary metabolic capabilities. Vegetated soils have been demonstrated to possess greater numbers of total bacteria and faster rates of pollution reduction than unplanted treatments.^[3] Microbial co-metabolism may be most critical for degradation of strongly hydrophobic pollutants that are not readily accumulated into plant roots, such as polychlorinated biphenyls (PCBs). In addition, bacterial species capable of biodegrading PCB were observed to be preferentially enriched in the rhizosphere of certain plant species.^[4] As observed for metal phytoremediation, plant species selection is important for effective phytostimulation of rhizosphere-mediated biodegradation of organic contaminants (Fig. 1).

Phytostabilization

This approach is the opposite of phytoextraction, in that vegetation is utilized primarily as a mechanism to immobilize heavy metal pollutants in the rooted soil profile. Phytostabilization may be suitable for situations where the primary hazard is wind or storm water discharge of the contaminants and engineering approaches such as excavation or solidification are considered excessively disruptive or impractical. Heavy metal contaminants can be effectively immobilized by combined use of metal tolerant, vegetated groundcover and soil amendments, such as organic composts or adsorptive minerals.^[5] Phytostabilization may be implemented as a temporary or long-term solution depending upon the level and type of contamination and site proximity to sensitive natural resources or populations. For long-term applications, it is effective to use perennial species that are acclimated to the site to avoid displacement of the essential plant community with subsequent site destabilization.

Rhizofiltration

This technology utilizes the highly reactive and extensive surface area of plant root systems when grown in aqueous

or hydroponics conditions. Rhizofiltration has been demonstrated as an effective approach to extract and concentrate a wide variety of metals, including lead, cadmium, and chromium, from wastewater streams.^[6] This method has been utilized as an effective treatment for both industrial waste effluents and field-scale constructed wetland applications.

LIMITS TO PHYTOREMEDIATION

Phytoremediation is restricted by the natural capabilities for plant growth and development, which include limited rooting depth, discontinuous growing season, and failure under extreme environmental conditions. In contrast, engineering-based technologies are capable of extracting pollutants from great subterranean depths, can operate year round, and in virtually any climatic circumstance. The relatively brief history of phytoremediation causes most field applications to remain largely experimental endeavors requiring careful monitoring, in-process optimization and management, and the possibility of failure to achieve target cleanup goals. To allow the required treatment period for most phytosystems (~3–10 seasons), the site must not possess contaminant levels of acute hazard to neighboring communities or resources, which would dictate more immediate cleanup technologies. In addition, extremely high levels of most pollutants are not typically treatable by biological methods, because of toxicity and/or insufficient rates of removal or degradation. Phytoremediation is an effective option for situations when contaminants are limited to standard rooting depth (~0–3 m) or if the material can be mechanically extracted and applied to a planted treatment facility. Mixed wastes, e.g., heavy metal and organic contaminants, may not be suitable for phytoremediation, as plants are rarely tolerant or capable of concurrent treatment of dissimilar chemical classes. In addition, there remain numerous chemical pollutants that are not effectively treated using currently available phytoremediation technologies.

CONCLUSION

Phytoremediation has gained great favor among concerned citizen groups and government regulators as a more affordable and less destructive method of pollution removal relative to intensely engineered technologies. These stakeholder groups have helped to drive field-scale implementation of phytoremediation treatments to allow further evaluation and development of this approach as a

more commonly utilized tool for environmental remediation. The range and reproducibility of phytotechnologies will be improved with additional study and refinement of such field trials. For a wide array of pollutants, phytoremediation is an ecologically compatible, cost-effective alternative, or complementary option for standard engineered approaches. Extensive efforts are ongoing to extend the range of biological capabilities and technical application of phytoremediation systems.

Researchers have used biotechnological strategies to either enhance existing traits or confer novel capabilities to plants through genetic engineering. Biotechnological improvement of plants for phytoremediation was first described by transfer of bacterial mercury detoxification genes to plants with subsequent enhanced ability of the engineered plant species to extract and degrade hazardous mercury compounds, a capability not found in naturally occurring plants.^[7] Since this report, numerous laboratories have advanced the understanding of molecular genetic mechanisms and successful implementation of biotechnological improvement of plants for environmental detoxification.^[8] Phytoremediation will continue to grow as an effective remedial technology with further development of well-documented field trials and exploitation of powerful biotechnological approaches for enhancement of plant utility against more complex environmental hazards.

Phytoremediation: Advances Toward a New Cleanup Technology

Adel Zayed

Paradigm Genetics, Inc., RTP, North Carolina, U.S.A.

INTRODUCTION

Decades of unrestricted use, disposal, and release of industrial-, defense-, and energy production-related chemicals have considerably accelerated the pollution of our environment with radionuclides, toxic metals, and organic pollutants. Environmental exposure to such toxic chemicals is a serious health risk for humans and animals. Unfortunately, existing technologies for the cleanup of contaminated environments are very costly and/or limited in various ways. Cleanup of toxic metal contaminated soils with existing technologies costs up to \$1,000,000 per acre without totally removing the pollutant from the environment. In the United States alone, the cost of cleaning up sites contaminated with toxic and radioactive metals is estimated to be \$400 billion.

Phytoremediation, the process by which various naturally occurring or genetically modified plants, including trees and grasses, are used to degrade, extract, detoxify, contain, and/or immobilize toxic pollutants from contaminated soil, water, and air, offers an attractive and cost-effective solution for the clean up of contaminated sites. The potential economic benefits of using plants for remediation are impressive. Growing a crop on an acre of land can be accomplished at a cost ranging from two to four orders of magnitude less than the current engineering cost of excavation and reburial. Plants provide a robust, solar-powered system that has little or no maintenance requirements. With their copious root systems, plants can scavenge large areas and volumes of soils, removing the toxic chemical. The rhizosphere soil (soil near plant roots) has microbial populations orders of magnitude greater than bulk soil (nonroot soil). Furthermore, plant-based systems are welcomed by the public due to their superior aesthetics and the societal and environmental benefits that their presence provides. There are several different ways that phytoremediation can be achieved (Table 1).

Research into phytoremediation may offer the remediation solution for at least 30,000 contaminated sites in the United States alone. Phytoremediation is applicable to a number of hazardous waste and other remedial scenarios, including remediation of metals, organics, and radionuclides from soils and water, which together offer a total

U.S. market opportunity of up to \$10 billion. Phytoremediation is also potentially applicable to all types of water treatments including industrial, agricultural, and municipal wastewaters, landfill leachate, stormwater, and drinking water with a potential market opportunity of up to \$40.7 billion (Table 2). Similar markets exist overseas, which are smaller but which offer greater long-term potential for growth.

TRANSGENIC PHYTOREMEDIATION APPROACHES

The ideal plant species for phytoremediation is one that can accumulate, degrade, or detoxify large amounts of the toxic chemical, grow rapidly on contaminated sites and produce a large biomass, tolerate salinity and other toxic conditions, and provide a yield of economic value, e.g., fibers. Metal hyperaccumulator plants occur naturally on metal-rich soils and accumulate metals in their above-ground tissues to concentrations between one and three orders of magnitude higher than surrounding "normal" plants grown at the same site.^[1,2] Unfortunately, most hyperaccumulator plants studied to date grow very slowly and accumulate little biomass. For phytoremediation to become a viable technology, dramatic improvements would be required in either hyperaccumulator biomass yield or nonaccumulator metal accumulation. The introduction of novel traits into high biomass or hyperaccumulator plants in a transgenic approach is a promising strategy for the development of effective phytoremediation technologies.

There are several conceivable strategies for the use of genetic engineering to improve phytoremediation. Strategies to improve metal phytoremediation involve the optimization of a number of processes, including trace element mobilization in the soil, uptake into the root, detoxification, and translocation within the plant.^[3] Strategies for enhancing phytoremediation of organics are potentially more straightforward and involve the introduction and/or overexpression of genes encoding biodegradative enzymes in transgenic plants to enhance their biodegradative abilities.^[4] In the last few years, progress has been made toward this goal and several types of

Table 1 Summary of phytoremediation processes and their definitions

Process	Definition	Contaminated substrate	Target contaminant
Phytoextraction	Use of plants to take up contaminants from soil and water and accumulate them in aboveground plant tissues, which may then be harvested and removed from the site.	Soils Sediments Sludges Wastewater	Toxic trace elements Radionuclides
Phytostabilization	Use of plants to immobilize contaminants chemically and physically at the site, thereby preventing their movement to surrounding areas.	Soils Sediments Sludges	Heavy metals
Phytovolatilization	Use of plants and their associated microbes to remove contaminants, e.g., Se and Hg, from the environment in volatile forms.	Soils Sediments Sludges Industrial wastewater Agricultural wastewater	Metalloids (e.g., Se, Hg) Chlorinated solvents
Phytodetoxification	Use of plants to change the chemical species of the contaminant to a less toxic form.	Soils Sediments Sludges Industrial wastewater Agricultural wastewater	Chromium Organic compounds Explosives Pesticides
Rhizofiltration	Use of plant roots to absorb and adsorb pollutants from water and aqueous streams.	Surface water Industrial wastewater Agricultural wastewater Acid-mine drainage	Water soluble organics Heavy metals

genetic modifications of plants for phytoremediation have been reported. For example, bacterial genes were transferred to plants to enhance their potentials for 1) phytovolatilization (e.g., transfer of *merA* and *merB* genes from bacteria into three different plant species to increase their tolerance to and volatilization of the toxic mercuric ion after its transformation into the much less toxic elemental mercury); 2) phytoextraction (e.g., transfer of *gsh1* and *gsh2* genes from *Escherichia coli* to *Brassica juncea* plants to increase Cd accumulation in shoots); and 3) detoxification (e.g., transfer of bacterial genes for removal of nitroso groups from explosive compounds into plants to detoxify trinitrotoluene, TNT). Another approach was to express mammalian genes in plants, e.g., genes encoding cytochrome P450 2E1, the liver enzyme responsible for activating trichloroethylene (TCE), resulting in an increase in TCE oxidation by two orders of magnitude. A more straightforward approach is to overexpress existing plant genes that control key-limiting processes in order to overcome these limitations and accelerate the phytoremediation process (e.g., overexpression of AtAPS1 in *B. juncea* resulted in twofold increase in selenium accumulation and the overexpression of NtCBP4 in *Nicotiana*

tabacum resulted in 2.5-fold increase in Ni tolerance and two-fold increase in Pb accumulation).^[5] These examples provide dramatic evidence of the potential of genetically engineered plants for bringing the promise of phytoremediation to fruition.

THE PHYTOREMEDIATION GENOME/PROTEOME

The vast majority of plant genes affecting the remediation of toxic elements and organics have not yet been identified. Identification of these genes is vital to the success of the transgenic phytoremediation approaches. The recent completion of the *Arabidopsis* genome sequencing project has paved the way for the development of high throughput functional genomic approaches to accelerate the determination of gene function.^[6] It is estimated that the *Arabidopsis* genome contains 80–90% of all the phytoremediation genes and gene families found in any macrophytes that could be used in phytoremediation applications.^[4] The *Arabidopsis* genome is estimated to have 25,500 genes in 11,000 gene families.^[4] Approximately

Table 2 Summary of the size of potential U.S. markets for phytoremediation

Market sector	Annual U.S. potential market
Metals from soils	\$1.2–1.4 billion
Metals from groundwater	\$1.2–1.4 billion
Organics from soils	\$2.3–2.6 billion
Organics from groundwater	\$2.3–2.6 billion
Radionuclides (all media)	\$1.5–2.0 billion
Industrial wastewater	\$7.0–10.0 billion
Municipal wastewater	\$18–28 billion
Landfill leachate control	\$0.6–1.2 billion
Agricultural runoff	\$0.4–0.5 billion
Stormwater management	\$0.2–1.0 billion
Treatment of drinking water	\$0.6–1.0 billion
<i>Total</i>	<i>\$35.3–51.7 billion</i>

From Ref. 2.

5% of the genome appears to encode membrane transport proteins responsible for the transport of metals and ions across plant plasma and organellar membranes.^[7] These proteins are classified in 46 unique families containing approximately 880 members. In addition, several hundred putative transporters have not yet been assigned to families. Only a small number of these transporter proteins have their function fully characterized. The vast majority, however, have no known or presumed function, and genetic and physiological analyses will be needed to determine their functions and their relative contributions to toxic metal uptake and transport in plants.^[4,7]

An analysis of the *Arabidopsis* genome using the amino acid sequences of proteins with known roles in remediation suggests that approximately 700 genes encode phytoremediation-related proteins (PRP). This portion of the *Arabidopsis* proteome has been termed the phytoremediation proteome and it consists of approximately 450 enzymes catalyzing redox reactions (e.g., cytochrome P-450s, oxygenases, and dehalogenases), approximately 250 transport proteins, and several metal-binding proteins, e.g., metallothioneins. The availability of the *Arabidopsis* genome and EST sequences and the identification of the phytoremediation proteome provide enormous opportunities to accelerate greatly our effort to clean up environmental pollution.^[4]

PHYTOREMEDIATION IN CONSTRUCTED WETLANDS

Constructed wetlands represent a cost-effective phytoremediation solution for the cleanup of large volumes of wastewaters contaminated with low levels of toxic trace

elements. They offer an efficient alternative to conventional water treatment systems because they are 1) relatively inexpensive to construct and operate, 2) easy to maintain, 3) effective and reliable wastewater treatment systems, 4) tolerant of fluctuating hydrologic and contaminant loading rates, and 5) providers of green space, wildlife habitat, and recreational and educational areas. In addition, ecosystems dominated by aquatic macrophytes are among the most productive in the world, largely as a result of ample light, water, nutrients, and the presence of plants that have developed morphological and biochemical adaptations enabling them to take advantage of these optimum conditions. Furthermore, these ecosystems are highly rich in microbial activities and therefore have high capacities to decompose organic matter and stabilize toxic trace elements. Constructed wetlands have been used for many years with great success to remove conventional pollutants (e.g., nitrate and phosphorus) from agricultural nutrient-laden runoff, drinking water, and domestic wastewater. Recently, there has been increasing interest in using constructed wetlands for the treatment of industrial wastewaters and acid-mine drainage containing heavy metals and toxic trace elements. A recent study demonstrated the successful use of wetlands in this area where a 36-ha constructed wetland removed 90% of the toxic selenium from 10 million liters/day of selenite-contaminated oil refinery effluent.^[8] Constructed wetlands remove metals primarily through immobilization of the sulfide for Cu, Fe, Mn, Zn, and Cd. Sulfides of most metals are very stable under the anoxic waterlogged conditions of the wetlands.^[9] In the case of metalloids such as Se, the soluble ions are taken up by plants and volatilized as a less toxic gas. Less is known about the use of constructed wetlands for the removal of toxic organics or pesticides although recent studies indicate that wetlands efficiently remove some chlorinated compounds present at low levels that are difficult to remove by other means.^[9] A significant amount of research is currently underway to determine the best wetland plant species, including algae and vascular plants, that can be used to maximize pollutant removal by wetlands.^[10]

FUTURE PROSPECTS

New uses of plants are emerging as a result of the recent advances in agricultural biotechnology. Phytoremediation is one of these new uses that has been extensively and effectively tested in the cleanup of real contamination sites and is becoming commercially feasible. The technology is currently being adopted and promoted by several government agencies (e.g., U.S. Environmental Protection Agency), and field demonstration projects are currently underway in many "superfund" sites across the

country.^[3] However, the existing knowledge about the rate and extent of degradation or extraction of pollutants by the phytoremediating crop is still limited, and specific data are needed on more plants, contaminants, and climate conditions. Additional progress in phytoremediation is likely to come from utilizing the recent genomic information to create new “superplants” overexpressing genes responsible for the removal, degradation, and/or sequestration of various contaminants. Further optimization of in-field performance of phytoremediation will require improvements in a number of agronomic practices, ranging from traditional crop management techniques to approaches more specific to phytoremediation, such as amendment of soil with chelators.

Pierce's Disease and Others Caused by *Xylella fastidiosa*

John S. Hartung

USDA—ARS, Beltsville, Maryland, U.S.A.

INTRODUCTION

In the past decade, *Xylella fastidiosa* Wells et al. has become one of the world's most important plant pathogens, causing devastating diseases of grapevine, sweet orange, coffee, almond, peach, plum, several shade trees, and oleander. The Gram-negative bacterium was formally named only in 1987, and is characterized by being nutritionally fastidious and extremely slow-growing in culture. These traits have made the pathogen difficult to study, and have contributed to its previous obscurity. Pierce's disease (PD) of grapevine, (*Vitis vinifera* L.), caused by *X. fastidiosa* has recently reemerged as a major problem for the California grape industry because of the introduction of a new insect vector.

The Spanish introduced the European grapevine into southern California early in the 18th century, where it became the basis for an important industry. In 1884, the "Mission" grapevines in Anaheim suddenly began to die rapidly. The United States Department of Agriculture dispatched Mr. Newton B. Pierce to investigate and report on the disease in 1889. Pierce reported that this previously undescribed vine disease resulted from blockage of the water-carrying vessels in diseased plants. Pierce was unable to culture a pathogen from diseased plants, and he reported the novel observation of growers that grafting contaminated buds onto healthy vines could transmit the disease. He also noted that unlike the susceptible, higher-value European varieties, the North American grape varieties were tolerant or resistant to the disease.

SYMPTOMS

The initial symptom of PD is a leaf scorch that begins at the outer margins of the lower leaves, then progresses inward on the leaves and upward along the vine. Eventually the affected leaves fall, beginning at the bottom of the vine, but the petioles remain attached. Irregular "green islands" remain on the stem where the bark fails to mature properly. Fruit dries on the vine, and in susceptible varieties the disease leads to rapid vine death.^[1]

DISEASE EPIDEMIOLOGY AND IMPORTANCE TO VITICULTURE

In the absence of a bacterium or fungus, PD was logically, though incorrectly, attributed to a virus for nearly a century. Early workers established important facts about the disease. First, the "PD virus" was shown to have an extraordinary range of plant hosts in California. This included 36 species belonging to 18 families that were naturally infected, and 75 species from 23 families that could be experimentally infected by insects.^[2] However, the majority of hosts were symptomless carriers. The transmission of the pathogen by 20 insect species^[3] was taken as further evidence that the pathogen was a virus, since insect transmission is typical of viral plant diseases. Leafhopper insect vectors (family Cicadellidae) feed exclusively in the plant xylem, consistent with Pierce's initial observation that the primary pathology was a dysfunction of the xylem. The extraordinary range of hosts and vectors make PD exceptionally difficult to control.

PD is endemic throughout North America where grapevines are grown in areas without a cold winter. There is evidence that temperatures below 10°C reduce *X. fastidiosa* populations, while freezing temperatures help grapevines recover from infection. Cold winters prevent the pathogen from overwintering in adult insect vectors, since they are killed by cold temperatures. It is believed that PD originated in the southeastern United States, and was introduced into California with native grape species that were being evaluated for resistance to *Phylloxera* root weevils. Similar shipments of North American grape species were sent to Europe in the same era for the same purpose, but PD did not become established there.

The introduction of PD to California in 1884 caused the failure of the grape industry in the Los Angeles basin. The industry in northern California has suffered only intermittent severe PD outbreaks during the past century. Growers in the southeastern United States have never been able to grow *V. vinifera*, because PD has killed every attempted vineyard. The southeastern United States is the home of the glassy-winged sharpshooter, *Homalodisca coagulata* Say, the most effective insect vector for the bacterium. This vector is so effective because it overwinters

as infective adults, allowing it to transmit the bacterium in early spring. This insect also feeds on mature wood, resulting in systemic infections. Introduced into California in the early 1990s, this insect has become established in at least nine counties, where it threatens the \$30 billion grape industry.

DETECTION, IDENTIFICATION, AND CONTROL

X. fastidiosa can be detected and identified by serological methods as well as by the polymerase chain reaction. The bacterium can also be cultured *in vitro*,^[4] but this takes several weeks. PD, like other diseases caused by *X. fastidiosa*, is difficult to control. Because the pathogen lives deep inside woody tissue, it is not affected by externally applied pesticides. Pruning of vines at the first sign of infection has provided some control in northern California, but will likely fail in the presence of the glassy-winged sharpshooter. Insecticides may be used to kill vectors, but they interfere with the long-term suppression of the vectors by other insects. PD management relies on planting *X. fastidiosa*-free grapevines, frequent monitoring of the vineyards, and removal of diseased vines before they can serve as inoculum sources. No useful levels of resistance have been found in varieties of wine grapes or in their rootstocks.

OTHER DISEASES CAUSED BY *Xylella fastidiosa*

Strains of *X. fastidiosa* cause important diseases of a wide range of perennial horticultural plants in North America. These include "phony" disease of peach, leaf scald of plum, and leaf scorch of almond, oak, maple, and mulberry.^[5] Oleander leaf scorch has become a plant disease problem in the southwestern United States recently, killing oleanders that are widely used as horticultural barriers on highways. The outbreak of oleander leaf scorch coincided with the introduction of the glassy-winged sharpshooter.

Perhaps the most economically important diseases caused by *X. fastidiosa* are found in Brazil. Citrus variegated chlorosis (CVC) was first described in sweet orange in São Paulo State in 1987.^[6] São Paulo is home to the largest sweet orange industry in the world, and currently 35% of the trees are infected with *X. fastidiosa*. The coffee industry in Brazil is also seriously affected by a disease known as requiema do café, also caused by *X. fastidiosa*.^[7] Both diseases are now widespread in Brazil and occur in several other South and Central American countries.

Symptoms of CVC appear as a bright yellow leaf mottle resembling symptoms of zinc deficiency. Localized, brown lesions appear on the upper surface of affected leaves. These lesions extend through the leaf and a sticky exudate is found on the underside. Fruit on affected trees fails to fill to proper size and remains attached to the tree. In contrast with PD, CVC does not cause defoliation or leaf scorch and it is not fatal to the tree. Symptoms of requiema do café include progressive defoliation from the lower part of a branch upward and conspicuously shortened branch internodes. The fruit on affected coffee bushes fails to fill to proper size, but requiema do café does not kill affected bushes.

THE *Xylella fastidiosa* GENOME

The geographical range of *X. fastidiosa* throughout the Americas, and its wide range of economic and asymptomatic hosts, have led researchers to investigate the population structure of *X. fastidiosa*. These studies have revealed four or five clonal lineages associated with the geographical region and economic host from which the strains were first isolated.^[8] Thus, although the pathogen can survive in a wide range of plants in nature, there are mechanisms acting to maintain separate clonal lineages associated with economic hosts.

The impact of CVC on the Brazilian sweet orange industry prompted the state of São Paulo to organize a consortium of researchers to study the pathogen. This effort led to the citrus strain of *X. fastidiosa* becoming the first plant pathogenic bacterium to have its genome completely sequenced.^[9] Analysis of the sequence data showed that *X. fastidiosa* lacks genes that are characteristic of many animal and plant pathogenic bacteria. These include genes that define and limit host range and those that encode the system required to export molecules involved in pathogenesis.

CONCLUSION

Conventional plant breeding to produce plant varieties resistant to *X. fastidiosa* is not practical for horticultural reasons. However, it may be possible to genetically engineer plants with resistance to *X. fastidiosa* by producing antimicrobial substances in the xylem fluid. In the case of grapevine or sweet orange, the genetic engineering could be done on the rootstock only, leaving the fruiting portion of the plant unaltered. This approach would more likely be accepted by consumers and would also be more efficient, since each grape or orange variety could be propagated on a common rootstock. However,

the possibility that the antimicrobial substances could accumulate in the fruit would have to be carefully monitored and addressed during the research and development phase of such a project, to ensure the safety of consumers.

The economically important hosts of *X. fastidiosa* have been introduced into their respective ecosystems. In contrast, species native to these regions are commonly infected by the bacterium, but suffer no apparent ill effects.^[3] The pathogen exploits an unusual ecological niche, living only in the water-conducting vessels of plants and in the mouthparts of certain plant sap-feeding insects. These facts, and the observation that *X. fastidiosa* lacks characteristic pathogenicity genes,^[9] have led to the suggestion that the bacterium may be an endophyte that has co-evolved with the flora of the Americas. Hence, the diseases caused by *X. fastidiosa* could be viewed as nature's way of defending the ecosystem from invasive plant species.^[10] A corollary of this view is that if *X. fastidiosa* is an endophyte that is somehow out of balance with its host, then perhaps the diseases could be managed by biological control, using other antagonistic endophytic organisms.^[11]

Plant Cell Culture and Its Applications

James M. Lee

Washington State University, Pullman, Washington, U.S.A.

INTRODUCTION

Plant cell cultures, also called cell suspension cultures, can be applied for the production of valuable pharmaceutical products. The large-scale cultivation technique of plant cells is similar to that of microbial suspension cultures. Plant cells can also be used as hosts for the production of mammalian protein products such as interleukins, monoclonal antibodies, and enzymes. In addition to its use as a production system for valuable compounds, plant cell cultures have been successfully employed for the development of mutants, production of polyploids, and genetic engineering of crops.

In the beginning of the 20th century, German botanist Gottlieb Haberlandt envisaged the possibilities and potentials of plant cell culture and made pioneering attempts to isolate and grow plant cells in culture. Since then, spectacular advancements have occurred in this field and plant cell cultures are now used for different industrial applications. It is now also possible to regenerate whole plants from single cells of a large number of plant species.

The use of isolated plant cells to investigate the physiological, biochemical, and molecular aspects of various cellular functions—especially in the absence of the influence of other cells—has been recognized for a long time. For instance, isolated plant cells have been extensively used for studies on photosynthesis, ion transport, secondary metabolite production, and cytodifferentiation. Plant cell cultures have also been exploited for the isolation of mutants, production of polyploids, and genetic engineering. However, from the current research trend, the most significant application of plant cell culture appears to be in the area of commercial production of industrial compounds.

Plant cells can be cultivated as suspension cultures in a large-scale bioreactor for the production of various primary and secondary metabolic products such as pharmaceuticals, food products, and agricultural chemicals. One of the major constraints for plant-cell based production systems is the low productivity of commercially attractive metabolites.

Another potential application of plant cell cultures is in the production of foreign proteins. Plant cells can offer advantages over mammalian cells because the plant cell medium is very simple and inexpensive. This article

reviews large-scale cultivation techniques, secondary metabolite production, and foreign protein production from plant cell cultures.

LARGE-SCALE CULTIVATIONS

The first step in creating the suspension culture is to develop a callus culture, which can be initiated by placing a small piece of plant tissue on solid media containing nutrients, salts, vitamins, and growth factors. After several days, an unorganized amorphous mass of cells will develop on the plate. Plant suspension cultures can be initiated by adding well-developed calli into a liquid medium containing ingredients similar to the solid medium, with the exception of agar.

Plant cell cultures are typically grown in shaker flasks in laboratories. Gentle shaking in shaker flasks is a very effective way to suspend the cells, enhance oxygenation through the liquid surface, and aid the mass transfer of nutrients without damaging the structure of delicate plant cells.^[1] The typical batch growth of tobacco cells includes approximately one to two days of lag phase, three to five days of exponential growth phase, and a stationary phase. Maximum cell concentration can be as high as 60% (wet cell weight) or 2.4% (dry cell weight).

For a large-scale cultivation, we can use many different types of conventional stirred-tank fermenters, composed mainly of a cylindrical vessel, impellers, an air sparger, and a means of controlling the temperature (Fig. 1a). The growth rates of plant cells in a stirred bioreactor are not as great as those achieved in a shaker flask, due to shear damage caused by agitation. If the agitation speed is reduced to avoid shear damage, the growth rate can also be decreased through inadequate mixing and air dispersion. One way to avoid this problem is to use an impeller with large blades instead of the standard flat-bladed impeller, as suggested by Hooker, et al.^[2]

Another type of bioreactor suitable for plant cell cultivation is the airlift bioreactor, composed of a cylindrical column with a draft cylinder as shown in Fig. 1b. The liquid circulation of the airlift fermenter is induced by sparged air that creates a different density in the bubble-rich part of the liquid in the riser than in the denser bubble-depleted part of the liquid in the downcomer. One major

Fig. 1 Typical bioreactors for large-scale plant cell cultures: (a) stirred tank and (b) airlift. (View this art in color at www.dekker.com.)

problem with the airlift bioreactor is foaming. Cells tend to rise with the air bubbles, become trapped in the foam, and eventually die due to lack of nutrients. The addition of antifoam agents can reduce this problem, although the agents can also adversely affect cell growth.

THE PRODUCTION OF SECONDARY METABOLITES

Many secondary metabolites can be produced from plant cell cultures.^[3] These include alkaloids, flavors, fragrances, organic acids, and steroids (Table 1). Secondary metabolites are seldom produced during the active cell growth phase. They are normally produced during the stationary phase. The product either accumulates within the cells or leaks into the medium.

Some metabolites—such as anthocyanin, anthraquinone, berberine, rosmarinic acid, and shikonin—can be produced with a higher titer than those in the parent plants.^[4] For example, shikonin can accumulate up to 14% of dry cell weight in plant cell cultures compared to 1.5% in a whole plant.

However, the major hindrance in the development of commercial processes is the low productivity of secondary metabolites from cell cultures. Therefore, a plant-cell based process can only be justified if it offers an economic advantage over chemical synthesis or traditional

extraction processes, or if no other alternative production route exists.^[5]

The production levels of secondary metabolites can be improved by adding elicitors to the medium, selecting the best cell line, optimizing the medium formulation, and designing the most appropriate bioreactor. However, efforts to further increase the level of metabolite production are obstructed by lack of basic knowledge of biosynthetic routes and the mechanisms regulating metabolite accumulation, which also prevents the use of modern metabolic or genetic engineering techniques.

THE PRODUCTION OF FOREIGN PROTEINS FROM GENETICALLY MODIFIED PLANT CELLS

Instead of producing natural metabolites, plant cells can be employed as host cells to express mammalian proteins. Several research groups tested the feasibility of producing foreign protein products such as immunoglobulin, monoclonal antibodies, enzymes, interleukins, and vaccines by genetically modifying tobacco cells.^[6]

There are several advantages to using plant—rather than mammalian—cells for the production of foreign proteins. Plant cell media are composed mainly of simple sugars and salts and are much less expensive than complex mammalian media. It is therefore much easier and more economical to purify secreted transgenic proteins from plant cell media. Additionally, owing to their rigid exterior walls, plant cells are more resistant than mammalian cells to the shear forces involved in large-scale cell culture. Furthermore, plant cell-derived transgenic proteins are likely to be safer for human use than those derived from mammalian cells, because plant cell contaminants and viruses are not pathogenic to humans.

In general, foreign proteins produced from genetically modified plant cells are correctly folded, glycosylated, and biologically active. The foreign proteins tend to be produced during the exponential growth period of batch cultures and secrete into the medium for separation more easily than do intracellular proteins. The level of intracellular transgenic protein production ranges from 0–0.28 mg/L culture, and that of extracellular protein released into the medium ranges from 0–2 mg/L culture. The percent of extracellular transgenic product relative to the amount of total soluble protein released into the medium ranges from 0–0.84%.^[6]

Table 1 Potential product from plant cell cultures

<i>Secondary metabolites</i>	Ajmalacine, anthocyanin, anthraquinones, quinoline, berberine, codeine, digitalis, ginsenoside, jasmine, L-dopa, quinine, rosmarinic acid, saponin, serpentine, shikonin, taxol, vanillin, vinblastine, vincristine
<i>Foreign proteins</i>	Enzymes, interleukins, GM-CSF, monoclonal antibodies, vaccines

The productivity of foreign proteins from plant cell cultures is significantly lower than that of animal cell cultures. However, it is still too early to draw any definitive conclusions in this regard because the research efforts in plant host systems have barely begun. Based on our research findings, this low productivity may be due to the protein instability in plant cell media and low expression levels of mammalian genes in plant cell host systems.^[7] Nevertheless, when making the above comparisons of transgenic protein production, we must consider that the cost of plant cell media is several orders of magnitude lower than the cost of animal cell media. Furthermore, the cost of the downstream processing of plant cell cultures is also significantly lower than that of animal culture systems. Therefore, plant cell systems may be economically competitive with animal culture systems, even at their current production level.

CONCLUSION

The field of plant cell culture has witnessed remarkable progress in the past few decades. Methods for the establishment of cell cultures and for regeneration of plants from single cells are now available for a large number of plant species. Plant cell cultures have been successfully used for the development of mutants and for molecular plant improvement, and their use as a system for the production of natural plant metabolites or foreign protein products is gaining considerable momentum. One major hindrance for commercial application is their low productivity, which must be overcome before the plant-cell based production system comes an economically viable process.

INTRODUCTION

In 1904 Hannig isolated immature embryos *in vitro* from several members of the brassicaceae and recovered fertile plants. Since then a range of plant culture techniques has been developed. These techniques are based in part upon the ability of plants to reproduce asexually (vegetative reproduction). Familiar examples would include potato tubers, offsets produced by bulbous plants and cuttings that can be rooted and established as new plants. For many plants, specialized techniques have been developed that allow for the multiplication of isolated cells, tissues, and organs. These techniques share a set of common characteristics; principal among them is that they are conducted using some form of culture vessel. Initially vessels were of glass construction, hence the term *in vitro*, literally meaning “in glass.” Plant culture techniques range from relatively simple systems such as the sowing of orchid seeds *in vitro* to the regeneration of whole plants from isolated protoplasts, ovules, or microspores (from immature pollen). These diverse methodologies are grouped under the term “plant cell, tissue, and organ culture,” although the terms “*in vitro* culture of plants” and “plant tissue culture” are also used. These methodologies are defined as the culture of isolated plant parts that include whole plants, seeds, embryos, organs, tissues, cells, protoplasts, and microspores on (or in) a nutrient medium under aseptic conditions. In addition to performing plant tissue culture *in vitro*, the techniques are further characterized by several other features:

- The environmental conditions are optimized with regard to physical (temperature and light period and quality) as well as nutritional and chemical (plant growth regulators) factors.
- Microorganisms, particularly bacteria and fungi, are excluded, as are other pests such as insects.
- The normal pattern of plant development is usually interrupted; isolated cells, tissues, and organs may

enter new patterns of development that lead to regeneration of new organs or result in the formation of embryos.

This article describes various techniques and concepts of plant cell, tissue, and organ culture.

PLANT TISSUE CULTURE TECHNIQUES

In vitro culture of plants has been applied as a practical tool in agriculture and horticulture and as a technique in many studies of plant biology. The basis of these applications is the ability (at least in theory) to clone or proliferate plant cells, tissues, and organs in large numbers. Ultimately, complete new plants can be produced from either preexisting shoot buds and meristems, or following regeneration via shoot organogenesis (morphogenesis) or through embryogenesis. The process of regeneration from cells that would not normally have participated in such events is an indication that plant cells are ‘totipotent’, retaining a latent capacity to reproduce a whole plant from somatic cells. Totipotency, however, is not a universal property of all plant cells.

The various techniques of plant tissue culture can be classified simply into organized and unorganized cultures with respect to the morphology of the established culture (Table 1). Strictly, unorganized cultures are tissue cultures, although the term is often used more generally to include all culture types. Organ culture generally describes cultures in which some form of organized growth is maintained, as in the continued growth of shoot or root apices. The definitions are not mutually exclusive, and organized cultures can contain mixtures of single cells and unorganized cell clumps, as well as organized structures. Equally, unorganized cells may also be induced to organize and regenerate plant organs through organogenesis or embryogenesis.

Regeneration via organogenesis or embryogenesis may take place either directly from isolated cells, tissues, or

Table 1 Classification and types of plant cell, tissue, and organ cultures

Type of culture	Key features	Selected applications
<i>Unorganized</i>		
Callus (or tissue)	Growth of amorphous cell masses arising from uncoordinated cell divisions from isolated plant parts (e.g., leaf, stem, or root sections) or cultured cells	Cloning of plants through embryogenesis or organogenesis Creation of genetic variation Secondary metabolite production Protoplast production
Cell suspension	Cells (and cell clumps) grown in an agitated liquid medium	As for callus
Protoplast	Culture of isolated cells without cell walls	Somatic hybridization Creation of cybrids and genetic variation
<i>Organized</i>		
Seed	Culture of seeds to produce whole plants	Excluding competition from microorganisms Replacing symbiosis (mycorrhiza)
Shoot tip (or shoot)	Isolated shoot tips or buds that continue shoot growth and multiplication	Induction of multiple shoot formation Production of clonal plants
Node	Cultures of lateral buds on stem tissue that maintain shoot growth	Axillary branching for shoot proliferation Single shoot formation
Shoot meristem	Culture of isolated shoot meristem plus one or two associated leaf primordia	Elimination of pathogens Phytopathogenic transport
Embryo	Culture of fertilized or unfertilized zygotic embryos	Preventing embryo abortion Overcoming incompatibility As a source of callus
Root	Proliferation of branching roots in isolation of shoots	Production of secondary metabolites As a source of callus Mycorrhizal production
Anther and microspore	Culture of complete anthers or isolated microspores	Production of haploid plants by androgenesis
Ovule	Culture of isolated ovaries or ovules	Production of haploid plants by gynogenesis Overcoming incompatibility

organs or following an intervening callus/tissue phase. Direct regeneration may occur from isolated tissues or organs that regenerate shoots or roots, or from cells induced to form embryos. Indirect regeneration occurs following the proliferation of unorganized cells established in tissue (callus) or cell suspension culture, and may also occur from semiorganized callus or nodules^[1] produced on pieces of tissue or organ isolated in culture.

REQUIREMENTS FOR PLANT CELL TISSUE AND ORGAN CULTURE

Cultures are started from small pieces of plant material usually referred to as explants. Plant cells will only grow in culture when provided with specialized media. Typically, culture media consist of mineral salts for supplying the macro- and micronutrients, and a carbon source (usually sucrose). Vitamins and amino acids in the culture

medium may improve growth but are not essential. Growth and development of plant cultures usually depends on the addition of plant growth regulators (PGRs). These compounds, both natural and synthetic, are capable of modifying plant growth and development (morphogenesis) at very low concentrations. Many culture media formulations have been developed for specific techniques or individual species.^[2,3] A formulation developed by Murashige and Skoog^[4] has been used more widely than others.

Plant material may be cultured in a liquid medium or in a semisolid medium partially solidified with a gelling agent such as agar or gellan gum. Cultures grown in a semisolid medium are kept static, whereas liquid cultures are usually agitated to ensure adequate gaseous exchange. Bioreactors have been developed in conjunction with liquid media to facilitate scaled up operations.^[5,6] Promising results have been obtained recently with temporary immersion vessels.

Plant culture media can also support the growth of microorganisms; consequently they are sterilized prior to use, usually by autoclaving. Components of media susceptible to degradation at high temperature are filter-sterilized and added after autoclaving of the media. Manipulations of culture media and plant material are carried out in laminar-flow cabinets that provide sterile working environments. Plant cultures are incubated in controlled-environment growth cabinets.

GENERAL METHODOLOGY USED IN PLANT CULTURE

The processes of plant tissue culture have been divided into five stages (0–IV), as shown in Table 2. The stages are useful for defining the procedural steps, and here we have identified the critical aspects of the biology at each stage for the principal culture techniques illustrated in Fig. 1.

Stage 0: Pretreatment of Motherplant and Explant

Attention must be paid to selection of appropriate starting material. In general, problems with infection of the cultures are greater with material taken from plants grown in the field than with plant material maintained under controlled environments. Growth, morphogenesis, and rates of propagation can be improved by appropriate environmental and chemical pretreatment of stock plants.

Stage I: Establishment of Aseptic Culture

Choice of starting material will depend on the technique used and the plant species being cultured. Material should be disease-free and capable of active growth. Material taken from seedling parts (such as hypocotyls or cotyledons) is usually more responsive than material from mature adult plants. During establishment, the aim is to obtain an aseptic culture of the plant material. Surface sterilization of plant material is achieved through aqueous

washing in germicidal agents such as alcohol or hypochlorite. Solutions of sodium and calcium hypochlorite containing between 0.25–1.5% available chlorine are commonly used. Traces of the surface sterilant are removed from plant material by washing several times in sterile distilled water. Explant preparation leads to the induction of wounding responses, some of which can be detrimental to the continued growth of the culture. In these circumstances material may be treated with antioxidants or adsorbents to remove toxic compounds. Antibiotics and fungicides are sometimes used to remove or control contaminants that occur in established cultures. A full account of the procedures used can be found in George.^[2]

In addition to achieving aseptic cultures, the establishment stage aims to initiate growth of the culture as well. This may involve the use of stress treatments, including cold, osmotic, and nutrient starvation. Such stress treatments are common for the induction of embryogenesis in isolated cells, particularly for androgenesis and gynogenesis. Plant growth regulators usually play an important part in the induction of organogenesis and embryogenesis, with auxins and cytokinins, often employed to induce them, either singly or in combination.

Stage II: Generation of Suitable Propagules

This stage concerns the generation of new plant units (propagules) that can give rise to whole plants. These could be axillary or adventitious shoots; branched or adventitious roots; haploid, double haploid, or somatic embryos; or storage or propagative organs (Fig. 1). Propagules may be derived via organogenesis, by shoots, roots, storage or propagative organs produced adventitiously, or by their *de novo* formation from callus, nodules, meristems, or suspension cultures. Alternatively, propagules may be derived via somatic embryogenesis, androgenesis, or gynogenesis, wherein reprogramming of the cells occurs, to form embryos from somatic cells, microspores, or ovules, respectively. Cytokinins are frequently involved in shoot production and proliferation, whereas growth regulators are often reduced in concentration or omitted for embryogenic development. Some propagules produced during stage II are used in further rounds of multiplication to increase the number of propagules.

Stage III: Preparation for External Environment

In the external environment, the plant material will be required to photosynthesize and survive away from an artificial supply of carbohydrate. Storage and propagative organs may need little if any preparation for this stage;

Table 2 Stages in process of plant cell, tissue, and organ culture

Stage	Activity
0:	Pretreatment
I:	Establishment
II:	Generation of propagules
III:	Preparation for external environment
IV:	Acclimatization in the external environment

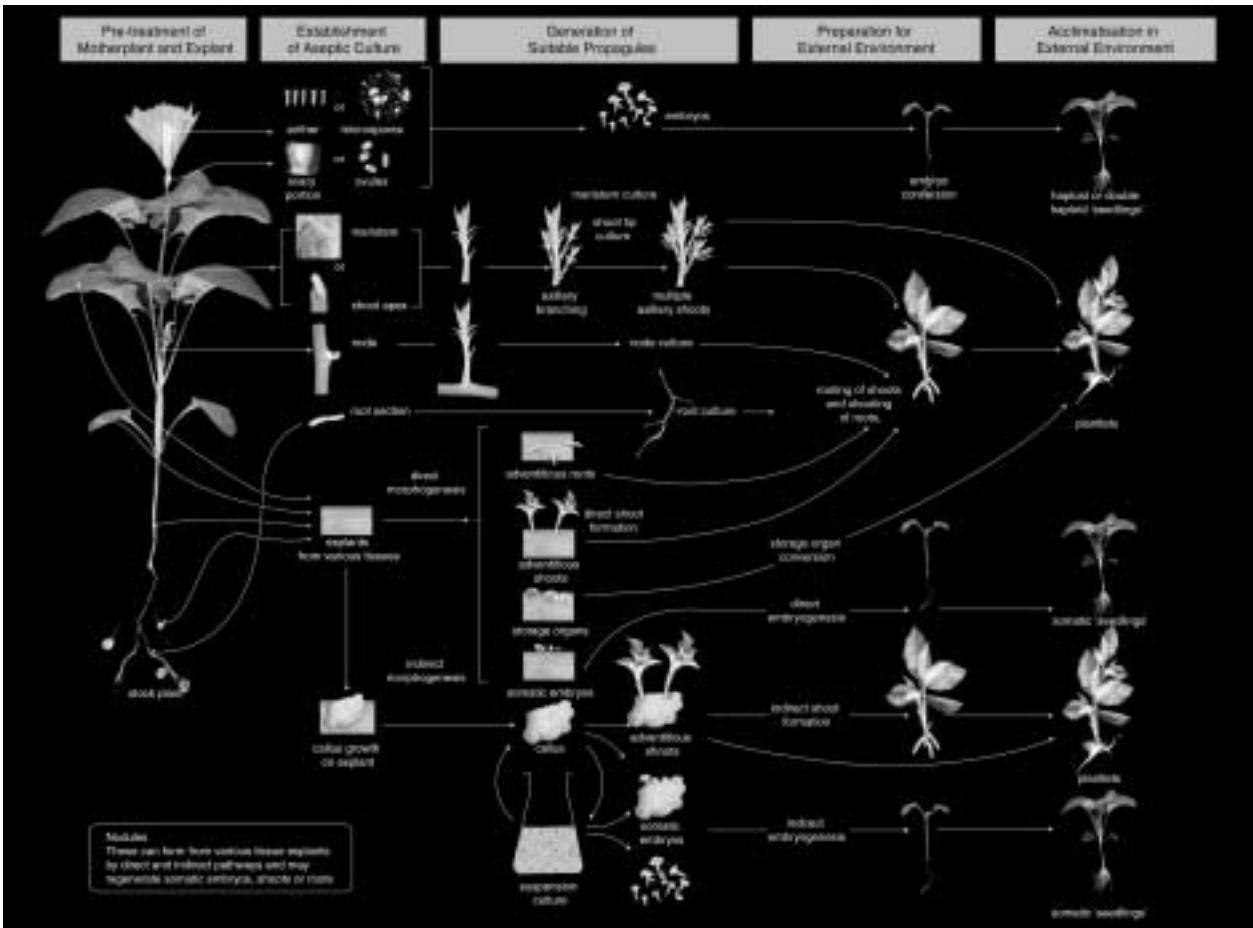

Fig. 1 Plant cell, tissue, and organ culture techniques. (View this art in color at www.dekker.com.)

however, shoots must be of adequate size and may be rooted prior to transfer. Some species form adventitious roots on shoots in culture, but are frequently induced by supplying exogenous auxin to the culture media. In root cultures, shoots are regenerated prior to planting out. Culture-derived embryos sometimes spontaneously convert (“germinate”) into plantlets, whereas in other instances they may need to be induced to convert. In some instances, encapsulated propagules are planted out as synthetic seed.^[7]

Stage IV: Acclimatization in External Environment

Plants growing in tissue culture have often been exposed to high humidity and low light levels, which may result in poor development and limited photosynthetic capacity on transfer to the external environment. Agar is usually washed from the roots prior to planting and the plants are gradually acclimatized to higher light levels and lower

humidity. Some shoots are rooted directly in the weaning stage and not in aseptic culture.

CONCLUSION

A wide range of techniques for the culture of isolated plant cells, tissues, and organs has been developed, as illustrated in Fig. 1. Although they share a set of common features, the underlying biology of the various techniques differs greatly. Various methods are used in the commercial production of a wide range of plant species, including ornamentals, agricultural and forestry species, and natural plant products.^[8–11] The techniques are also a core research tool for manipulation of gene function and regeneration of transgenic plants. From their beginnings a century ago, plant cell, tissue, and organ cultures have emerged as important practical tools that have provided fundamental insights into the biology of plants.

Plant Defenses Against Insects: Constitutive and Induced Chemical Defenses

Linda L. Walling

University of California, Riverside, California, U.S.A.

INTRODUCTION

Plants have elaborate mechanisms to recognize pathogens and pests and to deploy defense strategies to limit damage. Effective defenses maximize survival from immediate and future challenges and should not significantly compromise plant vitality, longevity, or reproductive success. To achieve this goal, plants utilize two lines of defense to control insects and mites. Both constitutive defenses (constantly expressed) and induced defenses (transiently expressed) channel carbon and nitrogen resources from vegetative and reproductive growth into protective mechanisms. The balance of constitutive and induced responses provides the plant flexibility to cope with a single stress or multiple environmental stresses that occur simultaneously. There are several recent reviews that provide molecular and ecological perspectives on plant defenses to insect and mite feeding.

The constitutive and induced defenses encountered by insects are dependent on their mode and site of feeding. Some insects cause tissue damage by crushing, tearing, rasping, or lacerating plants cells. Other insects use less destructive modes of feeding (piercing and sucking) to consume cellular fluids. It is not surprising that the constitutive and induced defenses encountered by tissue-damaging and piercing/sucking insects are often distinct. While chewing insects release stored chemical defenses, piercing/sucking insects encounter stored chemicals only if they damage cells along the path to their feeding site.

CONSTITUTIVE DEFENSES

Constitutive defenses include both physical barriers and stored chemicals.^[1] The cuticle and plant cell wall form the front line of plant defense. Cell wall composition and species-specific compounds that reinforce the wall (lignin, tannins, silicon, suberin) can make it difficult for insects to tear, chew, or penetrate tissue to reach feeding sites, such as the phloem or xylem. The chemical composition and cross-linking of cell wall constituents change after attack, making it a more formidable barrier for subsequent

microbial or insect invaders.^[2] “Plant Defenses Against Insects: Physical Defenses” provides additional details.

Stored chemicals (secondary metabolites) can influence insect growth, development, reproduction, survival, or colonization of plants.^[3] The chemical nature and location of these chemicals is dependent on the plant species, organ, or cell-type, and levels can increase after insect feeding. Genes that control secondary metabolite accumulation can be utilized in breeding programs to enhance insect resistance.

Trichomes (leaf hairs) act as physical barriers and chemical storehouses. Trichomes can impale or interfere with the movements of small insects, including insect predators and parasites. Trichomes and secretory glands are also rich sources of chemicals that are insect deterrents and can reduce insect feeding, oviposition, growth, or viability. See “[Plant Defenses Against Insects: Physical Defenses](#)” for details.

Finally, many defense compounds are stored as inactive glucose-conjugated molecules and are activated only after tissue damage. For example, over 2500 plant species store glucose-conjugated hydrogen cyanide (HCN) precursors and their activating enzymes in separate cells or cellular compartments.^[4] Upon insect attack, these molecules mix to produce HCN, a potent toxin. Another example is the glucose conjugates of hydroxamic acid (Hx-Glu), which are correlated with resistance to phloem-feeding and tissue-damaging insects.^[5] Hx-Glu levels are highest in young monocot leaves, which need enhanced defenses; young leaves are the preferred site for insect feeding due to their high levels of soluble nitrogen-containing compounds. Older leaves are also protected because Hxs are induced after insect attack.

INDUCED DEFENSES

Insects are active participants in plant-insect interactions. Insects introduce oral secretions into feeding sites. Some compounds (elicitors) in these secretions stimulate defense signaling and volatile production, while other elicitors clearly suppress defense mechanisms. Therefore, induced defenses are complex, often resulting in changes

in plant gene expression or volatile emission that are specific for a insect plant interaction.^[6-9]

The duration and intensity of the mechanical and chemical signals generated in each plant-insect interaction influences the nature of the local-and systemic-induced defenses. Plants respond to insect elicitors by modulating levels of plant-produced defense signals, such as salicylic acid (SA; an aspirin derivative) and jasmonic acid (JA) (Fig. 2). SA and JA control opposing defense strategies, which are not mutually exclusive. The magnitude and duration of the increases in JA and SA determine which defense pathways are activated. With tissue-damaging insects, JA-mediated wound responses often predominate; this provides a systemic protection against insects and increased susceptibility to pathogens. With insects that do little tissue damage, SA-mediated or JA-mediated bacterial defenses are activated, providing enhanced protection against pathogens and susceptibility to tissue-damaging herbivores^[1,7] See “[Plant Responses to Stress: Role of the Jasmonate Signal Transduction Pathway](#)” for details.

Activation of Wound Responses

The insects that damage plant tissue induce changes locally (in the damaged tissue) and systemically (in non-damaged tissue) (Fig. 1). The local wound response fa-

cilitates healing at the wound site and restoration of cellular homeostasis by increasing cell divisions, cell wall synthesis, and basal metabolism.^[2]

Wounding also causes the release of the lipid linolenic acid from plant membranes. Linolenic acid is used to synthesize a variety of biologically active oxylipins, including 12-oxo-phytodienoic acid (12-OPDA) and jasmonic acid (JA) (Fig. 2). These oxylipins induce a set of genes (including the bioactive wound peptide gene prosystemin) that amplify the octadecanoid (oxylipin) pathway in damaged leaves.^[1,10] Analyses of mutants that cannot perceive or produce abscisic acid or ethylene have shown that these phytohormones are essential for the wound response. In contrast, as described above, SA antagonizes the wound response (Fig. 2).

While JA, systemin, and 12-OPDA are important in activating wound-response genes in the damaged leaf, the nature of the signal that activates systemic wound responses remains controversial. Current data indicate that systemic signaling must rely on enhanced perception of oxylipins or a novel chemical signal^[11] (Fig. 2). Hydrogen peroxide, electrical signals, and hydraulic signals are also possible modulators of systemic wound responses.^[10,12]

Many wound-response proteins and secondary metabolites directly interfere with insect feeding or have

Fig. 1 Constitutive and induced defense responses to insect feeding. Insects encounter constitutive defenses at the site of feeding. Upon feeding, insects provide mechanical signals, introduce chemical signals from their oral secretions at their feeding site, and/or stimulate plants to produce signals that activate defense responses locally and systemically. This often results in a systemic resistance to further attacks. The nature of the systemic signals is unknown at the present time. Genes may be suppressed or activated. Induced proteins and chemicals may have antinutritive or antifeeding effects (direct defense) or may stimulate volatile release, influencing insect densities and attractiveness to natural enemies (indirect defense).

Fig. 2 Molecules important in defense-response signaling in plants. Linolenic acid is released from membranes after insect feeding and is catabolized via hydroperoxide lyase to produce C₆ volatiles (Fig. 3) or the octadecanoid pathway to produce a series of biologically active oxylipins, including 12-OPDA and jasmonic acid. The octadecanoid pathway increases the levels of the wound peptide systemin. Systemin, JA, and 12-OPDA enhance local expression of wound-response genes encoding proteins that have antinutritive or antifeeding effects. Systemin is an 18-amino acid peptide derived from prosystemin that activates the wound response. The amino acid sequence is shown using the single letter amino acid code. Ethylene, abscisic acid, and salicylic acid are known regulators of the octadecanoid pathway. Volicitin is an elicitor of volatile production found in lepidopteran oral secretions. It is formed by modifying the plant-derived linolenic acid.

antinutritive effects.^[1,6,10,13] Anti-feeding compounds (alkaloids, C₆ volatiles, phytoalexins) limit plant injury. Anti-nutritive compounds (proteinase inhibitors, polyphenol oxidase, proteases) reduce food quality or digestibility. These compounds restrain insect population expansion by slowing insect development and increasing the time available for attack by predators and parasites. Not surprising, plants that have increased or decreased levels of wound-response proteins (i.e., lipoxygenase, proteinase inhibitors, or polyphenol oxidase) have enhanced resistance or susceptibility to insects, respectively.

Activation of Pathogen-Response Pathways

Piercing/sucking insects use modified mouthparts called stylets to consume large quantities of fluids from plant cells to recover nutrients.^[11] The feeding sites may be veins of the phloem (whiteflies, aphids, mealy bugs, psyllids),

epidermal and mesophyll cells (thrips), mesophyll parenchyma (scale insects), or xylem (leafhoppers). The amount of damage caused by piercing/sucking insects varies considerably.

The piercing/sucking insects that cause little tissue damage (whiteflies, aphids) activate different signaling pathways than tissue-damaging insects and appear to be perceived as pathogens.^[11] Wound responses are not activated or are present transiently. Furthermore, these insects induce pathogenesis-related protein (*PR*) genes, which are usually induced by microbial pathogens. Their roles in insect defense are not understood. *PR* genes are regulated by a variety of defense signals including JA, ethylene, SA, and reactive oxygen species. Recent insect-plant studies indicate that even closely related insect species deliver different chemical or mechanical signals to plants, which are translated into distinct changes in plant gene expression.^[1,9]

Fig. 3 Classes of volatiles released after herbivore feeding. During herbivore attack, plants synthesize and emit a complex blend of organic volatile compounds. Volatiles are synthesized by the shikimic/tryptophan pathway, or lipoxygenase/hydroperoxide pathway, or isoprenoid pathway, or are derived from amino acids. Representative volatiles and their pathways are illustrated.

Volatile Synthesis and Release

In response to insect and mite attack, wounding or JA treatment, plants release a complex blend of volatiles.^[1,8] Six-carbon (C_6) volatiles (the odors of freshly cut grass) are released after wounding and are generated from linolenic acid (Fig. 3). The C_6 volatiles listed in Fig. 3 are known to influence insect reproduction or feeding (for a review, see Ref. 1). Some C_6 volatiles serve as insect attractants. Terpenoids are major constituents of the volatile emissions after insect or mite attack (Fig. 3). In addition, methyl salicylate, indoles, nitriles, and oximes are commonly detected (Fig. 3).

The quantities of each compound in a volatile blend creates important species-specific cues for insects, mites, and their natural enemies. Volatiles dictate insect feeding densities and attract insect parasites and predators. Predators/parasites are able to discriminate between the

volatile emissions from plants that are healthy, wounded, or infested with a host or nonhost insect.

Since the volatile blend emitted during each plant-insect interaction is unique, volatile synthesis must be influenced by insect-specific signals. Two elicitors of volatile production are known: volicitin and β -glucosidases. The discovery of volicitin has changed our perceptions of insect elicitors (Fig. 2). Volicitin is made from plant-derived linolenic acid, which is modified in the insect and subsequently reintroduced into the site of feeding via insect oral secretions.^[14] This coordinated biochemical initiative of the insect and plant is unique.

CONCLUSION

A broad range of technologies in molecular biology, genetics, and chemical ecology are currently being

applied to understand the complexity of plant responses to insect attack. These technologies will certainly be used to investigate the chemical diversity and biochemical origin of the elicitors in insect oral secretions that stimulate or suppress host-plant defenses. Integrated with the rapidly expanding knowledge about plant responses to known defense signals, such as JA, SA, ethylene, and reactive oxygen species, we will soon understand the nature and balance of the signaling pathways induced and suppressed by insects. These data will be useful to understand the cross-talk between insect-and pathogen-defense signaling pathways that ultimately dictate the antinutritive and anti-feeding compounds that accumulate after attack. It is anticipated that these findings will identify novel mechanisms that can be used in classical or molecular breeding strategies to enhance plant defenses to insect feeding.

Plant Defenses Against Insects: Physical Defenses

Sanford D. Eigenbrode

University of Idaho, Moscow, Idaho, U.S.A.

INTRODUCTION

Only nine of the 29 insect orders include plant-eating species or phytophages, suggesting there are unique challenges facing potential herbivores. Four principal challenges can be identified: 1) the exceptional hardness and toughness of many plant tissues; 2) the problem of obtaining adequate attachment to the surfaces of plants in order to feed or oviposit; 3) the nutritional deficiency of plant tissues as a sole source for building animal bodies; and 4) the diverse and abundant secondary chemicals in many plant tissues that appear to serve as plant defenses. The first two of these challenges are physical.

The degree to which the physical properties of plants have been shaped to provide defense against insects is difficult to ascertain. Certainly, stiffened or hardened tissues that support the aerial plant organs and a tough, waterproof integument are requisite for successful exploitation of a terrestrial environment. Nonetheless, these characteristics demonstrably limit insect herbivory and have apparently provoked the evolution of specialized adaptations by phytophagous insects for coping with plant physical characteristics. This article reviews the physical plant characteristics that have been shown to impart defense against insect herbivores.

TOUGHNESS AND HARDNESS OF PLANT TISSUES

Plant tissues are both tough and hard. Toughness is measured in terms of resistance to shearing, whereas hardness is measured in terms of a material's resistance to deformation. Structural polysaccharides in plants (cellulose, hemicelluloses, and pectins), lignin (various polymers with phenylpropane units), and cutin and suberin (polymers saturated and unsaturated long-chain fatty acids) are tough materials that resist shearing. The polysaccharides and lignin contribute to the stiffening of all cell walls, especially in vascular tissues, whereas cutin comprises the protective cuticle covering the primary epidermal cells of fruits and other reproductive structures, leaves, and shoots. Suberin performs a similar function for the epidermis of roots. Some plant tissues, notably within

Graminae, are infused with crystals of silica, or other hard minerals.

ADAPTATIONS

The majority of plant-feeding insects do not digest cellulose and other hard or tough materials but must process these tissues to access nutrients in the plant cytosol. Chewing insects must be able to shear these materials to remove pieces of plant material and crush or lacerate the cells to extract nutrients. Adaptations to achieve this include unique forms of mandibular teeth and powerful adductor muscles. The enlarged and strongly sclerotized head capsules of larval lepidoptera, symphyta (sawflies), and phytophagous coleoptera, and attine ants specialized for cutting leaves are evidence for this type of adaptation.

In addition to being tough, structural materials in plants are hard. Hardness causes physical wear to mandibular dentition. Microscopic examination of chewing insects reveals dramatic erosion of mandibular dentition as a result of a few weeks of feeding on hard plant tissues.^[1]

Hardness and toughness potentially act synergistically to impede chewing herbivores. The force required to shear a material is considerably greater with a dull rather than a sharp mandible. The tips of the teeth on some phytophagous insects are infused in turn with their own mineral constituents, including zinc and iron, as an apparent response to the challenge of feeding on hardened plant tissues.^[2]

Other strategies for dealing with toughened tissues include those of homopterans and heteropterans adapted for extracting phloem or xylem tissues, and mites and thrips, which lacerate plant epidermal cells to extract nutrients. These strategies largely circumvent the problem of cutting or shearing large amounts of cell wall. Some of the earliest insect herbivores—the Paleodictyoptera—extracted nutrients from plants by piercing and sucking, possibly to cope with plant toughness and hardness.

Typically, plant toughness is measured crudely, using a penetrometer that measures the maximum force required to pierce plant tissue. This method has been criticized because it undoubtedly does not measure the physical factors that come into play precisely during mastication of

plant tissue by an insect. Nonetheless, there are good examples in the plant resistance literature in which plant toughness measured this way has been related to susceptibility to chewing injury.^[3]

SURFACE STRUCTURES INFLUENCING ATTACHMENT AND HERBIVORY

The epidermis of plants is often covered with hairlike structures known as trichomes. Trichomes may be simple filaments or branching structures, minute and supracellular or large and multicellular, sparsely distributed or forming a dense pubescence on the plant surface. Some are complex structures that terminate in single- or multicellular secretory glands. Trichomes have been shown to be involved in defense against insects.^[4] The density, erectness, length, and shape of trichomes can influence their effects on insects. Trichomes may impart defense by forming a barrier that prevents some insects contacting the plant surface. Trichomes tend to be composed of a high proportion of cutin with relatively little cytoplasm. As a result, trichomes contribute to overall plant toughness and toughness of the plant integument, therefore interfering with ingestion. Simple trichomes can also interfere with attachment by feeding or ovipositing insects, and by eggs laid on the leaf surface. Individual insect-plant associations are differently affected by the presence of trichomes. This was assessed by Webster and by Norris and Kogan,^[5] who reviewed the results of 59 reports in the host plant resistance literature comparing insect attack on pubescent and hairless or glabrous varieties of crop plants. In 32 of these cases, trichomes provided some kind of resistance against insects, but in 13 cases trichomes conferred increased susceptibility (the remainder of the cases were equivocal). Most of the cases in which trichomes conferred susceptibility involved increased oviposition preference for pubescent plants. Apparently, some herbivorous insects have adapted to cope with plant trichomes. For example, the dense vesture of trichomes on the lower surface of *Quercus ilex* cause the aphid *Myzocallis annulatus* to frequently fall from this surface, whereas the *Q. ilex* specialist *M. schreiberi* walks freely on the plant.^[6]

Modified trichomes with hooks or secretory glands can affect insects uniquely. Hooked trichomes can help climbing plants attach to supports. In *Phaseolus vulgaris*, hooked trichomes have also been shown to provide protection against leafhopper nymphs by fatally impaling them.^[7] The exudates of glandular trichomes may be sticky and trap small insects. In *Solanum* and *Lycopersicon*, the stickiness is caused by polymerization of phenolics catalyzed by polyphenol oxidases. Substrate and enzyme are compartmentalized in the trichome gland

but come into contact and react when insects rupture the glands during feeding. Trichome exudates also often contain topical toxins, repellents, or deterrents that contribute to defense against insects. Although these are beyond the scope of this article, they can work in concert with the physical characteristics of trichomes to enhance defense. For example, in *Solanum berthaultii*, sesquiterpenes produced by one type of glandular trichome cause aphids to move more rapidly, thus making it more likely for them to become trapped in sticky exudates produced by another type of glandular trichome.^[8]

The cuticles of terrestrial plants are covered with a layer of long-chain hydrocarbons, related long-chain oxygenated alkyl compounds, and other lipophilic chemicals known as epicuticular waxes. These materials undoubtedly play a primary role in waterproofing the cuticle, but they can also influence insects on plants.^[9] Epicuticular waxes sometimes occur as dense vestures of minute crystals or wax blooms that confer a whitish appearance to the plant surface. Prominent wax blooms typically occur on crop plants such as *Brassica* spp., *Sorghum bicolor*, and peas. Such wax blooms can strongly reduce the ability of insects to attach to the plant surface, thereby providing some protection against herbivory. As a result, crops with genetically reduced wax blooms are more susceptible to certain insects.^[10]

INDUCIBILITY OF PHYSICAL DEFENSES

Plant defenses against insect herbivores are frequently inducible in response to insect feeding, and physical defenses apparently are no exception. Both trichome density^[11] and leaf toughness^[12] have been reported to increase following herbivory. As is true for other types of defenses, induced trichome density can be species-specific; for example, feeding by larvae of the cabbage butterfly *Pieris rapae* induced increased densities of trichomes in black mustard, *Brassica nigra*, whereas equivalent injury from flea beetles, *Phyllotreta cruciferae*, had no such effect.^[11]

EFFECTS OF PHYSICAL DEFENSES ON INSECT NATURAL ENEMIES

The net defensive effect of most plant characteristics depends not only on their direct effects on insect herbivores, but also on how these characteristics influence the natural enemies of the herbivores. The effect of trichomes and wax blooms on insect herbivores is complicated because these features can also disrupt attachment or impair the mobility of predators and parasitoids. For example, on a range of *Brassica oleracea* genotypes varying

in surface waxes, the effectiveness of two predator species was significantly correlated with the attachment forces these predators could generate on the plant surfaces.^[13] Wax blooms on some of these genotypes reduced predator attachment forces by as much as two orders of magnitude and severely impaired predator mobility. Apparently as a result of this type of interaction, genetic variants in *Brassica* spp. and in peas with reduced wax bloom are more resistant to certain types of herbivory in the field than are varieties with typical waxy bloom [Rutledge, 2002 #3734]. Both simple and glandular trichomes also have been found to impede natural enemies. Repeatedly, in solanaceous crops and wild species, it has been shown that glandular trichomes producing sticky exudates trap predators and parasitoids, thereby reducing the effectiveness of these natural enemies at suppressing herbivores. Simple trichomes also can alter predator and parasitoid movement patterns and affect their ability to locate prey.

CONCLUSION

Whether physical characteristics of plants have evolved as defenses against insect herbivores is difficult to ascertain. Nonetheless, certain plant physical factors negatively affect herbivores and reduce herbivory. Some of these characteristics have been harnessed by plant breeders as part of their efforts to breed crops with resistance to insects. The possible negative effects of some physical factors such as toughness and trichomes on crop plant quality complicate these breeding efforts. In addition, individual herbivore species respond differently to physical characteristics. Moreover, some physical characteristics have strong effects on the natural enemies of insect herbivores, further complicating the net effects of physical traits on insect herbivory. Thus, as is the case with most efforts to achieve crop protection through breeding, it is necessary to understand the response to physical factors by at least the dominant species in the arthropod community targeted for management.

Plant Defenses Against Insects: Role of Endophytes

Stanley H. Faeth

Arizona State University, Tempe, Arizona, U.S.A.

INTRODUCTION

Endophytic fungi are a remarkably diverse and abundant group of microbes that live asymptotically, at least for part of their life cycle, within host plant tissues. As such, insects that feed upon plant tissues regularly encounter endophytic infections, or their chemical byproducts. Because some endophytes produce mycotoxins, they were originally envisioned as host plant mutualists by providing defense against insects and vertebrate herbivores. However, accumulating evidence suggests that many, if not most, endophytes have neutral or even positive effects on insects, especially specialists. For horizontally transmitted (via spores or hyphae) endophytes, transmission and colonization may be facilitated by insects, and thus evolution of strong antagonistic effects on insect herbivores is not expected. Defense against insect herbivores was originally envisioned as especially strong for systemic, vertically transmitted endophytes in grasses, as reproduction of these endophytes is closely linked with host survival and reproduction.^[1] However, recent evidence suggests that even these endophytes have few protective effects against insects, perhaps because the cost of alkaloid defense outweighs the benefits to the host in most environments.

ENDOPHYTES AND PLANT DEFENSES

The term “endophyte” loosely refers to fungi that live asymptotically within plant tissues, although other microbes, such as bacteria and viruses, also inhabit plant tissues, and endophytic fungi may only be asymptomatic for part of their life cycle. Endophytic fungi are very abundant and often extremely diverse in both woody^[2-4] and grass host plants (e.g., Ref. [5].) Curiously, endophytic fungi are the only plant-associated microorganisms that are postulated to directly increase host plant defenses against both vertebrate and invertebrate herbivores.^[6,7] Endophytic fungi have been termed “acquired chemical defenses”^[8] in grasses and “inducible defenses” and herbivore “antagonists” in woody plants.^[6,9] Long-lived, slowly evolving plant hosts were thought to keep pace

with rapidly evolving insect herbivores by allying with endophytic fungi and their mycotoxins.^[6]

The main mechanism for increased plant resistance to insect herbivores is fungal production of mycotoxins. Endophytes may also alter plant physiology and morphology and thus increase resistance to stressful environments, competitive abilities, or uptake of limiting nutrients.^[10] Endophytic mycotoxins, notably alkaloids, are now well documented for some systemic endophyte infections in pooid grasses, but relatively few mycotoxins have been isolated from the more diverse and localized infections in grasses and woody plants.^[5]

Horizontally Transmitted Endophytes

The vast majority of fungal endophytes in plants, including grasses, form localized infections within plant tissues and are transmitted horizontally (from plant to plant) via hyphal fragments or spores, usually by wind or rainsplash. Sporulation implies that the asymptomatic nature is lost, and this usually occurs during senescence of plant tissue, when many of these fungal endophytes become saprophytic. Some endophytes in woody plants have been shown to increase host plant resistance to insect herbivores, especially sedentary insects, such as gall-forming insects.^[11] Although originally proposed as plant defenses, most of this diverse group of microorganisms appear neutral, and even occasionally positive (e.g., Ref. [12]), in their interactions with insect herbivores.^[2,3,5] An important caveat is that very few endophytes in relatively few host plants have been tested for resistance to insect herbivores. Nevertheless, the general lack of insect resistance due to these endophytes may not be surprising. Damage to plant tissues increases the likelihood of successful colonization of spores and hyphae. Therefore one would not expect endophytes to evolve to deter feeding, and thus damage, by insects through the production of mycotoxins. Furthermore, mobile insects may ingest hyphae and spores and transmit them via saliva or frass to colonization sites within or between host plants.^[2] Although originally touted as a mechanism by which slowly evolving host plants enlist microbial partners to defend against rapidly evolving

insects, most horizontally transmitted endophytes appear to have few negative effects on invertebrate herbivores.^[5]

Vertically Transmitted Endophytes

Although far less diverse and less common than horizontally transmitted endophytes, seed-borne, systemic endophytes in cool-season, pooid grasses have nonetheless attracted much more attention for several reasons. First, the pooid grasses are economically important forage and turf grasses. Two agronomic grasses, tall fescue and perennial ryegrass, were introduced to North and South America and Australia and New Zealand from Eurasia, and now are the most widely cultivated grasses in North America, and are often infected by an asexual, vertically transmitted endophyte, *Neotyphodium*. Second, the systemic, seed-borne endophytes in pooid grasses were first known for their dramatic toxic effects on livestock, but later also on insect pests of grasses. Third, the mechanism of toxic effects, fungal production of alkaloids, is well established for the vertically transmitted endophytes in grasses. Systemic endophytes such as the asexual *Neotyphodium* and its sexual counterpart, *Epichloë*, produce a wide array of alkaloids in four major classes, and often at very high levels, depending on endophyte and host genotype and environmental factors, at least in some infected agronomic grasses. Some of these alkaloids, especially peramine, which is the most common alkaloid found in infected grasses, have deterrent and toxic effects on insect herbivores. However, deterrent effects of peramine on insects do not occur until concentrations are greater than 4 ppm dry mass, and many infected plants are often below these levels. Others, such as the ergot alkaloids, appear more effective against vertebrate herbivores. Fourth, evolutionary theory predicts that strictly vertically transmitted symbionts such as *Neotyphodium* should interact mutualistically with their hosts because the fitness of the symbiont is tightly linked to that of its host. Defense against herbivores via endophytic alkaloids is considered the primary vehicle for benefits to the host plant.

In general, systemic, vertically transmitted endophytes in agronomic grasses have negative effects on some, but not all, insect herbivores, root feeders, and seed predators of grasses.^[5] Most of these insects are introduced generalist pest species, such as aphids, Argentine stem weevil, fall armyworm, and sod webworm. Although relatively few have been studied, this generality does not appear to hold for systemic infections in native grasses. Despite earlier notions that most native grasses infected with vertically transmitted endophytes are toxic or deterrent to herbivores, recent evidence suggests the contrary.^[13,14] Instead, most native, cool-season grasses infected with seed-borne

endophytes are not more resistant to either vertebrate or insect herbivores than their uninfected counterparts, and in some cases, less resistant.^[13] The contrast between marked negative effects of systemic endophytes in agronomic grasses and the relatively benign effects in native grasses is directly related to differences in alkaloid production. In native grasses, vertically transmitted endophytes produce fewer types and far lower and more variable levels of alkaloids than infected agronomic grasses, probably due to greater genetic diversity of host and endophyte, coupled with complex interactions with more variable environments.^[13,15]

Faeth^[13] listed several reasons why endophytes in native grasses do not generally form defensive mutualisms via alkaloids. First, nitrogen-rich alkaloids may be costly to produce and native grasses generally inhabit poorer nutrient environments than agricultural areas. Second, grasses generally tolerate grazing and herbivory rather than rely upon chemical defenses. Third, alkaloidal defenses may not be effective against specialized insect herbivores, which comprise the bulk of herbivorous insect species in natural communities. Fourth, herbivory in natural populations is generally more sporadic and less intense than agronomic pastures, and thus the cost of alkaloid production may outweigh any consistent benefits. Persistence of systemic endophytes in natural grass populations may be related to other potential benefits of endophyte infection, such as increased drought resistance, rather than fitness benefits related to resistance to insect or vertebrate herbivores. Alternatively, seed-borne endophytes may not be mutualistic at all, but rather persist in natural populations by several other mechanisms.^[16]

CONCLUSION

Although endophytes were originally envisioned as potent bodyguards of their hosts against insect herbivores, accumulating evidence suggests that the many endophytes do not have adverse effects on insects. Some endophytes, particularly those that are systemic, vertically transmitted in some agronomic grasses, do increase host plant resistance to herbivores through production of high levels of alkaloids. But these toxic endophytes represent the end of a continuum of endophyte interactions with host plants, ranging from parasitic to mutualistic, found in natural populations. There is growing recognition that mycotoxin-producing endophytes have great potential in crop and turfgrass improvement, especially in terms of resistance to pest insect species. In a larger sense, much of the basic ecology, evolution, physiology, and patterns of biodiversity of endophytes is still unknown.

Plant Diseases Caused by Bacteria

Clarence I. Kado

University of California, Davis, California, U.S.A.

INTRODUCTION

In the microbial world, bacteria feed on dead or living substrates to proliferate and survive. Some bacteria have evolved to become highly specialized in their feeding activities. Those that feed on living plants are pathogenic members of the gram-negative bacteria families Rhizobiaceae, Enterobacteriaceae, Pseudomonadaceae, Xanthomonadaceae, Ralstoniaceae, and Burkholderiaceae. Gram-positive pathogens are cormeform bacteria in the families Microbacteriaceae and Coyrnebacterineae. They form irregular rods and are non-spore formers. To recognize, infect, and consume plants, pathogenic species are equipped to sense and attach themselves to the host plant, invade and colonize host plant parts, secrete virulence effectors, and move into the intercellular spaces between cells or inside vessel elements. These processes culminate in disease symptoms. This article introduces the major types of disease symptoms caused by phytopathogenic bacteria. References for some specialized texts are provided for readers desiring more detailed information.

FOUR CLASSES OF DISEASE SYMPTOMS

Plant disease symptoms caused by pathogenic bacteria are classified into four general categories: 1) Overgrowths—non-self-limiting growths of plant tissues caused by cell enlargement (hypertrophy) and cell division (hyperplasia), resulting in excessive organ proliferation (fasciations) and/or undifferentiated tissue formation into tumors; 2) Rapid cell death (necrosis)—the rapid killing of cells caused by toxic proteins, effectors (e.g., hormones, proteases, kinases), and organic compounds produced by the invading pathogenic bacteria; 3) Generalized wilt—water stress of plant parts caused by blockage of vessel elements in the host due to exocellular polysaccharides, plant hormones, and other unidentified vessel occlusion factors elaborated by invading phytopathogenic bacteria; and 4) Soft-rot—maceration of plant tissue by invading bacteria that secrete powerful degradative enzymes capable of dissolving pectin (cell cementing material), cellulose, and complex proteins. In addition to these four types of symp-

toms, some plants become infected but remain symptomless. However, the pathogen isolated from these symptomless plants (which are often wild species,) can cause visible disease symptoms in cultivated species. Finally, there are plant diseases whose symptoms appear only after the crop is harvested and processed.

EXAMPLES OF EACH DISEASE TYPE

Overgrowths

Representative members of plant pathogenic bacteria that cause overgrowths can be found in the Rhizobiaceae, Enterobacteriaceae, Pseudomonadaceae, and Corynebacterineae families. *Agrobacterium tumefaciens*, a member of the Rhizobiaceae, causes a tumor disease called crown gall in a wide range of plant hosts when tested experimentally. In nature, crown gall occurs mainly on woody species such as peaches, plums, apricots, pears, cherries, almonds, walnuts, roses, brambles, kiwi, apples, and grapevines. *Agrobacterium rhizogenes* causes an interesting disease called hairy root, due to the abnormal proliferation of numerous roots from the site of infection. Besides root proliferation, fasciations in the form of leaf and flower proliferation into a witch's broom (Fig. 1) can occur when plants are infected by *Rhodococcus fascians*. *R. fascians* harbors a linear plasmid that encodes a number of virulence effectors, such as isopentenyl adenosine monophosphate, a precursor of the cell growth hormone cytokinin. Olive knot, a tumor disease of olive trees and oleander shrubs, is caused by *Pseudomonas syringae* pv. *savastanoi*, a member of the Pseudomonadaceae (Fig. 2). *Pantoea herbicola* pv. *gypsophila* is a member of the Enterobacteriaceae that causes galls on the ornamental baby's breath plant, *Gypsophila paniculata*. *P. herbicola* pv. *gypsophila* produces cytokinin during infection.^[1]

Rapid Cell Death

Necrosis-producing bacteria are mainly represented in the Enterobacteriaceae, Pseudomonadaceae, and Xanthomonadaceae. *Erwinia amylovora*, a member of the

Fig. 1 Fasciation disease of carnation caused by *Rhodococcus fascians*.

Enterobacteriaceae and the causal agent of the fire blight disease of Rosaceae plants such as pears and apples, elaborates proteins, toxins, and virulence effectors that rapidly kill cells and assist in advancing the invading bacteria. The pathogen gains access into the host via

blossoms and wounds. Necrosis of the blossom petiole followed by drooping of blackened leaves is typical of fire blight (Fig. 3). *Pseudomonas syringae* pv. *syringae*, a member of the Pseudomonadaceae that causes leaf blights on a wide range of plants and bacterial canker of peaches

(a)

and other *Prunus* species, produces peptide toxins (e.g., syringomycin), polysaccharides, plant hormones, and at least 11 virulence effector proteins during tissue colonization. The effectors cause cell death by altering the movement of ions across cell membranes, initiating water

leakage from within cells (which temporarily fills intercellular spaces, resulting in a symptom called water-soaking), and by altering normal cellular processing mechanisms. *Xanthomonas axonopodis* pv. citri, a member of Xanthomonadaceae, causes citrus canker whose

Fig. 5 Early symptoms of angular leaf spot of cotton caused by *Xanthomonas campestris* pv. *malvacearum*.

Fig. 6 Early leaf spot symptom on the edge of an *Anthirium* leaf caused by *Xanthomonas campestris* pv. *dieffenbachiae*.

symptoms are typified by raised pustulelike or blisterlike lesions on fruits and leaves. Lesions appear about 7 to 14 days after inoculation followed by the formation of craterlike spots lined with tan-colored tissue. An oily water-soaked margin accompanied by a yellow halo occurs around the spots. On fruit, the blisterlike lesions are pronounced (Fig. 4). Another member of the Xanthomonadaceae is *X. campestris* pv. *malvacearum*, the causal agent of angular leaf spot of cotton (Fig. 5). The many lesions on the leaf enlarge and coalesce into angular regions, and leaves later drop off prematurely. *X. campestris* pv. *dieffenbachiae* causes leaf spots on *Anthirium* species (Fig. 6), from where the pathogen prolifically invades the vascular system, in which massive amounts of ooze are produced (Fig. 7).

Generalized Wilt

Vascular wilt-inducing bacteria are as economically important as necrogenic pathogens. *Clavibacter michiganense* subspecies, which are non-spore-forming, gram-positive members of the Microbacteriaceae, cause wilt diseases of specific plants. For example, *C. michiganense* subsp. *michiganensis* causes a wilt disease of tomato plants called bacterial canker. The wilt symptoms are followed by tissue necrosis producing scorched-appearing foliage, cankers (depressions in the stem caused by

Fig. 7 Ooze from *Anthirium* stem systemically infected by *Xanthomonas campestris* pv. *dieffenbachiae*.

death of tissue beneath the epidermis), killing of the pith, and spots on the fruit. Another member of this gram-positive group is *C. michiganense* subsp. *insidiosus*, which causes a wilt disease of alfalfa. Infected alfalfa plants are often severely stunted (Fig. 8). *Ralstonia solanacearum*, the sole plant pathogenic member of the family Ralstoniaceae, causes wilt disease of at least 30 plant families. Plants of the Solanaceae family such as potato, tomato, eggplant, and bell pepper are very susceptible to *R. solanacearum* strains classified as Race 1. *R. solanacearum* strains of Race 2 infect banana and cooking banana, causing Moko and Bugtok diseases, respectively (Fig. 9). *Erwinia salicis*, a member of the Enterobacteriaceae, causes wilt of the cricket bat willow tree through vessel occlusion, which is followed by necrosis of the vascular cylinder.

Soft-Rot

Bacteria that cause tissue dissolution resulting in soft rot are mainly members of the Enterobacteriaceae and Pseudomonadaceae. A prototypical example of the Enterobacteriaceae is *Erwinia carotovora* subsp. *carotovora*, a relatively fast growing, rod-shaped bacterium that initiates infection through wounds. Infection progresses as the pathogen elaborates a number of enzymes that break down pectin into consumable oligosaccharides, as well as cell

wall material and proteins into utilizable substrates. *E. carotovora* subsp. *carotovora* infects tubers, roots, and corms. The organism also causes the blackleg disease of potato, typified by the rapid collapse of the potato plant in the field (Fig. 10). A member of the Burkholderiaceae, *Burkholderia cepacia* is a complex species that is currently divided into genomovars (genetic species) I, III, and VI. Plant pathogenic strains in genomovar I cause a soft rot of onion bulbs called sour skin disease. Like other soft-rot pathogens, *B. cepacia* produces a number of enzymes and virulence effectors that facilitate dissolution of the onion bulb tissues (Fig. 11). Certain strains of *B. cepacia* are used as biocontrol agents, whereas other strains are opportunistic human pathogens that infect individuals with cystic fibrosis.^[2]

SYMPTOMLESS DISEASES

Besides the four basic plant disease symptoms, some bacterial diseases do not produce symptoms in the field. For example, the economically important pink disease of pineapple becomes apparent only when the fruit is canned. Pink disease is caused by *Pantoea citrea*, a member of the Enterobacteriaceae that infects the fruit via the florets and produces enzymes that oxidize glucose into ketogluconates, which upon heating results in the

Fig. 8 Alfalfa wilt caused by *Clavibacter michiganense* subsp. *insidiosus*. Stunted plant on the left is infected. Healthy plant is on the right.

formation of a red pigment that stains the canned pineapple fruit, resulting in an unmarketable product^[3,4] (Fig. 12).

Xylella fastidiosa, a member of the Xanthomonada-ceae, remains latent in a large number of symptom-free wild plants such as California blackberry, Russian thistle, Creek Nettle, Sudan grass, and at least 36 distinct plant species, including wild grape (*Vitis californica* Benth).^[5] When experimentally inoculated with *X. fastidiosa*, these

plants remain symptomless, yet remain as carriers of the pathogen.^[5] Asymptomatic wild plant species apparently tolerate the pathogen, even though their xylem is filled with the bacterium. Hence, these wild plants serve as the reservoir of *X. fastidiosa*. In contrast, cultivated plants when infected by *X. fastidiosa* develop severe leaf symptoms such as marginal scorching (Fig. 13) and fruit wilt (raisining) (Fig. 14). *X. fastidiosa* is transmitted from diseased and symptomless plants to crops by the waxy-winged and sharpshooter leaf hoppers. Pierce's disease of grapevines, leaf scorch of almond and plum trees, and variegated chlorosis of citrus are some of the diseases caused by *X. fastidiosa*. *Clavibacter xyli* subsp. *xyli* (now called *Leifsonia xyli* subsp. *xyli* by some researchers) causes ratoon stunting disease of sugarcane. The disease is difficult to diagnose, because modern commercial varieties of sugarcane usually exhibit no external symptoms of infection. Producers may not know they have a problem until yields come in below expectations. Even though older varieties of sugarcane may show reduced vigor (stunting), this symptom is

Fig. 9 Moko disease of a young banana plant caused by *Ralstonia solanacearum* (Race 2). (View this art in color at www.dekker.com.)

Fig. 12 Pink disease of pineapple caused by *Pantoea citrea*. (View this art in color at www.dekker.com.)

not diagnostic, because it can also be caused by poor growing conditions.

CONCLUSION

Overgrowths, rapid necrosis, generalized wilt, and soft rot are four distinct symptom classes of plant diseases caused by plant pathogenic bacteria. Each type of symptom reflects the specific type of infecting bacterial species. Overgrowth or tumor-inducing bacteria are generally equipped to elaborate phytohormones. Necrogenic bacteria are known to inject an array of toxic peptides and virulence effectors. Wilt-causing bacteria invade and proliferate in the vascular elements, interrupting fluid transport in the plant. Soft-rot-causing bacteria elaborate

a series of degradative enzymes that hydrolyze pectin, cell wall components, and complex proteins. All plant pathogenic bacteria infect their respective plant hosts to create a niche for competitive survival and perpetuation in nature. The host generally provides the food substrates for bacterial survival. In this article, broad examples of diseases caused by plant pathogenic bacteria were provided. Also, examples of asymptomatic diseases are addressed and represent a significant area. Here, native, symptom-free plants are not harmed by the latently infecting bacteria, but modern day, genetically-altered crops are highly susceptible to the same plant pathogenic bacteria that resides in asymptomatic wild species. It appears, therefore, that crop breeding programs have reduced natural resistance to various pathogenic effectors of the plant pathogen.

Plant Diseases Caused by Phytoplasmas

Elisabeth Boudon-Padieu

Institut National de la Recherche Agronomique, Centre de Recherches de Dijon, Dijon, France

INTRODUCTION

Plant diseases caused by phytoplasmas were first described as “virus-like” yellow diseases because symptoms could be induced in healthy plants after grafting with shoots from affected plants, or by insect transmission. However, there was no evidence of the putative viruses. Plant yellow diseases share common symptoms that include leaf yellowing, virescence or phyllody of flowers, absence or anomalies of fruit, and decline or dieback. In 1967, these diseases were associated with organisms observed in thin sections of phloem tissues from dwarfed mulberry plants. The organisms resembled a class of prokaryotic animal pathogens called mycoplasmas, and hence were named mycoplasma-like organisms (MLOs). Subsequently, they have come to be known as phytoplasmas. Unlike mycoplasmas, phytoplasmas have not been cultured *in vitro*. However, with the development of serological and molecular assays, knowledge on the etiology and epidemiology of phytoplasma diseases has greatly improved.

BIOLOGY OF PHYTOPLASMAS

First assumed to be unknown viruses,^[1] then called mycoplasma-like organisms,^[2,3] phytoplasmas^[4] are obligate, intracellular, parasitic, wall-less bacteria that are transmitted by phloem-feeding insect vectors and by grafting. They are heterogeneous in size and polymorphous, appearing in infected plant tissues and insect vectors as round bodies 50–1000 nm in diameter.^[2,5,6] In the plant, they occupy only phloem sieve tubes and are distributed to all organs.^[5] However, their distribution is uneven, and their movement and multiplication are not fully understood. Phytoplasmas persist over the winter in dormant wood and in roots. Phytoplasmas multiply and persist in the bodies of vector insects, especially in the gut wall cells and secretory cells of salivary glands.^[6] However, because they are not transmitted to the progeny, plant hosts are essential for the survival of phytoplasmas.

CLASSIFICATION OF PHYTOPLASMAS

Because they have not been grown *in vitro*, phytoplasmas have long remained mysterious organisms with unknown

phylogenetic characters. Numerous strains of phytoplasmas have been transmitted by grafting, insect feeding, or infection by parasitic higher plants (i.e., dodders). The bacteria have been maintained by subgrafting under greenhouse conditions. In the 1980s and 1990s, serological and DNA-based assays were developed to better understand the geographical distribution and phylogeny of these pathogens. Phytoplasmas have a small genome size, ranging from 500 to 2200 kb.^[4] By analyzing the 16S rRNA gene, more than 200 phytoplasmas have been grouped within the class Mollicutes, in a homogeneous clade that contains about 20 groups and subgroups, distinct from other Mollicutes.^[4] Data obtained by sequence analysis of other rDNA regions support such classification. Additionally, data on serological relationships confirm ribosomal grouping. Biological traits such as natural host range and pathogenicity do not clearly agree with the groupings established by molecular data.

PLANTS AFFECTED BY PHYTOPLASMAS

Phytoplasmas have been reported only from angiosperms. They have been detected in hundreds of plant species in numerous families in all continents.^[3,4] Although phytoplasmas were described as plant pathogens, numerous plants can be symptomless when infected. This is of particular importance with weed species that can be discrete reservoirs. Phytoplasma diseases severely affect numerous crops, and their economic importance can be very high because infected plants cannot be cured.

SYMPTOMS ASSOCIATED WITH PHYTOPLASMA INFECTION

Phytoplasma infection alters the formation and development of flowers, fruits, seeds, tubers, and roots. It is also associated with the decline of grapevines, fruits, forest trees, and shrubs. Sometimes, similar symptoms develop on plants of the same species infected with different phytoplasmas. For example, grapevine yellows, which occur in four continents and show similar symptoms, have been associated with at least five different phytoplasmas.^[7] Similarly, symptoms of stolbur on tomatoes (i.e.,

hypertrophied calyxes containing virescent stamina, petals, and pistils, together with yellowing or reddening and epinasty of leaves) in Europe, South America, and Australia have been associated with four different phytoplasmas. Plants of *Catharanthus roseus*, a species widely used to maintain phytoplasmas by subgrafting, display a variety of symptoms when infected with different phytoplasmas, including severe decline vs. active growth of stems with short internodes or proliferation of axillary buds into witches' brooms and development of small flowers vs. virescence and phyllody.

INSECT VECTORS OF PHYTOPLASMAS

All insect vectors of phytoplasmas belong to families in the order Hemiptera. However, only a limited number of vector species are known among leafhoppers (Cicadellidae), planthoppers (Fulgoroidea), and psyllids (Psyllidae). Vector transmission can be very specific when the insect species is a monophage or oligophage. Only psyllids are known as vectors of fruit tree phytoplasmas that belong to the apple proliferation group, whereas several insect species are vectors of phytoplasmas of the larger group of aster yellows.^[3,4,8] Flavescence dorée (FD), a phytoplasma that attacks grapevines, is exclusively transmitted by the vine-feeding leafhopper *Scaphoideus titanus* Ball.^[7] Alternatively, insects belonging to the same family can be vectors of the same or closely related phytoplasmas. At least three planthoppers in the Cixiidae family have been shown to be vectors of phytoplasmas of the stolbur group,^[9] which are ubiquitous pathogens of numerous crops and weeds in Europe and Australia. Altogether, a long-lasting coevolution of phytoplasmas with their insect vectors could account for their intimate and complex relationships.

INSECT TRANSMISSION

Phytoplasmas are transmitted by insect vectors in the persistent mode, with a latency between feeding acquisition and the moment when insects are infective (i.e., able to inoculate healthy plants). As an example, a latency of 4–5 weeks is required in the case of FD phytoplasma transmitted by the natural vector *S. titanus* or by an experimental vector *Euscelidius variegatus*.^[6] Leafhoppers are then infective for the rest of their life, but they do not pass phytoplasmas to their progeny.

Transmission cycles of phytoplasmas are complex systems that depend on the biology of plant and insect hosts, and demonstrate some plasticity under different

environmental conditions. As indicated above, plant hosts are essential for the survival of phytoplasmas. Phytoplasmas transmitted by a unique vector species with one generation a year and a limited period of activity require at least one perennial host plant as an overwintering reservoir. Phytoplasmas transmitted by a species with one generation a year and instars developing throughout the year, or by a species that undertakes several generations a year, can persist both in insects after acquisition (larval instars or adults of the winter generation) and in plant hosts.^[8] Ubiquitous phytoplasmas are transmitted by one or several polyphagous insect species to several cultivated and wild plants. The basis for vector specificity is not known and might prove essential in preventing the dissemination of phytoplasma diseases.

DISSEMINATION OF PHYTOPLASMAS

The feeding activity of insect vectors is responsible for the short-range dissemination of phytoplasmas. Hence the incidence of a disease in a crop is related to the proportion of infective insects within the vector population. Conversely, long-distance spread occurs when the phytoplasma, the susceptible host, and the insect vector meet in a new region. Resident insect species might prove to be efficient vectors of an exotic phytoplasma, or an exotic vector species may transmit a local phytoplasma. Hence, the appearance of a disease in a new area may result either from the introduction of a phytoplasma source with infected planting material and/or the introduction of a potential insect vector species.

MANAGEMENT OF PHYTOPLASMA DISEASES

Primary control of phytoplasmas relies on exclusion and prophylaxis. Care should be taken to avoid introducing infected germplasm into new regions. Because there is no evidence for seed transmission of phytoplasmas, efforts should be focused on ensuring phytoplasma-free vegetative planting material. Fully dormant lignified propagation materials suspected of infection can be disinfected by soaking in water at 50°C for 45 min.^[10] The introduction of exotic insect species should also be avoided. Control measures for an established disease require knowledge of the biology of insect vector and other inoculum sources. When vector refuges are known, control of the species can be achieved with targeted spraying of insecticides or with destruction of host plants. Similarly, destruction of phytoplasma reservoirs is recommended to lower the

inoculum pressure. In perennial crops, removal of infected trees is recommended when the disease pressure is high (i.e., in epidemic phase). Pruning of affected parts of the tree may limit crop loss; however, it does not control the spread of the disease if vectors are not controlled at the same time. Cases of natural recovery of woody plants are known, but this mechanism has not been elucidated. Natural recovery could be used to return to a satisfactory sanitary status when the disease pressure is not too high, provided that insect vectors are controlled during and after the recovery process. Phytoplasmas, lacking a cell wall, are sensitive to tetracycline. However, this antibiotic is bacteriostatic rather than bacteriocidal. Injection of trees may be efficient but not durable, and it would be detrimental to the environment and result in the selection of antibiotic-resistant pathogens. Finally, cross-protection and induced resistance, which are partial resistance induced by a primary infection with another pathogen or with an attenuated strain of the same pathogen, have been reported, but more research must be performed in the latter fields.

FUTURE PROSPECTS

Numerous reports in the past 10 years indicate that the incidence of known diseases associated with phytoplasmas is increasing. Research on phytoplasma–host interactions should yield effective strategies for managing these diseases. Of particular interest are interactions with insect organs at the cellular level and plant resistance response mechanisms. The introduction of plant resistance to vector feeding or phytoplasma multiplication is a long-term objective. Additionally, a search for natural enemies of insect vector species could also lower the incidence of these diseases to an acceptable level.

CONCLUSION

Phytoplasmas have long remained mysterious plant pathogens. In the last decade, important information has been obtained on their biology, transmission, vectors and host plants. However, new plant diseases associated with phytoplasmas are being described in all continents, probably due to extending rate of exchange between distant countries and more and more frequent introduction of exotic plant germplasm and pests in new areas. More knowledge is needed on the origin of phytoplasmas and on environmental factors which contribute to the emergence of new diseases.

Plant Diseases Caused by Subviral Agents

Peter Palukaitis

Scottish Crop Research Institute, Invergowrie, U.K.

INTRODUCTION

Plant diseases also can be caused by other viral-like pathogens referred to collectively as subviral agents. These include replicating small RNAs without genes, known as viroids, and other subviral pathogens known as satellites, which require helper viruses for parts of their life cycle. The latter include satellite viruses, which encode their own coat protein but depend on another virus for their replication and movement, and satellite RNAs and DNAs, which depend on another virus for all of these functions. Satellites can modify the diseases induced by their helper viruses.

VIROIDS AND DISEASES CAUSED BY VIROIDS

Viroids were first described conceptually in the early 1970s, although the diseases that many caused were known for most of the last century.^[1,4] Viroids are naked, highly structured RNAs of small size (245–401 nucleotides), which do not encode proteins and thus depend on polymerases encoded by their host plants for their replication. They appear to contain the ability to move throughout their host plants.^[4] At present, there are 28 viroid species^[2,4] (Table 1). The two families of viroids (Avsunviroidae and Pospiviroidae) show differences in structure, conserved sequences, and ability to undergo autocatalytic cleavage, via ribozymes.^[2,4] These physical differences also correlate with their sites of replication; i.e., the viroids in the Avsunviroidae are replicated by a polymerase in chloroplasts, and at least some viroids in the Pospiviroidae have been shown to be replicated by a nuclear RNA polymerase.^[4]

Viroids have been found to be the causal agents of a number of plant diseases, primarily in tropical zones, and to a lesser extent in temperate zones.^[4] The major diseases caused by viroids include the spindle tuber disease of potatoes, the sunblotch disease of avocados, various diseases of citrus, cucumber grapevine, hops, pear, and apple, and a number of diseases of ornamental plants^[4] (Table 1). However, the most devastating disease caused by viroids is the decline observed in coconut palm in the Philippines. It is estimated that about 40 million trees here

have been lost due to this disease, known locally as “cadang-cadang.”^[4] The mechanisms by which viroids induce disease are not known, although it is believed that they alter developmental processes in their host plants, as well as activate disease response genes.^[4] In various crop species, the control of the spread of viroids has been accomplished by a combination of removing infected materials, cleaning up breeding lines (through either meristem tip culture coupled with thermotherapy, or by obtaining new sources of disease-free germplasm), and other rigorous phytosanitary measures, especially for orchard plants.^[4] This has led to the control of a number of viroid diseases in Australia, Europe, and North America.

SATELLITES AND DISEASES CAUSED BY SATELLITES

In contrast to viroids, which are not encapsidated into particles, satellites depend upon “helper viruses” either for their replication as well as encapsidation into the particles of their helper virus (satellite RNAs and satellite DNAs), or for their replication alone, as they encode and are encapsidated by their own coat proteins (satellite viruses).^[1,3] Satellites differ from defective RNAs and subgenomic RNAs of plant viruses in not having extensive nucleotide sequence identity with their helper virus.^[3,5] There are only four known satellite viruses (Table 2). Except for Panicum mosaic satellite virus, which intensifies the disease elicited by its helper virus satellite viruses, the other satellite viruses do not significantly affect the diseases caused by their respective helper viruses. Thus far, there are six definitive satellite DNAs (Table 2), but there more being characterized.^[3] Satellite DNAs all contain singlestranded DNA genomes and all are associated with singlestranded, circular, DNA viruses (geminiviruses). Except for the satellite DNA of tomato leaf curl virus, which contains 682 nucleotides, the other satellite DNAs all contain about 1300 nucleotides.

By contrast, there is considerably more variation in type, size, number, and helper viruses among the satellite RNAs. These are grouped on the basis of whether they encode proteins (large satellite RNAs) or do not do so, and are either linear molecules (small linear satellite RNAs) or form circular molecules (circular satellite RNAs), at least

at some stage in their replication cycle^[3,5] (Table 2). The large satellite RNAs vary in size from about 800–1500 nucleotides. Some encode proteins required for their replication, while others do not. The small linear satellite RNAs contain about 300–900 nucleotides and the circular satellite RNAs are 220–457 nucleotides.^[3–5] In a number of cases, members of these various classes of satellite RNA have the ability to alter the diseases induced by their helper viruses. In some cases, the satellite RNAs intensify such disease, while in other cases, they may attenuate the virus-induced disease.^[5] In the case of some satellite RNAs, different variants can attenuate symptoms or exacerbate

the disease induced by the helper virus, and in one case, the same satellite RNA species can intensify symptoms on one host and attenuate symptoms on another host.^[5]

The small, circular, satellite RNAs have sizes and structures similar to that of a number of viroids.^[4,6] In common with some of these viroids, these satellite RNAs replicate through a rolling circle mechanism, generating multimeric copies of these RNA molecules. These multimeric copies may or may not be encapsidated by the helper virus.^[4] The major satellite RNA molecules present in the cell and inside virus particles are of the monomer species, processed and circularized via ribozymes.

RIBOZYMES: AUTOCATALYTIC RNA

Ribozymes, or RNA enzymes, are RNA sequences that fold into particular structures, allowing them to cleave and/or ligate RNA molecules. A number of these have been found associated with viroids in the family Avsunviroidae, and with the circular satellite RNAs.^[1,4–7] The ribozymes associated with subviral agents are classified into two types of autocatalytic structures called hammerhead ribozymes and hairpin ribozymes.^[7] These have been studied quite extensively in recent years, in order to understand their mechanisms of cleavage. Various applications for the use of these ribozymes have been suggested, including in molecular medicine.^[8,9]

CONCLUSION

Viroids and satellites have provided some valuable tools in our understanding of basic molecular processes, and in furthering our knowledge about pathogenic agents and the roles of RNAs in pathogenicity. More of these agents are being discovered each year, and these pathogens are being recognized as the etiological agents of either new or previously unclassified diseases.^[1–4] There is a web site available that contains the nucleotide sequences of all of the known isolates of viroids and satellite RNAs, as well as the secondary structure of these agents. This site also provides information on the presence and structure of any ribozymes associated with such RNAs.^[6] Although considerable work has gone into modifying viroids or satellite RNAs for agricultural applications, most of these efforts have not as yet yielded any success. On the other hand, one satellite virus has been modified successfully to express additional RNA sequences in plants, resulting in suppression of the expression of target genes by the RNA silencing pathway.^[10] The discovery of ribozymes in several subviral agents has generated considerable interest, although applications of this technology to

Plant DNA Virus Diseases

Robert L. Gilbertson

Maria R. Rojas

University of California, Davis, California, U.S.A.

INTRODUCTION

The majority of plant virus diseases are caused by viruses with single-stranded RNA genomes. Three families of plant viruses have DNA genomes, and some DNA viruses cause economically important diseases, particularly in tropical and subtropical regions. Members of the family Caulimoviridae have a circular double-stranded (ds) DNA genome. The type member, *Cauliflower mosaic virus* (CaMV), is the source of the 35S promoter, which is widely used in plant biotechnology. Banana streak and rice tungro are important diseases caused by caulimoviruses. Members of the family Geminiviridae have a circular single-stranded (ss) DNA genome and distinctive twinned icosahedral virions. The whitefly-transmitted geminiviruses (genus *Begomovirus*) have emerged as one of the most economically important groups of plant viruses. Geminiviruses cause devastating diseases such as African cassava mosaic, bean golden mosaic, beet curly top, cotton leaf curl, maize streak, and tomato yellow leaf curl. Viruses in the family Circoviridae have a multipartite circular ssDNA genome, and members of the genus *Nanovirus* cause plant diseases. Banana bunchy top, the most important viral disease of banana, is caused by *Banana bunchy top virus*. Management of diseases caused by DNA viruses involves an integrated approach involving virus-free propagative material, resistant varieties, synchronized planting dates, insect vector management, sanitation, and host-free periods.

CAULIFLOWER MOSAIC: THE FIRST PLANT DISEASE SHOWN TO BE CAUSED BY A DNA VIRUS

In 1968, Shepherd and colleagues established that CaMV, the causal agent of cauliflower mosaic disease, has a genome composed of dsDNA.^[1] Subsequently, a number of diseases were shown to be caused by dsDNA viruses related to CaMV. These viruses were placed in the family Caulimoviridae, which is the only recognized family of plant-infecting dsDNA viruses. The family Caulimoviridae includes two major genera: *Caulimovirus* and *Badnavirus* (Table 1). CaMV is the type species of the

genus *Caulimovirus*. The genome of these viruses is composed of a single circular dsDNA (approximately 8.0 kilobase (kb) pair), which is encapsidated in isometric (spherical) particles approximately 50 nm in diameter.^[1,2] Caulimoviruses cause mosaic-type diseases (mosaic, mottle, ringspots, and malformation in leaves and stunted plant growth) of dicot crop, ornamental, and weed plants; examples include cauliflower mosaic, carnation-etched ring, dahlia mosaic, and strawberry vein banding.^[1,2] Caulimoviruses have narrow host ranges and are spread, plant-to-plant, by aphids or via propagative material, but not through seed.

BADNAVIRUSES: BACILLIFORM dsDNA VIRUSES CAUSING BANANA STREAK AND RICE TUNGRO DISEASES

In the late 1980s, a new type of DNA virus was identified with a circular dsDNA genome of approximately 7.5 kb, and bacilliform (bullet)-shaped virions (100–300 × 30 nm).^[3,4] These viruses were placed into the genus *Badnavirus* (ba [bacilliform]-dna [DNA]-virus) in the family Caulimoviridae (Table 1).^[4] Badnaviruses cause diseases including banana streak, rice tungro, and cacao swollen shoot (Table 2).^[2,4] Banana streak is a mealybug-transmitted disease found in many banana growing regions. In addition to causing losses due to reduced size and production of banana fruit, the dsDNA genome of *Banana streak virus* (BSV) can become integrated into the banana genome, complicating the production of BSV-free propagative material. Rice tungro is a devastating disease of rice in certain areas of Asia, and its impact was particularly severe on high-yielding rice varieties introduced during the green revolution.^[5] The disease is caused by a complex of two viruses: *Rice tungro bacilliform virus* (badnavirus) and *Rice tungro spherical virus* (ssRNA virus), and is spread by leafhoppers. The development of rice varieties resistant to the insect vector has been an effective management tool in certain areas (Table 2).^[5] Cacao swollen shoot is a mealybug-transmitted disease of considerable importance in West Africa and Sri Lanka, where it reduces yield and quality of cacao by inducing swelling and necrosis of stems and roots.^[2]

Table 1 Classification and characteristics of DNA viruses of plants

Family	Genus	Genome	Virion shape and size	Insect vector and mode of transmission	Plants infected
Caulimoviridae	<i>Caulimovirus</i>	dsDNA monopartite	Spherical 50 nm in diameter	Aphids nonpersistent	Dicots, narrow host range
	<i>Badnavirus</i>	dsDNA monopartite	Bacilliform 130 × 30 nm	Mealybugs semipersistent	Monocots and dicots, individual viruses have narrow host range
Geminiviridae	<i>Rice tungro bacilliform virus</i>	dsDNA monopartite	Bacilliform 130 × 30 nm	Leafhoppers semipersistent	Monocots, mostly rice, narrow host range
	<i>Mastrevirus</i>	ssDNA monopartite	Germinate 18 × 30 nm	Leafhoppers persistent, nonpropagative	Monocots, including maize and wheat, narrow host range
	<i>Curtovirus</i>	ssDNA monopartite	Germinate 18 × 30 nm	Beet leafhopper persistent, nonpropagative	Dicots, wide host range
	<i>Begomovirus</i>	ssDNA most bipartite	Germinate 18 × 30 nm	Whiteflies (<i>Bemisia</i> spp.) nonpropagative?	Wide range of dicots, individual viruses have narrow host ranges
Circoviridae	<i>Nanovirus</i>	ssDNA multipartite	Spherical 18–20 nm in diameter	Aphids persistent, nonpropagative	Monocots, bananas, and <i>Musa</i> spp., narrow host range

Table 2 Plant diseases of major economic importance caused by DNA viruses

Disease	Host of economic importance	Geographical distribution	Causal agent	Spread	Management
Rice tungro	Rice	South and Southeast Asia, China	Complex: <i>Rice tungro bacilliform virus</i> (caulimovirus) and <i>Rice tungro spherical virus</i> (ssRNA virus)	Leafhoppers, propagative material	Vector resistance, planting date, rice-free period
African cassava mosaic	Cassava	Africa	<i>African cassava mosaic virus</i> (geminivirus)	Whiteflies, propagative material	Virus-free planting material, sanitation and roguing, resistance
Bean golden mosaic	Common bean	South and Central America, Mexico, SE U.S.A.	<i>Bean golden mosaic virus</i> and <i>Bean golden yellow mosaic virus</i> (geminivirus)	Whiteflies	Host-free period, time of planting, resistance, vector management
Cotton leaf curl	Cotton	Pakistan, India	Complex: <i>Cotton leaf curl virus</i> (geminivirus) and nanovirus-like satellite DNA	Whiteflies	Host-free period, resistance
Tomato yellow leaf curl	Tomato	Asia, Africa, Caribbean basin, SE U.S.A.	Various species of <i>Tomato yellow leaf curl virus</i> and <i>Tomato leaf curl virus</i> (geminivirus)	Whiteflies, propagative materials (transplants)	Host-free period, time of planting, resistance, vector management
Banana bunchy top	Banana	Australia, Africa, Asia, South Pacific	<i>Banana bunchy top virus</i> (nanovirus)	Aphids, propagative material	Quarantine, virus-free planting material, roguing

GEMINIVIRUSES: THE FIRST SINGLE-STRANDED DNA VIRUSES SHOWN TO CAUSE DISEASES IN PLANTS

Viruses in the family Geminiviridae have circular ssDNA genomes (3.0–5.5 kb) encapsidated in small (18 × 30 nm) twinned icosahedral virions.^[3,6,7] The family name comes

from the distinctive virion shape and from the latin word “geminus,” meaning twin. Plant diseases caused by geminiviruses were recognized long before the nature of the causal agent was determined, and the first recorded observation of a plant disease—an aesthetically pleasing yellow vein symptom described in a Japanese poem in 752 A.D.—may have been caused by a geminivirus.^[3,6] Today, the yellow variegation (mosaic) of the ornamental

Fig. 1 Symptoms of diseases caused by various geminiviruses. A. Abutilon mosaic caused by *Abutilon mosaic virus*; B. African cassava mosaic caused by *African cassava mosaic virus*; C. (View this art in color at www.dekker.com.)

flowering maple (*Abutilon* spp.) is due to infection by the geminivirus *Abutilon mosaic virus* (Fig. 1A).

In the late 1970s, geminiviruses were identified and characterized and shown to be the causal agents of many important diseases, including African cassava mosaic, maize streak, and bean golden mosaic (Fig. 1).^[2,6,7] Geminiviruses have been classified into four genera based on the insect vector, host range, and genome structure (Table 1),^[2,3,6,7] and are now among the best characterized and most economically important plant viruses.

GEMINIVIRUS DISEASES HAVE EMERGED AS MAJOR THREATS TO CROP PRODUCTION

Geminiviruses cause many important diseases (Table 2, Fig. 1).^[2,6,7] In southern Africa, India, and islands in the Indian Ocean, maize streak is the most damaging viral disease of maize, causing streaking of leaves, stunted growth, and reduced yields (Fig. 1C).^[2,6] The development of moderately resistant varieties has helped reduce losses due to this leafhopper-vectored mastrevirus. Curly top disease is caused by three curtovirus species vectored by the beet leafhopper (*Circulifer tenellus*) (Table 1). Disease symptoms include twisted, crumpled, and yellowed leaves; stunted and distorted growth; and vascular discoloration (Fig. 1E).^[6] The disease occurs in the western United States, certain Mediterranean countries, and South America. In the early 1900s, curly top nearly destroyed the sugar beet industry in the United States until resistant varieties were developed. The disease still causes losses in tomato and other crops in the U.S. State of California, and an annual spray program is used in an attempt to control the disease by reducing populations of the leafhopper vector.

Diseases caused by whitefly-transmitted geminiviruses (genus *Begomovirus*) (Table 1) have emerged as major constraints on vegetable and field crop production in tropical and subtropical regions throughout the world (Table 2).^[6-8] This is due to a worldwide increase in the population and distribution of whiteflies (*Bemisia* spp.) and monoculture of susceptible crops in areas with indigenous weed-infecting geminiviruses. Diseases caused by begomoviruses are characterized by mosaic/mottle, curling, crumpling, and/or yellowing of leaves; stunted and distorted growth; and a reduction in yield quantity and quality (Fig. 1).^[2,3,7] African cassava mosaic is a devastating disease in many countries of Africa, causing significant yield losses (e.g., approximately 50% of total production) (Table 2, Fig. 1B).^[6] In the late 1990s new, highly pathogenic forms of *African cassava mosaic virus* appeared, arising by genetic recombination. They

have caused even greater losses. Bean golden mosaic (Fig. 1D) causes significant losses (as high as 100%) to common bean production in South and Central America and Mexico, and management options remain limited. Some bean varieties possess moderate resistance, but one of the most effective strategies has been a bean-free period of 2–3 months (Table 2).^[2] Cotton leaf curl has devastated cotton production in some parts of Pakistan and India, and is caused by a complex of a begomovirus and a nanovirus-like satellite DNA (Table 2).

Tomato yellow leaf curl disease (TYLCD), caused by *Tomato yellow leaf curl virus* (TYLCV), was first recognized in Israel around 1940 and is the most damaging viral disease of tomato. The disease is characterized by stunted and erect growth; small, chlorotic leaves that roll upward; and flower abortion (Fig. 1F). In plants infected early in development, yield loss may reach 100%. In some regions, TYLCD limits the commercial cultivation of tomatoes. TYLCD is now found throughout the Middle East, Southeast Asia, India, many countries of Africa, southern Europe, the Caribbean Basin, and the southeastern United States (Table 2).^[2]

In the early 1990s, TYLCV was inadvertently introduced into the Dominican Republic where it destroyed a flourishing tomato processing industry.^[8,9] Using the tools of biotechnology, it was established that the virus in the Dominican Republic was identical to TYLCV from the eastern Mediterranean, and that tomato was the primary host.^[9] A regional integrated management strategy was implemented that involved 1) a mandatory three-month whitefly host-free period; 2) planting of early maturing hybrid varieties (early season) and TYLCV-resistant varieties (late season); and 3) the selective use of new systemic neonicotinoid insecticides (e.g., imidacloprid). The disease has been effectively managed in the Dominican Republic, and yields are higher than before the introduction of the virus.^[9]

BANANA BUNCHY TOP DISEASE: AN ECONOMICALLY IMPORTANT DISEASE CAUSED BY A NANOVIRUS

Banana bunchy top disease (BBTD) is the most important viral disease of banana. First described in the South Pacific in the late 1800s, the disease spread to Australia, Africa, India, the Philippines, and Sri Lanka.^[10] BBTD is characterized by the bunchy appearance of the upper portion of the plant, narrow and dwarfed leaves, and dark green streaks on leaves and stems. Infected plants become severely stunted and yield losses can reach 100%. The disease is transmitted by aphids and via propagative materials. Originally thought to be caused by a luteovirus,

BBTD was subsequently shown to be caused by a spherical virus with a multipartite circular ssDNA genome. The virus was named *Banana bunchy top virus* (BBTV). Effective management of BBTD involves the use of quarantines, virus-free propagative material, and a strict regime of sanitation and eradication of diseased plants (Table 2). This approach has been highly effective in Australia, but less effective in other areas.^[10] Other diseases caused by viruses similar to BBTV include faba bean necrotic yellows, coconut foliar decay, and subterranean clover stunt.^[2,3] These viruses have been placed into the genus *Nanovirus* in the family Circoviridae (Table 1).^[3]

CONCLUSION

Although DNA viruses represent a minority of the total viruses that infect plants, they cause many economically important plant diseases, particularly in tropical and subtropical regions. Management of these diseases has been difficult and successful cases have always involved an integrated regional approach that is based on a thorough understanding of viral biology and disease epidemiology.^[5,9,10]

Plant–Pathogen Interactions: Evolution

Ian Crute

Institute of Arable Crops Research, Rothamsted, Harpenden, U.K.

INTRODUCTION

All plant pathogens cause disease on a restricted range of plant species but the extent of host specificity differs considerably, presumably as a consequence of different sorts of evolutionary trade-off. The driving force in the evolution of plant–pathogen interactions is conceived as an “arms race” between defense and pathogenesis with the ability to cause diseases of plants almost certainly originating several times during evolution. Two distinct evolutionary routes are likely: 1) acquisition of the capacity to invade living plant tissues by saprotrophic organisms formerly deriving nutrition from dead plant material, and 2) acquisition of pathogenic traits by organisms involved in previously established mutualistic symbioses. Organisms pathogenic on plants may derive their nutrition by either biotrophic or necrotrophic processes. The former involves an intimate association with living cells, and the capacity to stop them dying, while the latter involves the capacity to kill cells, sometimes without direct contact.

DISCUSSION

Co-evolution can be conceived as a process whereby components of non-host resistance are sequentially assembled in evolutionary time and give rise to the degree of host specificity observed in present-day host–pathogen associations. The suggestion is that the diversity of these defenses parallels the evolution of plant species and the pathogens to which they are accessible. An alternative hypothesis is that all plant cells have the capacity to recognize non-self and to actively elaborate a defense response. In this hypothesis, it is envisaged that the defense response of all plants is essentially similar except for subtle variations on the theme; host specificity and the process of co-evolution reside in the recognition process. It is known that micro-evolutionary change over short time periods is mediated by a gene-for-gene relationship involving the recognition of pathogen derived molecules for which within-taxa variation occurs. It is envisaged that recognition events mediating non-host resistance could involve taxon-specific molecules that are invariant and

biologically essential to the potential pathogen. Consequently, genotype-specific interactions between host plants and their pathogens mediated by gene-for-gene recognition may simply represent the “tip of an iceberg” in this type of surveillance and response based defense. Recognition specificity may be contributed primarily, but not exclusively, by a leucine-rich repeat domain (LRR) common to the proteins encoded by different classes of plant resistance (R) gene. This domain comprises a variable number of repeats of the motif xxLxLxx (where L is a conserved aliphatic residue, leucine or isoleucine) putatively providing an array of solvent-exposed ligand-binding surfaces. For several R gene families, regions of the LRR have been shown to be under diversifying selection as indicated by a ratio of greater than one for the synonymous to non-synonymous substitutions of the nucleotides encoding residues in the region. The way in which the molecular machinery for signal recognition and transduction is assembled within and between individual plants may be subject to combinatorial variation. Such variation may allow individual plants to recognize and respond effectively to molecules that represent the invariant signature of potential pathogens to which the plant is a non-host. At the same time, the system can provide access to the necessary genetic variation to facilitate a micro-evolutionary response to the tiny sub-set of pathogens of the host species that are detected only by genotypically variant molecular cues on which selection acts to enhance pathogen success.

EVOLUTION AS AN “ARMS RACE”

Plants are intrinsically resistant to the vast majority of agents known to have pathogenic competence. Despite the constant assault on aerial and subterranean plant organs by potential pathogens, most plants are healthy; this healthy state is a consequence of effective defense mechanisms. The driving force in the evolution of plant-pathogen interactions is therefore an “arms-race” between defense and pathogenesis. This “arms-race” commenced before plants colonized land, and certain proteins involved in the mediation of defense against microbial pathogens by both vertebrate and invertebrate animals, as well as plants,

share structural homology^[1,2] that may represent conservation of function dating from before divergence of the plant and animal kingdoms.

EVOLUTIONARY ROUTES TO ESTABLISHMENT OF PATHOGENIC INTERACTIONS WITH PLANTS

The ability to cause diseases of plants undoubtedly originated several times during evolution given the phylogenetic diversity of present-day plant pathogens. However, despite this polyphyletic origin there are likely to have been two distinct routes to the establishment of plant pathogenesis: 1) acquisition of the capacity to invade living plant tissues by saprotrophic organisms formerly deriving nutrition from dead plant material, and 2) acquisition of pathogenic traits by organisms involved in previously established mutualistic symbioses. There is evidence for both bacteria and fungi that horizontal transfer of blocks of genes (“pathogenicity islands”) has contributed to the evolution of plant pathogenic capability.

MODES OF NUTRITION AND HOST SPECIFICITY

Two other general observations about the diversity of present-day plant–pathogen interactions are relevant to consideration of their evolutionary origins: mode of nutrition and host specificity. Organisms pathogenic on plants may derive their nutrition by either biotrophic or necrotrophic processes. The former involves an intimate association with living cells and the capacity to stop them dying, while the latter involves the capacity to kill cells, sometimes without direct contact.

All plant pathogens cause disease on a restricted range of plant species but the extent of host specificity differs considerably, presumably as a consequence of different sorts of evolutionary trade-off. For example, there may be trade-off between a pathogen’s host range, its capacity to kill plant tissues, its capacity to persist and reproduce on any particular host, and its mode of transmission between hosts. In diverse ecosystems (unlike agriculture) propagules of a pathogen with a wide host range will more readily make contact with a new susceptible host than will a pathogen with a restricted host range. However, pathogen reproductive success will not necessarily always be correlated with wide host range or host mortality. Based on observation of existing host–pathogen associations, it frequently appears to be the case that co-evolution results in an increasing degree of host specific adaptation. For

this to be true there must be a fitness deficit for maintaining pathogenic capacity on a wide range of hosts. Investigations of bacterial pathogens provide some evidence for this contention.

Pseudomonas syringae and *Xanthomonas campestris* comprise host-specific biotypes (pathovars). A few genes encoding “effector proteins” have been characterized from these bacteria that have pleiotropic effects on virulence and host range.^[1] Specific gene-for-gene mediated recognition (discussed later) of the “effector protein” by plants carrying a particular “matching” resistance gene (R gene) results in an incompatible interaction—the host is classed as resistant and the pathogen is classed as avirulent. For this reason, genes encoding “effector proteins” were first recognized by this avirulence trait (and called *avr* genes). However, in addition to being the means by which plants recognize and respond to the presence of the bacterium, “effector proteins” also fulfill a virulence function as demonstrated by comparative studies of the growth in planta of bacterial isolates with or without functional *avr* genes.

PRESENT-DAY HOST–PATHOGEN INTERACTIONS: SOME EXAMPLES

A few observations from present-day host–pathogen interactions, placed into a phylogenetic context, serve to illustrate some of the points developed above.

Among the Peronosporales (Oomycetes), there are species of *Pythium* that are considered to be saprotrophs, those that are weak pathogens and those that are destructive, necrotrophic, polyphagous root pathogens. Within the same taxonomic family (Pythiaceae), *Phytophthora cinnamomi* is also a necrotrophic, polyphagous root pathogen (known to attack over 950 plant species) but, while most other species of *Phytophthora* share the necrotrophic mode of nutrition, they exhibit a much more restricted host range. Species in the closely related family Peronosporaceae (the downy mildews) are, by comparison, biotrophic pathogens that exhibit a high degree of host–species specificity with individual pathogen species adapted to distinct host families and sub-specific variants being pathogenic on only one or a few closely related plant species within that family.

Within the Ascomycotina, the tribe Helotiales comprises a large number of destructive necrotrophic pathogens but some, such as *Sclerotinia sclerotiorum* and *Botryotinia fuckeliana*, invade a large diversity of host species while others are restricted to particular host families, genera, or individual species. In contrast the tribe Erysiphales (the powdery mildews) comprises a number of exclusively biotrophic genera. While the pathogenesis

of most species and sub-specific variants (*formae speciales*) is restricted to one or a few closely related species, others, such as *Erysiphe orontii*, *E. cichoracearum* and *Oidium lycopersicae* have a wide host range.

HOST SPECIFICITY AND CO-EVOLUTION

There is an assumption that to derive nutrition from living plant tissues, a potential pathogen must be able to evade or render ineffective a multiplicity of constitutive physical and chemical defenses in addition to those that are provoked in active response to attempted colonization. The inaccessibility of most plant species to all but a small number of potential pathogenic agents is referred to as “non-host resistance.” Co-evolution can be conceived as a process whereby the components of non-host resistance are sequentially assembled in evolutionary time and give rise to the degree of host specificity observed in present-day host-pathogen associations. The suggestion is that the diversity of these defenses parallels the evolution of plant species and the pathogens to which they are accessible. Such defenses might include: insensitivity to pathogen-derived toxins or hydrolytic enzymes, failure to deliver physical or chemical cues necessary for pathogen development, as well as synthesis of preformed or induced antimicrobial metabolites. In fact, experimental evidence to support these ideas is scarce. In a few specific cases, the importance of plant surface topography as a stimulus for elaboration of infection structures has been clearly demonstrated^[3] as has the importance of anti-microbial detoxification mechanisms for successful pathogenesis.^[4]

An alternative hypothesis is that all plant cells have the capacity to recognize non-self and to actively elaborate a defense response.^[5] In this hypothesis, it is envisaged that the defense response of all plants is essentially similar except for subtle phylogenetic variations on the theme; host specificity and the process of co-evolution reside in the recognition process. Pathogenesis results when an invader fails to deliver a signal that the plant’s surveillance apparatus can detect or, alternatively, when the cellular machinery required for the surveillance apparatus to function is destroyed (in the case of pathogens that rapidly kill cells without requiring close contact). It is known that micro-evolutionary change over short time periods is mediated by a gene-for-gene relationship involving the recognition of pathogen derived molecules for which within-taxa variation occurs (discussed later). It is envisaged that recognition events mediating non-host resistance could involve taxon-specific molecules that are invariant and biologically essential to the potential pathogen.^[6] Consequently, genotype-specific interactions between host plants and their pathogens mediated by

gene-for-gene recognition (discussed in the following) may simply represent the “tip of an iceberg” in this type of surveillance and response based defense. The identification of a plant receptor involved in response to a conserved domain of bacterial flagellin provides evidence for this notion.^[7]

THE EVOLUTION OF SPECIFIC RECOGNITION: THE GENE-FOR-GENE RELATIONSHIP

The gene-for-gene relationship is a compelling and unifying concept in plant pathogenesis. Table 2 in Crute et al. provides a summary of the basic properties of a gene-for-gene interaction.^[8] Over the last century, many hundreds of so-called plant R genes have been identified by their capacity to mediate pathotype-specific resistance to particular pathogens. Over the last ten years, some tens of these R genes have been isolated and sequenced^[11] with details of their evolutionary origins and the way they are organized within plant genomes emerging from associated studies.^[9–12] Several different classes of R genes exist in plants^[11,12] and access to whole genome sequences now indicates the existence of about 150 “resistance gene analogs” (RGAs) in one genotype of *Arabidopsis thaliana* and about 1700 in rice (of which function has only been attributed to relatively few).^[12] R genes with structural homology are now known to mediate resistance to parasitic agents as diverse as fungi, oomycetes, bacteria, viruses, nematodes, and aphids.

Although allelic variation at single R gene loci does occur, RGAs are commonly clustered within complex loci comprising a variable number of paralogs that have arisen by gene duplication.^[9,10,12] Out-crossing and recombination, random mutation, interallelic recombination, gene conversion and unequal crossing-over (resulting in gene duplications and deletions) provide mechanisms for the generation of allelic and haplotypic variation on which selection can act. Time-scales over which variation is generated and selected as well as the processes involved in selection are the subject of debate and investigation.^[9–12] In addition, selection may favor the observed physical association of genes that are structurally unrelated but contribute to R gene function.^[7,9]

CONCLUSION

The protein products of R genes are believed to function as components of a signal-transduction system. A putative receptor system recognizes molecules indicative

of pathogen presence and activates the plant's generic defense responses. The receptor and signaling system has numerous components that are being revealed by genetics and cell biology^[1] with previously characterized R genes representing one such component. Recognition specificity may be contributed primarily, but not exclusively, by a LRR common to the proteins encoded by different classes of R gene. This domain comprises a variable number of repeats of the motif xxLxLxx putatively providing an array of solvent-exposed ligand-binding surfaces. For several R gene families, regions of the LRR have been shown to be under diversifying selection as indicated by a ratio of greater than one for the synonymous to non-synonymous substitutions of the nucleotides encoding residues in the region (excluding the conserved aliphatic residues).^[2,9,10] On the basis of phenotypic specificity, there is no evidence that any one R allele has affinity for more than one ligand. However, there is no intrinsic reason why this would not be the case and the degree of ligand affinity is likely to be another attribute of RGAs on which selection will act.

Astronomical sequence variation is likely to be manifested by RGAs represented within a single plant genome, within the genepool of a particular plant population and among the diversity of a genotypes represented by any particular plant species. Within and between individual plants the way in which the molecular machinery for signal recognition and transduction is assembled may be subject to combinatorial variation. Such variation may allow individual plants to recognize and respond effectively to molecules that represent the invariant signature of potential pathogens (such as bacterial flagellin) to which the plant is a non-host.^[7] At the same time, the system can provide access to the necessary genetic variation to facilitate a micro-evolutionary response to the tiny sub-set of pathogens of the host species that are detected only by genotypically variant molecular cues on which selection acts to enhance pathogen success. Experimental evidence will probably be forthcoming to establish whether genotype-specific and non-host resistance are indeed mediated through essentially similar signaling pathways differing only in the number of ligands detected or the extent to which the ligand molecule is variant and dispensable or invariant and indispensable to the potential pathogen.

Plant-Produced Recombinant Therapeutics

Lokesh Joshi
Miti M. Shah
C. Robert Flynn
Alyssa Panitch

Arizona Biodesign Institute, Arizona State University, Tempe, Arizona, U.S.A.

INTRODUCTION

The technology of bioengineering plants to produce recombinant therapeutics has become commonplace. Transgenic plants are emerging as suitable alternatives to transgenic animals and bioreactor-based systems for recombinant protein production (e.g., bacterial, yeast, and insect cells). This trend is yielding a recombinant protein expression system that has increased economic viability and a greater capacity for producing lifesaving protein therapeutics and biopolymers. In addition, plant products are free of mammalian viruses, prions, or other adventitious organisms harmful to humans, making them safer production systems. A wide variety of recombinant protein molecules have been successfully produced in plants (Table 1). This section briefly describes some representative proteins and the role of PTMs on these molecules.

IMMUNOGLOBULINS

IgG and IgA are multifunctional glycoprotein immune molecules that bind to antigens, form immune complexes, and activate classical and alternative complement pathways, respectively. This activity leads to the destruction and clearance of the pathogen. Both IgG and IgA are glycosylated, and although glycosylation is not required for antigen binding, it is critical for activation of the complement pathway.^[1] Deglycosylated or underglycosylated immunoglobulins (IgG and IgA) are unable to activate the effector mechanism and therefore fail in the clearance of the pathogen and other antigenic moieties. Plants are able to perform expression and assembly of immunoglobulin (Ig) heavy and light chains into functional antibodies.^[2] Plants have been used for production of different forms of antibodies that include full-size IgG and IgA, chimeric IgG and IgA, single-chain Fv fragments (ScFv), Fab, and heavy-chain variable domains; the last three types do not require glycosylation. Among the antibodies that have been successfully produced in plants are those against surface antigen of *Streptococcus*

mutans, the causative agent of dental caries,^[3] herpes simplex virus,^[4] carcinoembryonic antigen (CEA), a tumor-associated marker,^[5] and single-chain Fv fragments against non-Hodgkins lymphoma.^[6] The majority of plant-derived antibodies possessed high-mannose and hybrid-type, α 1-3 fucose- and β 1-2 xylose-containing structures that lack β 1-4 galactose and the terminal sialic acid residues. Expression of mammalian β 1-4 Galtransferase in plants resulted in synthesis of galactose-containing antibodies. About 30% of N-glycans of the antibodies were galactosylated.^[7] Plant-derived antibodies do not show any alterations in affinity toward antigens or stability in vivo or in vitro.

VACCINES

Plants are a prime candidate for the production of vaccines because of the lower cost of production and the feasibility of producing “edible vaccines.” This technology can be transferred to developing nations relatively easily compared to other expression systems. Some of the representative examples are provided here:

Rabies vaccine: The rabies virus glycoprotein G and nucleoprotein N are both very important in designing an appropriate vaccine. G protein is the major antigen responsible for induction of protective immunity, and N protein is responsible for induction of virus-specific T cells. A plant-derived oral vaccine against a fusion protein consisting of glycoprotein G, nucleoprotein N, and alfalfa mosaic virus coat protein was made, which produced significant immune response and rabies virus-specific antibodies in both mice and humans.^[8]

Human cytomegalovirus: Human cytomegalovirus (HCMV) is a member of the herpes virus family that is transmitted by blood and body secretions. In immunocompromised individuals, infection of HCMV can lead to damage of the central nervous system and death. Glycoprotein B, a transmembrane envelope protein, was used to produce oral vaccine against the viral infection. The affinity of recombinant glycoprotein B was examined in

Table 1 A brief list of representative biomolecules engineered in plants

Biomolecule	Engineered plant
Human and animal vaccines	Tobacco, potato, corn, lettuce, tomato, alfalfa, <i>Arabidopsis</i>
Immunoglobulins	Tobacco, alfalfa, rice, wheat, soybean
Other therapeutic proteins	Tobacco, canola, rice, turnip, alfalfa, <i>Arabidopsis</i>
<i>Biomaterial:</i>	
Collagen	Tobacco
Spider silk	Tobacco, potato

See Ref. 18 for a more complete list of plant-derived pharmaceuticals.

vitro by its ability to bind monoclonal antibodies. Plant-derived glycoprotein B showed a high affinity to antibodies.^[9]

Gastroenteritis coronavirus: Swine-transmissible gastroenteritis virus (TGEV) is the causative agent of acute diarrhea of newborn piglets. Neutralizing antibodies against this virus is mainly directed toward a surface component, glycoprotein S. Glycoprotein S from TGEV, produced recombinantly in plants, can function as a vaccine against infection when injected intramuscularly in animals. Glycoprotein S has three glycosylation sites, which play an essential role in conformation of this protein. However, no further information on glycosylation of the recombinant glycoprotein S is available.^[10]

Measles virus: Measles is a highly contagious viral disease. Severe infection may lead to pneumonia, encephalitis, and death. Hemagglutinin, a surface protein from measles virus, was expressed in plants. For recognition of hemagglutinin by B lymphocyte cells, an appropriate conformation of the protein is essential. Folding, stability, and protease susceptibility of this protein is dependent on four N-glycosylation sites. Plant-derived hemagglutinin was found to be stable and able to induce an immune response in animal model systems upon oral administration. This indicates that plants are able to achieve sufficient glycosylation required for stability and folding of the protein.^[11]

OTHER PROTEIN THERAPEUTICS

Follicle-stimulating hormone: Follicle-stimulating hormone (FSH) is a pituitary heterodimeric glycoprotein hormone that requires N-glycosylation for subunit folding, assembly, targeting, and stability. FSH produced in plants possesses terminal mannose residues and is reported to be biologically active.^[12]

Lactoferrin: Lactoferrin is a milk protein. In humans, it is known to contain two N-acetylglucosamine-type N-glycans that also contain fucose and sialic acid residues. Lactoferrin belongs to the family of transferrin with iron-

binding properties. It has also been found to possess antibacterial, antifungal, antiviral, and antiinflammatory activities. Full-length lactoferrin with antimicrobial properties is produced in plants.^[13]

Erythropoietin: Erythropoietin (EPO), an N-glycosylated protein that regulates the formation of erythrocytes in mammals, was recombinantly produced in plants. EPO produced in tobacco cells was glycosylated with N-linked oligosaccharides that did not possess terminal sialic acid residues. EPO produced in tobacco exhibited in vitro biological activities by inducing the differentiation and proliferation of erythroid cells. However, it did not show in vivo biological activities.^[14] The authors speculated that this was attributable to the different glycosylation of EPO produced in tobacco cells as compared to authentic human EPO and was cleared from circulation by asialo-receptors.

Macrophage Activating Factor: Macrophage activating factor (MAF), also known as vitamin D-binding protein and Gc-globulin, is a multifunctional abundant serum protein. Threonine-420 of domain III of MAF is O-glycosylated. Upon infection with pathogen or tumor cells, activated T and B lymphocyte cell surface exoglycosidases remove sialic acid and galactose residues, leaving a GalNAc attached to the threonine.^[15] This GalNAc is essential for MAF to bind to the C-type lectin on the cell surface of mononuclear phagocytes, which leads to their activation. Activated phagocytes remove pathogens and tumor cells from the body. Efforts are underway to express this serum glycoprotein in plants.

Acetylcholinesterase: Acetylcholinesterase (AChE) catalyzes the degradation of acetylcholine, a neurotransmitter. AChE is a potential therapeutic against organophosphate-based chemicals and warfare agents. Sialic acid residues on the N-glycans of AChE are crucial in determining the circulatory clearance rate. Production of AChE in HEK-293 cells led to hyposialylation of the protein, which was responsible for rapid clearance of recombinant AChE from the circulation. Recombinant human AChE was produced in tomato plants by Mor et al.^[16] Kinetic studies of the recombinant AChE using inhibitors showed that the plant-produced AChE had an

inhibition profile similar to the commercially available AChE purified from human erythrocytes. However, in vivo activity, serum half life, and glycosylation studies of plant-produced AChE have not yet been reported.

BIOMOLECULES

Collagen: Collagen is the major protein in the extracellular matrix and is thus the most prominent animal protein. There are more than 20 different types of collagens described so far. The triple-helical domains of collagens have the repeating amino acid sequence (Gly- X-Y)_n, where X and Y are frequently proline and hydroxyproline, respectively. Collagen molecules go through multiple PTMs involving at least eight enzymes and cofactors. Specific proline and lysine residues are hydroxylated, and some of the hydroxylysine residues are further modified by glycosylation with galactose-glucose disaccharide units. Hydroxylation of proline to hydroxyproline residues assists in trimer assembly of collagen polypeptide chains. Collagens and their derivative molecules (gelatin) have multiple applications but are currently only available from animal sources. There is a need for alternative sources to produce large quantities of pure and safe collagens. Human collagen α -1 (C1 α 1) has been expressed by itself and with the multisubunit recombinant prolyl-4-hydroxylase,^[17] in transgenic tobacco, collagen trimers have been produced that are stable up to 37°C. These reports suggest that the production of human collagen is possible in plants. However, further research is required to understand and improve recombinant collagen synthesis and assembly in plants.

CONCLUSION

The discovery of and demand for medically important proteins are growing rapidly. It is becoming increasingly critical to ensure their availability in sufficient quantity for research, therapeutics, and diagnostic uses. Transgenic plants are emerging as suitable systems for the production of functional recombinant human proteins. Plants have the distinct advantages over other expression systems of product safety, economical production, and ease of scale-up. Plants are also able to perform most PTMs that are carried out by mammals, such as glycosylation, phosphorylation, and hydroxylation. However, the PTMs in plants are under-studied and require more attention because it is important to control the addition of and evaluate the structural and functional roles of these modifications on recombinant products for regulatory purposes as well as for desired physiological

activities, when used for therapeutic purposes in humans and animals.

Plant Response to Stress: Abscisic Acid and Water Stress

Jun Huang
Jian-Kang Zhu

The University of Arizona, Tucson, Arizona, U.S.A.

INTRODUCTION

Plant growth and yield potential are significantly influenced by various abiotic stresses such as drought, salinity, and cold. A common feature found in plants grown under water stress is a transient increase in the level of the phytohormone abscisic acid (ABA), which returns to control level promptly following relief of the stress. ABA plays important roles in many aspects of plant growth and development such as embryo maturation, seed dormancy, germination, stomatal aperture, as well as sugar signaling and regulation of expression of stress-responsive genes. Utilizing genetic and biochemical approaches, the ABA biosynthetic and catabolic routes have been recently outlined in higher plants. An important challenge in the future is to understand how plant cells sense and transduce the water stress signal to induce ABA biosynthesis and inhibit ABA degradation.

ABA ACCUMULATION IN PLANTS UNDER WATER STRESS

The natural *S*-(+)-ABA is ubiquitous in all photosynthetic organisms but not in bacteria.^[7] In mesophytic plants, the endogenous levels of ABA can rise 10-fold to 50-fold in water-stressed leaves, and return to prestress levels once the plants are rewatered, usually within 4–8 hr.^[8] The primary cue for initiating ABA accumulation in water-stressed tissues is not clear, although an acute rise in ABA content correlates well with leaf water potential falling below -1.0 MPa and decreased stomatal conductance. The increased ABA levels are probably caused by greater rates of synthesis and increased import from surrounding tissues, whereas the decreased concentration is because of reduced synthesis, robust catabolism, inactivation by conjugation of ABA to its glucose ester (GE), and possible effluxes.^[3,7] The increased rate of de novo ABA synthesis in water-stressed tissues requires gene transcription and protein synthesis because it can be blocked by inhibitors of transcription such as actinomycin

D and cordycepin, and by inhibitors of protein synthesis such as cycloheximide.

BIOSYNTHESIS OF ENDOGENOUS ABA

Through the cloning of genes from mutants impaired in ABA biosynthesis, combined with the use of inhibitors of ABA biosynthesis and in vivo $^{18}\text{O}_2$ labeling studies, it is clear that ABA is derived from an oxygenated carotenoid precursor (C_{40}). The studies also suggest that the early steps of ABA biosynthesis are localized to the plastids.^[6,7]

Based on our current understanding,^[1,2,6,7] the major ABA biosynthesis route has emerged (Fig. 1). In the plastids, the carotenoids are synthesized from the C_5 precursor, isopentenyl pyrophosphate (IPP). Plastidic IPP is synthesized from glyceraldehyde-3-phosphate and pyruvate via 1-deoxy-D-xylulose-5-phosphate (DXP). Subsequently, IPP is converted to a xanthophyll zeaxanthin via several intermediate products including a C_{20} geranylgeranyl pyrophosphate (GGPP), a C_{40} phytoene, and β -carotene.

The epoxidation of zeaxanthin and antheraxanthin to all-*trans*-violaxanthin is catalyzed by zeaxanthin epoxidase (ZEP; encoded by *ABA1/AtZEP1* in Arabidopsis and *ABA2* in tobacco). Subsequently, during the first committed step in ABA biosynthesis, 9-*cis*-violaxanthin and 9'-*cis*-neoxanthin (C_{40}) are further oxidatively cleaved by 9-*cis*-epoxycarotenoid dioxygenase (NCED; encoded by *AtNCED* in Arabidopsis and *VP14* in maize) to generate xanthoxin (C_{15}) and a C_{25} apocarotenoid by-product. Following entry into the cytosol, xanthoxin is converted first to ABA aldehyde by xanthoxin oxidase/short-chain alcohol dehydrogenase (encoded by Arabidopsis *ABA2/GINI*), and then to ABA by ABA aldehyde oxidase (AAO). The function of AAO requires an activated form of a molybdenum cofactor, which is generated by a sulfurase enzyme (encoded by *ABA3/LOSS*). It should be pointed out that there appears to be an alternative route converting abscisic alcohol to ABA.^[5-7] The NCED-catalyzed oxidative cleavage of 9-*cis*-violaxanthin and 9'-*cis*-neoxanthin is considered as the critical rate-limiting step in the ABA biosynthesis pathway in higher plants.^[1,9]

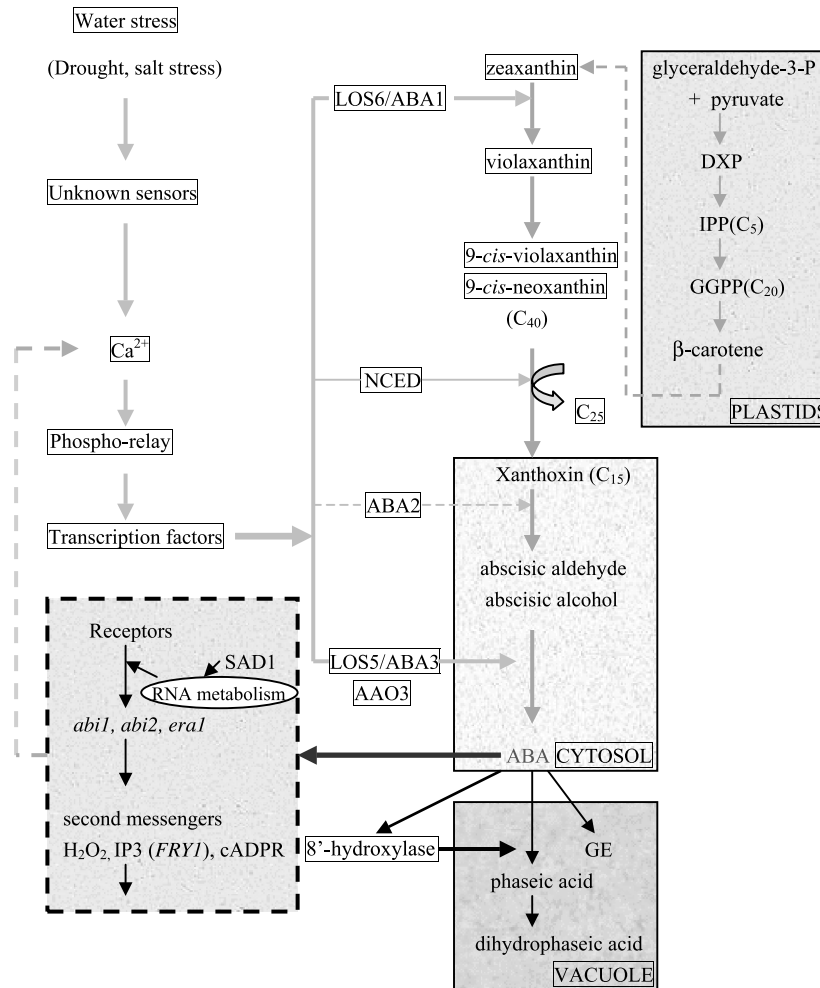

Fig. 1 Water stress induces ABA accumulation (closed boxes) by inducing biosynthesis genes. Also shown is the positive feedback regulation (thick arrows) of the biosynthesis genes by ABA. The ABA signaling components (dashed box) may also impact ABA biosynthesis through feedback regulation. (View this art in color at www.dekker.com.)

CATABOLISM OF ABA

The amount of ABA present in a tissue is regulated dynamically through not only biosynthetic inputs as described above, but also through catabolic outputs, as summarized below. Of several metabolic pathways by which endogenous ABA can be degraded or inactivated, the predominant catabolic pathway is through the 8'-hydroxylase-catalyzed formation of 8'-hydroxy ABA, which is unstable and can cyclize to result in (-)-PA. PA can be further reduced to dihydrophaseic acid (DPA).^[7] Other minor alternative catabolic pathways may also exist because trace amounts of other metabolites, including (+)-7'-hydroxy ABA, are found in certain plants. ABA can also be inactivated through the formation of ABA conjugates such as ABA GE.

REGULATION OF ABA BIOSYNTHESIS AND CATABOLISM GENES BY WATER STRESS

The expression levels of several ABA synthesis genes including *ZEP* (*LOS6/ABA1*, zeaxanthin epoxidase), *NCED3*, *AAO3*, and *MCSU* (*LOS5/ABA3* and molybdenum cofactor sulfurase) are upregulated by drought and salt stress, but not obviously induced by cold.^[2,5,10] Some of the ABA biosynthesis genes are also upregulated by ABA itself, suggesting that there is a positive feedback loop in regulating ABA biosynthesis^[11,8] (Fig. 1). In *Arabidopsis*, *ZEP* is expressed in most tissues and upregulated by water stress in roots and shoots of wild-type plants, but not in ABA-deficient or ABA-insensitive mutants.^[8] Furthermore, the expression of both *ZEP* and *NCED3* fluctuates in leaves in a diurnal pattern.^[6]

NCED3, expressed in all tissues examined, is the only member of the nine-gene family in *Arabidopsis* that is highly induced by NaCl and dehydration, but its induced expression by exogenous ABA varies among ecotypes. Expression studies in other species indicate that water stress-induced ABA levels correlate well with both transcript and protein accumulation of *NCED*. The fact that *NCED* is not substantially upregulated by ABA supports the notion that it is the initial rate-limiting step in ABA biosynthesis.^[81] *ABA2* is expressed constitutively and not significantly upregulated by exogenous ABA or water stress. *AAO3* is induced by water stress in leaves but not in roots.^[6] The catabolic enzyme, 8'-hydroxylase, is also induced by exogenous ABA, although the identity of the gene encoding this enzyme has not been reported. Water stress appears to induce the expression of the ABA biosynthetic genes, possibly through a Ca²⁺-mediated protein phosphorylation cascade (Fig. 1). The signaling pathways downstream of ABA also modulate ABA biosynthesis by affecting the positive feedback regulation of the biosynthesis genes. Through an unknown mechanism, ABA sensitivity is controlled by RNA metabolism, which in turn is regulated by ABH1 and SAD1.^[4] The *sad1* mutation impairs the ABA upregulation of *AAO3* and *MCSU* genes and results in ABA deficiency and a drought-hypersensitive phenotype, indicating that the feedback loop of ABA biosynthesis is indirectly regulated by SAD1. The feedback loop is also partially impaired in the ABA-insensitive mutant *abi1*, but not in *abi2*.^[81]

CONCLUSION

Although substantial advances are being made in our understanding of the ABA biosynthesis genes, little is known about their regulation by water stress. The crosstalk between ABA signaling cascades and ABA biosynthetic and catabolic pathways is not clearly understood. The identification of osmotic stress sensor(s) and ABA receptor(s) and their downstream signaling components awaits further genetic, molecular, biochemical, and cell biological studies. Understanding these pathways will facilitate efforts to manipulate the endo-

genous ABA content to improve water stress tolerance in plants.

Plant Response to Stress: Abscisic Acid Fluxes

Wolfram Hartung

Universität Würzburg, Würzburg, Germany

INTRODUCTION

Water relations and stress tolerance of plant cells and tissues of crop plants are significantly improved when abscisic acid (ABA) concentrations are high. This occurs by closing the stomata, stimulation of water uptake into roots, and induction of developmental changes that improve the stress tolerance in plants. Such plants perform particularly well under arid conditions. Stress-tolerant crop varieties often exhibit high ABA concentrations and treatments that intensify long distance ABA signaling reduce water consumption and, in the case of grapevine, improve the quality of the berries. The knowledge of mechanisms that increase ABA concentration in organs under mild and severe stress are also of special interest for agricultural and horticultural scientists.

ABA accumulation in cells, tissues, and organs may be a result of an altered ABA metabolism (increased biosynthesis and/or decreased degradation). The rates of these biochemical processes, however, are rather slow. ABA fluxes that may be influenced under stress can be a much more effective, sensitive, and rapid mechanism to maintain ABA homeostasis and to change rapidly ABA concentrations in cellular compartments, cells tissues, and organs. In this article, ABA fluxes will be discussed at the membrane, tissue, and organ level. Mild (hypoosmotic) stress conditions that are not sufficiently severe to stimulate ABA biosynthesis in leaves and root tips are discussed predominantly.

ABA FLUXES ACROSS BIOMEMBRANES

Roots

ABA fluxes across membranes have been investigated in detail using the efflux compartmental analysis. When barley roots were stressed hypoosmotically with sorbitol ABA, fluxes across the plasmalemma of both cortical and xylem parenchyma cells were reduced, and the flux across the tonoplast was stimulated, resulting in an increased cytosolic ABA concentration in the root cells.^[1,2]

ABA fluxes into the surrounding rhizosphere can be particularly severe when the soil solution is alkaline. Under such conditions, ABA leaks from roots into the soil

solution, especially when they lack Casparian bands in their hypodermis. An undesirable efflux can be avoided when the ABA concentration in the soil solution of the rhizosphere is sufficiently high. Thus, an equilibrium between internal and external ABA is maintained.^[3]

Mesophyll Cells, Epidermal Cells, and Guard Cells

ABA fluxes across plasma membranes and tonoplasts of mesophyll and guard cells have also been investigated using the efflux compartmental analysis. Again, sorbitol was used as an osmoticum to establish hypoosmotic and hyperosmotic stress. ABA flow across the plasma membranes of the guard cells of *Valerianella locusta* is reduced significantly under hypoosmotic stress, whereas the ABA flux across the tonoplast is only slightly affected. This results in a transiently increased apoplastic and a reduced cytosolic ABA concentration. It was concluded^[2] that the ABA increase in the apoplast is of special physiological importance in terms of stress, because those structures that may recognise ABA at the guard cells seem to be located on the outer surface of the guard cell plasma membrane.^[3] The ABA fluxes across the plasma membrane of barley epidermis cells have also been investigated. They are facilitated by a carrier that becomes active when the apoplastic pH of stressed leaves is increased and excess ABA has to be removed from the leaf apoplast to the surrounding tissues.^[4]

It should be pointed out that efflux experiments described here have been performed under equilibrium conditions. In an intact plant, however, delivery of ABA from other organs and changes of ABA metabolism must also be considered. All of these additional processes that have an impact on ABA gradients across membranes have been incorporated into a mathematical model that quantitatively describes ABA flows under the complex fluctuating conditions that occur in the natural habitat.^[3]

Stem and Mesocotyl Parenchyma

During its long distance transport in the xylem of bean internodes and maize mesocotyls, ABA can be redistributed to the surrounding tissues. If ABA_{xy1} is low, those

tissues can release ABA into the xylem with rates of approximately $1 \text{ pmol m}^{-2} \text{ s}^{-1}$.^[5,6] These tissues play an important role for the ABA homeostasis in the xylem vessels of stems.

ABA FLUXES BETWEEN TISSUES

The ABA flows between root cortex and root stele are of particular physiological interest with regard to stress. Large quantities of root ABA have to be transported laterally from the cortex across the endodermis into the xylem parenchyma and into the xylem vessels. In the case of a symplastic transport, ABA has to pass the plasma-membrane of xylem parenchyma cells to reach the xylem vessels. This is a rate limiting step that is much slower than water transport into the xylem. When the water flow is increased by transpiration, ABA_{xyl} is diluted. An apoplastic transport of ABA by solvent drag across the endodermis would compensate or even overcompensate this dilution, provided their Casparian bands are permeable for ABA. Indeed, a significant apoplastic bypass flow of ABA could be detected in maize roots. The intensity of the apoplastic bypass flow of ABA depends on the species, the pH of the root cortical apoplast and the apoplastic ABA concentration.

The other important apoplastic barrier of the roots, the exodermis, prevents ABA loss into the soil solution, especially under nontranspiring conditions. This explains the tolerance of plants with exodermises to alkaline soils of arid habitats compared to those without an exodermis, mainly the Fabaceae, which are unprotected.^[5-8]

LONG DISTANCE ABA FLOWS BETWEEN ORGANS

Root-to-shoot flows of ABA are of special interest under conditions of mild stress when water relations of the leaves are not affected. The roots, however, experience stress as the soil is drying. ABA flows between organs have been investigated predominantly with *Ricinus communis* and *Lupinus albus*, which allow harvest of both transport fluids, phloem and xylem sap. Long-distance signaling has been reviewed recently in detail.^[5,6,9]

The ABA flow from the root to the shoot in the xylem is increased by moderate salt stress in lupins tenfold, and in castor bean fivefold. This ABA did not originate exclusively from biosynthesis in the roots. A significant portion is recirculated in the phloem from the leaves via roots back to the shoot. This portion of recirculated ABA was increased under salt stress in *Lupinus* and in *Ricinus* two to three fold. The ABA signal in the xylem of *Ricinus* is also increased threefold when nitrate in the nutrient medium is replaced by ammonium. Under phosphate de-

ficiency that often occurs in alkaline soils of extreme arid habitats, the root-to-shoot flow of ABA is increased tenfold, whereas nitrate deficiency has only a weak negligible effect. Potassium deficiency causes a fourfold higher root-to-shoot ABA flow in the xylem.^[10]

When nitrate or ammonium is sprayed to the leaves of *Ricinus* and the root medium is kept N-free, ABA biosynthesis of nitrate-sprayed plants is increased, resulting in stimulated ABA transport in the phloem to the roots where most of the ABA is metabolised. In ammonium-sprayed plants, a significant amount of ABA biosynthesis can be observed in the roots, resulting in an increased root-to-shoot flow compared to nitrate-sprayed plants. This resembles strongly the situation of plants where roots were supplied with ammonium. A shoot-to-root signal of ammonium-sprayed plants that causes ABA biosynthesis in the roots and ABA transport in the xylem must be postulated. This signal is unknown.^[9]

ABA Flows from the Shoot to the Root

A role of ABA as a shoot-to-root signal has been postulated for *Ricinus* seedlings that increases the ABA flow in the phloem under mild water deficiency by fiftyfold. Intact lupins and castor beans showed a two- to fivefold increase of phloem ABA flow under conditions of salt and ammonium stress but not under conditions of phosphate and nitrate deficiency. Maize plants that were cultivated with only their seminal roots experience water stress in the leaves because water flow was restricted by the constant number of xylem vessels. As a result, not only was ABA increased in the leaves (tenfold), but also surprisingly in the roots. This is most likely due to increased phloem transport because an increase of ABA synthesis in the unstressed, well-hydrated and nutrient-supplied roots seems to be extremely unlikely. The ABA delivered by phloem transport to the roots may stimulate the development and the hydraulic conductivity of the root systems under stress.^[7,9]

LONG DISTANCE FLOW OF ABA CONJUGATES

It has been postulated repeatedly that ABA conjugates, predominantly the ABA-glucose ester (ABA-GE), act as hormonal root-to-shoot stress signals. Indeed, an increased xylem transport of ABA-GE has been observed in the xylem sap of drought- and salt-stressed barley, maize, rice, and sunflower plants. Since ABA-GE is extremely hydrophilic, it is transported in the xylem over long distances without any loss by redistribution to the surrounding stem parenchyma. On the other hand, it cannot pass apoplastic barriers in roots and be taken up into mesophyll cells after its arrival if the leaf apoplast is

extremely small. Specific esterases in the root and leaf apoplast release free ABA from its conjugate. Afterward, ABA can be redistributed to the surrounding cells. In leaves the activity of these esterases is increased significantly under salt stress which provides a further mechanism to increase the ABA at the site of action in stressed leaves.^[7,9,11]

CONCLUSION

Environmental stresses influence flows of the stress hormone ABA on cellular, tissue, and organ levels, which results in altered concentrations of this universal plant stress hormone at the primary site of the target cells and tissues. Flows are altered already under mild stress conditions. Thus, ABA can be increased without affecting the biosynthesis and metabolism of ABA. The root-to-shoot ABA signal can be intensified by special cultivation techniques, such as partial root drying (PRD). In both the greenhouse (tomato^[12]) and under field conditions (grapevine^[13]), when water was withheld from only a part of the root system while the other was irrigated, ABA concentration in the xylem was increased markedly. Changes of fertilization (ammonium versus nitrate) may also enhance long-distance flows from the roots to the shoots^[9,10] The resulting ABA increase in the leaves and the fruit reduces the water consumption without significant negative effects on the yield. Additionally, PRD has a positive effect on those factors that control the fruit quality of tomato and grapevine (sugars, acids, pigments, etc.). The knowledge of the mechanisms that modify ABA fluxes in crop and fruit plants is of practical and commercial interest, especially for agriculture in arid climates.

Plant Response to Stress: Biochemical Adaptations to Phosphate Deficiency

William C. Plaxton

Queen's University, Kingston, Ontario, Canada

INTRODUCTION

Phosphate (Pi) is an essential macronutrient that plays a central role in virtually all metabolic processes in plants, including photosynthesis and respiration. Despite its importance, Pi is one of the least available nutrients in many ecosystems, and is a frequent limiting factor for plant productivity. Although plentiful in the earth's crust, soil Pi often exists in insoluble mineral forms that render it unavailable to plants. Agricultural Pi deficiency is alleviated by the massive application of Pi fertilizers, currently estimated to be about 40 million metric tons per year worldwide. However, the assimilation of Pi fertilizers by crops is quite inefficient, as a large proportion of applied Pi becomes immobile, or may runoff into and thereby pollute nearby surface waters. Moreover, the world's reserves of rock Pi (mined for production of Pi fertilizers) are expected to be depleted within the next century. Thus, studies of the complex mechanisms whereby plants acclimate to nutritional Pi deficiency are of great importance. This could lead to the development of rational strategies for engineering Pi-efficient transgenic crops that would reduce or eliminate our current overreliance on expensive, polluting, and nonrenewable Pi fertilizers. The aim of this article is to provide a brief overview of the fascinating biochemical adaptations of Pi-starved (–Pi) plants.

THE PLANT PHOSPHATE-STARVATION RESPONSE

Plants have evolved the ability to acclimate, within species-dependent limits, to extended periods of Pi deficiency. Pi deprivation elicits a complex array of morphological, physiological, and biochemical adaptations, collectively known as the *Pi-starvation response*. Plant morphological/physiological adaptations that enhance the acquisition of limiting Pi from the soil include increased root growth relative to shoot growth, as well as root colonization by mycorrhizal fungi.^[1,2]

Mycotrophic Versus Nonmycotrophic Plants

Symbiotic mycorrhizal fungi help mycotrophic plants increase Pi-uptake from Pi deficient soils. In return, the host plant supplies sucrose to fuel the energy demands of the mycorrhizal symbiont. Mycorrhizae colonize the roots of most plants, except for the nonmycotrophic minority that include members of the Cruciferae, Chenopodiaceae, and Proteaceae families. It is notable that many nonmycotrophs, such as buckwheat and white lupin, are notorious for their ability to thrive on infertile soils. This reflects the view that relative to mycotrophic plants, the nonmycotrophs appear to have evolved to allow more efficient acclimation to low Pi conditions.^[2]

BIOCHEMICAL ADAPTATIONS OF PHOSPHATE-STARVED PLANTS

Adaptation #1: Increased Efficiency of Cellular Phosphate Uptake

Multiple plasmalemma Pi transporters are differentially expressed under varying Pi nutritional regimes.^[1] The widely accepted dual Pi uptake model is characterized by constitutive low-affinity and Pi-starvation inducible (PSI) high-affinity Pi transporters that respectively function at high (mM) and low (μ M) concentrations of external Pi. High-affinity Pi transporters likely play a crucial role in the acquisition of limiting external Pi by –Pi plants.^[1,2] Genome sequencing has indicated that *Arabidopsis* contains nine members of the high-affinity Pi transporter gene family, but only a single low-affinity Pi transporter gene.

Adaptation #2: Induction of Phosphate Scavenging and Recycling Enzymes

2A: Acid phosphatase

Acid phosphatase (APase) induction is a universal symptom of plant Pi stress.^[2,3] APases function as intracellular

Fig. 1 Phosphate scavenging and recycling enzymes of $-Pi$ plant cells. (a) General reaction catalyzed by acid phosphatase. R denotes an organic molecule. (b) Model of Pi scavenging from extracellular nucleic acids by secretory nucleolytic enzymes. Asterisks denote PSI proteins. (Adapted from Ref. 4; modified figure reproduced with permission of The American Society of Plant Biologists.)

(vacuolar) or extracellular (secreted) Pi salvage systems that catalyze the hydrolysis of Pi from phosphate-monoesters (Fig. 1(a)). The existence of 22 *Arabidopsis* genes that putatively encode different APases indicates that plant APase biochemistry is relatively complex.

2B: Secreted nuclease and phosphodiesterase

Nucleic acids present in decaying organic matter represent an important source of extracellular Pi that may be exploited by $-Pi$ plants. Degradation of extracellular DNA and RNA by PSI-secreted nucleases, phosphodiesterase, and APase liberates Pi from nucleic acids for its subsequent uptake by PSI high-affinity Pi transporters of $-Pi$ plant roots (Fig. 1(b)).^[2,4]

2C: Replacement of membrane phospholipids with nonphosphorus galacto- and sulfonyl-lipids

$-Pi$ plants can scavenge and conserve Pi by replacing their membrane phospholipids with amphipathic galacto- and sulfonyl lipids. *Arabidopsis* mutants defective in sulfolipid synthase (the terminal enzyme of sulfonyl lipid synthesis) were recently reported to show impaired growth during Pi deprivation.^[5]

2D: Induction of metabolic phosphate recycling enzymes

Several PSI glycolytic bypass enzymes such as PPI-dependent phosphofructokinase (PPI-PFK), phosphoenol-

pyruvate (PEP) phosphatase, and PEP carboxylase (PEP-Case) may facilitate intracellular Pi recycling, because Pi is a by-product of the reactions catalyzed by each of these enzymes (Fig. 2). Their reactions may also facilitate respiration and/or organic acid excretion, while generating free Pi for its reassimilation into the metabolism of the $-Pi$ cells.^[2]

2E: Organic acid excretion

Scavenging of Pi from extracellular sources may be aided by the enhanced excretion of organic acids due to PEPCase induction. Roots and suspension cell cultures of $-Pi$ plants have been demonstrated to markedly up-regulate PEPCase.^[1,2,6-8] PEPCase induction during Pi stress has been correlated with the excretion of significant levels of organic acids such as malate and citrate. This leads to acidification of the rhizosphere, which thereby contributes to the solubilization and assimilation of mineral Pi from the environment.^[1,2,7]

Adaptation #3: Induction of Alternative Pathways of Cytosolic Glycolysis

As a consequence of the large decline (up to 50-fold) in cytoplasmic Pi levels that follows severe Pi stress, large reductions in intracellular levels of ATP and related nucleoside phosphates can also occur (Table 1).^[2,7,8] This may hinder carbon flux through the enzymes of classical glycolysis that are dependent upon adenylates or Pi as cosubstrates (Fig. 2). Despite depleted intracellular Pi

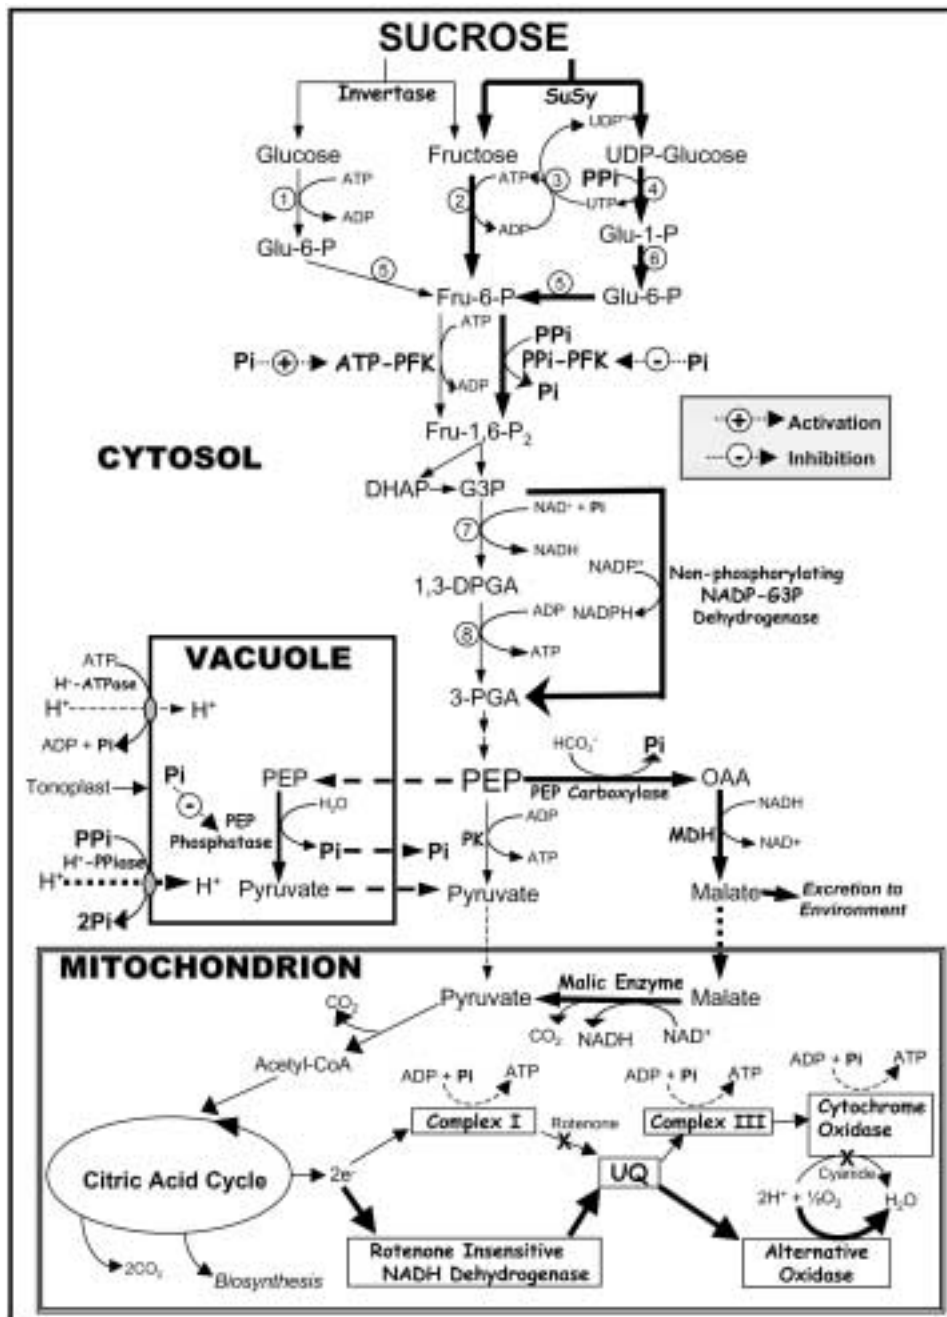

Fig. 2 A model suggesting various adaptive metabolic processes (indicated by bold arrows) that may promote the survival of $-P_i$ plants. Alternative pathways of cytosolic glycolysis and mitochondrial electron transport, and tonoplast H^+ -pumping facilitate respiration and vacuolar pH maintenance by $-P_i$ plant cells because they negate the dependence on adenylates and P_i , the levels of which become markedly depressed during severe P_i starvation. Organic acids produced by PEPCase may also be excreted by roots to increase the availability of mineral-bound P_i (by solubilizing Ca-, Fe- and Al-phosphates). A key component of this model is the critical secondary role played by metabolic P_i recycling systems during P_i deprivation. Enzymes that catalyze the numbered reactions are as follows: 1) hexokinase; 2) fructokinase; 3) nucleoside diphosphate kinase; 4) UDP-glucose pyrophosphorylase; 5) phosphoglucose isomerase; 6) phosphoglucose mutase; 7) NAD-dependent G3P dehydrogenase (phosphorylating); and 8) 3-phosphoglycerate kinase. Abbreviations are as in the text and as follows: DHAP, dihydroxyacetone-phosphate; Fru, fructose; Glu, glucose; MDH, malate dehydrogenase; OAA, oxaloacetate; 3-PGA, 3-P-glycerate; PK, pyruvate kinase; UQ, ubiquinone.

Table 1 Metabolite levels in black mustard suspension cells^a

Metabolite	nmol.gram fresh wt ⁻¹		Change due to Pi-deprivation
	+Pi cells	-Pi cells	
Pi	17,400 ± 1,200	400 ± 60	44-fold decrease
ATP	138 ± 12	36 ± 5	4-fold decrease
ADP	53 ± 9	4.7 ± 0.8	10-fold decrease
PPi	136 ± 12	124 ± 9	Not significant

^aMetabolite levels in *Brassica nigra* (black mustard) suspension cells cultured for 7 days in the presence and absence of 10 mM Pi (+Pi and -Pi, respectively). All values represent means ± S.E.M. of duplicate determinations performed on three separate cell cultures.

(Data from Ref. 8. Reproduced with Permission of The American Society of Plant Biologists.)

and adenylate pools, -Pi plants must continue to generate energy and carbon skeletons for key metabolic processes. As indicated in Fig. 2, at least six Pi- and adenylate-independent glycolytic bypass enzymes (sucrose synthase (SuSy), UDP-glucose pyrophosphorylase, PPI-PFK, nonphosphorylating NADP-glyceraldehyde-3-phosphate (G3P) dehydrogenase, PEPCase, and PEP phosphatase) have been reported to be plant PSI enzymes.^[2,6-8] These enzymes are hypothesized to represent PSI bypasses to the adenylate or Pi-dependent glycolytic enzymes (i.e., invertase/hexokinase, ATP-PFK, phosphorylating NAD-G3P dehydrogenase, and pyruvate kinase), thereby facilitating glycolysis during severe Pi stress. Furthermore, as Pi exerts reciprocal allosteric effects on the activity of ATP-PFK (potent activator) and PPI-PFK (potent inhibitor) (Fig. 2),^[7] the large reduction in cytoplasmic Pi in -Pi plants should promote the in vivo activity of PPI-PFK while curtailing that of ATP-PFK.^[2,8]

Pyrophosphate helps Pi-starved plants to conserve ATP

PPi is a byproduct of a host of anabolic reactions, including the terminal steps of macromolecule synthesis. In animals, the high energy phosphoanhydride bond of PPi is never utilized because PPi is always hydrolyzed by abundant inorganic pyrophosphatase (PPIase), making macromolecule synthesis thermodynamically favorable.^[7] However, the large amounts of PPi produced during biosynthesis may be employed by plants to enhance the energetic efficiency of several cytosolic processes. In contrast to animals, the plant cytosol lacks soluble PPIase and thus contains PPi concentrations of up to about 0.5 mM.^[2,7-9] Furthermore, plant cytosolic PPi levels are remarkably insensitive to abiotic stresses such as anoxia or Pi starvation, which elicit significant reductions in cellular ATP pools (Table 1).^[2,7-9]

Adaptation #4: Induction of Tonoplast H⁺-Pumping Pyrophosphatase

In addition to the SuSy pathway of sucrose conversion to hexose-monophosphates, and PPI-PFK, PPi could be employed as an alternative energy donor for the active transport of protons from the cytosol into the vacuole (Fig. 2). That PPI-powered processes may be a crucial facet of the metabolic adaptations of plants to environmental extremes causing depressed ATP (but not PPi) pools is further indicated by the significant induction of the tonoplast H⁺-PPIase by anoxia, or by severe Pi starvation.^[7,9] As indicated in Fig. 2, the induction of PPI-dependent cytosolic bypasses (i.e., tonoplast H⁺-PPIase, PPI-PFK, and SuSy) may serve -Pi plants by: 1) circumventing ATP-limited reactions; 2) conserving limited cellular pools of ATP; while 3) recycling valuable Pi from PPi.

Adaptation #5: Induction of Alternative Pathways of Respiratory Electron Transport

Respiratory O₂ consumption by plant mitochondria can be mediated by the phosphorylating cytochrome pathway or by nonphosphorylating alternative pathways (Fig. 2). The significant reductions in cellular Pi and ADP pools that follow extended Pi deprivation will impede respiratory electron flow through the cytochrome pathway at the sites of coupled ATP synthesis. However, the presence of nonphosphorylating pathways of electron transport provides a mechanism whereby respiratory flux can be maintained under conditions when the availability of ADP and/or Pi are restrictive. Plants acclimate to Pi stress by increased engagement of the nonphosphorylating (i.e., rotenone- and cyanide-insensitive) alternative pathways of respiratory electron transport^[2,10,11] (Fig. 2). Moreover, increased levels of alternative oxidase protein may occur in -Pi plants.^[10,11] This allows continued functioning of

the citric acid cycle and respiratory electron transport chain with limited ATP production. By preventing severe respiratory restriction, the alternative oxidase has been hypothesized to prevent undesirable redirections in carbon metabolism as well as the excessive generation of harmful reactive O₂ species in the mitochondrion of -Pi plants.^[10,11] This has been corroborated by the impaired growth and metabolism of -Pi transgenic tobacco plants that are unable to synthesize a functional alternative oxidase protein.^[10]

CONCLUSION

Studies of plant responses to nutritional Pi deprivation have revealed some remarkably adaptive mechanisms that contribute to the survival of -Pi plants. Although these adaptations are not identical in all plants, certain aspects are conserved in a wide variety of plants from very different environments. The biochemical adaptations of -Pi plants provides an excellent example of how the unique flexibility of plant metabolism and energy transduction helps them cope in a typically stressful environment. These adaptations also provide a useful system for studies of plant signal transduction and gene expression. Future investigations of these pathways should provide further links between the biochemical and molecular control of plant metabolism. A better understanding of the extent to which changes in flux through alternative enzymes and pathways influences plant stress tolerance is of significant practical interest. This knowledge is relevant to the ongoing efforts of agricultural biotechnologists to engineer transgenic crops that have improved resistance to environmental extremes, including Pi starvation.

Plant Response to Stress: Critical Periods in Plant Development

G. Nissim Amzallag

Judean Regional Center for Biological Research, Carmel, Israel

INTRODUCTION

Development is not a continuous phenomenon. Discrete phases, also termed phenophases, are each characterized by a specific pattern of organogenesis or by specific sensitivity to environmental factors. Replacement of a phenophase by another one generates an intermediate stage of transition that may be termed a critical period. "Between successive critical levels [periods] the system retains its qualitative properties; it must be characterized here by a low sensibility to external and internal changes in developmental conditions (high resistance)." From this observation, Zhirmunsky and Kuzmin concluded that critical periods, characterized by a strong increase in sensitivity to external factors, must be the privileged time for the emergence of new structures and physiological characteristics.

Critical periods have not been given attention in physiology, partly because they are so evanescent, and partly because they are interpreted as a passive transition in the expression of two successive developmental programs. However, their investigation reveals a quite different reality: Critical periods appear to be crucial for maturation of an emerging phenophase and for its adaptive adjustment to environmental constraints.

PHYSIOLOGICAL ADAPTATION TO STRESS

In many plant species, an increase in tolerance to a stress may be achieved following preexposure to a moderate stress.^[1] In *Sorghum bicolor*, for example, a three-week pretreatment with 150 mM NaCl (a sublethal concentration) induces an ability to tolerate a concentration of 300 mM NaCl, which is lethal for non-pretreated plants. Further investigations^[1] reveal that increased tolerance is induced by pretreatments starting during a short period of competence, termed a developmental window. During this short period, growth and development are strongly affected in plants exposed to stress, and a large increase in diversity emerges within an initially homogeneous population.^[1] These observations suggest that the developmental window is not a simple phase of competence for

expression of genes for salt resistance. Self-organizing processes seem inherent to maturation of the adaptive response. In *Sorghum*, the developmental window corresponds to the transition from juvenile to mature vegetative development. Other developmental windows have been identified during transition periods,^[1] linking them to critical periods in development.^[2,3]

WHAT IS A DEVELOPMENTAL WINDOW?

A direct link is not always observed between whole plant and cellular levels of tolerance to moderate salinity.^[4] Similar findings are reported concerning heavy metal toxicity or cold tolerance.^[1] In all these cases, the whole plant level of organization remains the determining factor for tolerance to moderate levels of stress. This suggests that the main perturbation following exposure to a sublethal level of stress concerns integrative physiology: between-organs relationships and their controlling factors, the plant growth regulators (PGRs). This is why alleviating effects to moderate levels of stress have been frequently observed following exogenous supply of PGRs.^[5] Moreover, physiological adaptation may result from a simple change in hormone metabolism or in cellular sensitivity to the hormone.

Indeed, changes in hormone sensitivity are observed in plant tissues. Some authors consider these changes to be the main mode of hormone action, in contrast with the well accepted dose-response mode.^[6] These two antagonistic approaches may be integrated in the same framework when considering that dose-response characterizes phenophases and that changes in cellular sensitivity to PGRs are specific to a developmental window. This assumption has been confirmed by observation of changes in hormone sensitivity during this period and by following emergence of new physiological functions on the basis of these changes.^[7,8]

Plants cannot move toward a more appropriate environment. In an ecological perspective, the existence of a developmental window after germination may be justified as a process of adjustment of the seedling to a necessarily unpredictable environment. However, this developmental

window has also been identified as a period of hormone resetting for plants growing in optimal environments.^[7,8] In *Sorghum bicolor*, the developmental window identified during early vegetative development corresponds to the transition from seminal to adventitious root systems. As a new organ, the adventitious root system is integrated in the regulation network during aperture of the developmental window already identified for salt-adaptation. For this reason, the developmental window is identified as a critical period of transition between two phenophases. In this context, physiological adaptation to a moderate environmental stress becomes a companion phenomenon of adaptive adjustments to integration of the adventitious roots during normal development. Moreover, the new emerging phenophase is not the simple expression of a preexisting program of development. It is partly elaborated as a function of the initial phenophase and the internal factors disturbed by their emergence. This requirement of an adaptive dimension of development has been suggested from theoretical considerations (“... adaptive changes in the system’s structure and the character of its regulations will be required to balance the new developmental conditions.”).^[9]

CHARACTERIZATION OF A CRITICAL PERIOD

Intuitively, a critical period includes two steps. The first corresponds to dismantlement of the initial hormone regulation network, leading to a transient increase in autonomy of the different parts of the network. The second corresponds to emergence of a new network of regulation through integration of disturbing factors, endogenous as well as exogenous. This dynamic may be followed through measurement of changes in strength of the regulation network. An index, termed connectance, has been defined as the mean strength of linkage between organs generating together the organism. Connectance is measured on a population that is homogeneous as possible exposed to an environment that is as uniform as possible. In such conditions, the r coefficient for linear regression provides information about the degree of linkage in the regulation network. This linkage may be direct or indirect, so that connectance cannot be correctly estimated by analysis of a single couple of parameters. However, when considered together, the r values calculated for all the possible couples inform about the strength of the network.

The r coefficients are not normally distributed, so that connectance cannot be correctly evaluated by averaging their absolute values before transforming them into z values (normally distributed), according to the formula $z = 0.5 \ln[(1+r)/(1-r)]$. Connectance is defined as the mean value of all these calculated z coefficients.

Time variations in connectance may be followed after harvesting populations every 2–3 days. By this method, a drop in connectance is especially observed during the beginning of a critical period, and is followed by a gradual increase in emergence of a new phenophase.^[10,11] This result does not only confirm initial assumptions, but also provides a tool for investigating factors influencing the expression of a critical period, its intensity (amplitude of drop in connectance), and its duration (time required for stability of the new regulation network). This approach reveals that expression of a critical period varies according to environmental conditions and the genotype considered. Consequently, beyond developmental contingencies related to internal disturbing events, expression of a critical period appears as regulated.

Evidence indicates that brassinosteroids (BRs) are involved in expression of a critical period through their effect on cellular sensitivity to other growth factors. This is why BRs differ so much from other PGRs. They interact with almost all the PGRs already identified, and are involved in stress alleviation.^[12] In consequence, BRs should be considered as metahormones of plant development.

CONCLUSION

Development is generally understood to be the expression of a genetic program, so that an adaptive dimension is not required. In such a context, when developmental modifications and an explosion of diversity are transiently observed in an initially homogeneous population, they are automatically related to a genetic or environmental (hypothetic) heterogeneity. In this context, it is not surprising that so few studies about critical periods have been published.

Two redundant levels of regulation (local and global) of development coexist in plants, so that a transient decrease at the global level does not immediately generate an observable modification.^[13] This is why changes in regulation network are frequently unobtrusive. The redundancy in regulations hides the transient changes induced in the network, at least as long as the environmental conditions do not affect this latter level of regulation. However, a strong perturbation in many physiological and developmental factors is observed during this period as soon as plants are exposed to suboptimal conditions.

The concept of critical periods is well known in physics and in chemistry, in which nonlinear processes now play a central role. Ignoring such a reality in biology invites contradictory conclusions about the effects of stress and plant response to it. It is unlikely that the concept of critical period will be restricted to interorgan relationships and response to stress at the whole plant level. The concept is probably useful in a series of phenomena, from

molecular interactions in the cell^[14] to species interactions in a biocoenosis.^[15]

Plant Response to Stress: Genome Reorganization in Flax

Christopher A. Cullis

Case Western Reserve University, Cleveland, Ohio, U.S.A.

INTRODUCTION

The plant genome is in a dynamic state, and a range of environmental pressures can stimulate particular alterations. Flax, a bifunctional crop that can be grown for fiber (flax) or oil (linseed), is particularly susceptible to such alterations. Some varieties undergo heritable genomic and phenotypic alterations during a single generation's growth in certain particular destabilizing environments. These genomic changes have been shown to occur in all types of sequences, including highly repetitive tandem arrays, intermediately repetitive dispersed regions, and low-copy number sequences. The genomic changes have been shown to occur during the vegetative growth, resulting in chimeric plants. However, in all the cases that have been characterized to date, the genomic alterations have become homozygous in the plant prior to the reproductive structures being differentiated. Therefore, because flax is essentially a self-fertilizing plant, all the progeny for a particular plant are identical, but could be different from the parent plant. More important, all the progeny from a series of plants grown under the same environment are identical, illustrating that there is reproducibility in response to such environmental pressures. Some of the genomic alterations appear to be adaptive to the conditions under which they are induced, but in every case these possible adaptive changes are part of a large number of genomic regions that are disrupted under any given growth conditions.

Why Study Flax?

The initial observations of flax were made by Durrant when he investigated the previously reported effect of growth conditions on the vigor of the flax seed. A series of flax varieties were grown under a variety of conditions and allowed to self. The seed was collected and grown under a uniform set of conditions. The progeny for the different parental treatments had different phenotypes. For one particular variety, Stormont cirrus, a small number of the treatments (including an imbalance of nutrients or particular temperature regimes) resulted in lines that bred true for the altered phenotypes, irrespective of subsequent

growth conditions, although the phenotype resulting from most of the environmental conditions depended on growth conditions in the immediately preceding generation. These stably altered types were termed genotrophs, and the progenitor line termed plastic, Pl. These lines were, for all intents and purposes, different genetic types. The lines differed in many characteristics, including plant height. The plant height characteristic illustrates a number of points relating to the induced changes. As seen in Fig. 1, all the plants derived from a single set of growth conditions are uniform, but different from those grown under a different set of conditions. This height difference is observed irrespective of the growth conditions, and is mainly due to a change in the length of the first few internodes.

WHAT CHANGES OCCUR IN RESPONSE TO NUTRITIONAL AND TEMPERATURE STRESS?

Although much remains to be learned about the induction process in flax, four aspects are established. First, Stormont Cirrus is a predominantly self-fertilizing plant because anther dehiscence and pollination usually occur during flower opening. Second, nearly all of the seeds planted grow under the inducing conditions and can contribute to the next generation.^[1] Thus it is extremely unlikely that any form of selection, in the conventional sense, from a heterogeneous population of plants, is the causative agent for the observed change. Third, all of the self-fertilized progeny from all the individuals growing in a specific environment are identical, but different from all the progeny of individuals grown in a different environment. Fourth, the induction of the changes has been repeated with Pl, resulting in the appearance of similar phenotypic, biochemical, and molecular changes.^[1-3]

The described phenotypic variations among the genotrophs (height, weight, capsule hair, septa number, and isozyme mobility) are but the tip of the iceberg when compared to the extent of variation seen at the DNA level. With regard to nuclear DNA, the extreme types differ by 15% of their total DNA as determined by Feulgen

Fig. 1 Mature plants of the small (left two pots) and large (right two pots) genotrophs grown under the same conditions demonstrating the uniformity of the plants and the height difference. These plants were ten generations post the initial inducing generation.

staining.^[4] This level of variation has been confirmed by the characterization of nuclear DNA by renaturation analysis, the cloning of families of repetitive sequences,^[5] the detailed characterization of the families of large (25S+18S) and small (5S) ribosomal RNA genes,^[6] RAPD analysis,^[7] and representational difference analysis.^[8] A notable characteristic of all the DNA comparisons is the specificity of the changes between PI and the genotrophs. Independent induction events have resulted in identical new structures at many loci, confirming the precise nature of the induced changes. For example, specific polymorphisms have been repeatedly generated in independently induced genotrophs in subsets of the 5SRNA gene family,^[6] and specific RAPD polymorphisms have repeatedly appeared.^[7] Within the flax genome, therefore, there exists a set of regions that are particularly labile and that can be altered in response to environmental stresses.^[3] Such a labile subset that responds during *in vitro* regeneration in barley has also been described.^[9] An important observation is that the availability of these sites is dependent on the physiological status of the plant. Therefore, the array of genomic alterations that occurs in response to any particular set of conditions will depend on the particular stress conditions applied.

WHEN IN DEVELOPMENT DO THE INDUCED CHANGES OCCUR?

Two of the genomic changes that have been characterized in detail are variations in ribosomal RNA gene number and a 5.8 kb insertion sequence named LIS-1. The latter is present in a number of genotrophs and in many other flax and linseed varieties. Both of these sequences have been followed during the growth of plants under inducing conditions, particularly under reduced mineral nutrition, and have shown similar responses. The variation in ribosomal RNA gene number occurred during vegetative growth of PI under inducing conditions,^[10] and was complete before the plants flowered. Similarly, the appearance of LIS-1 was followed in PI while growing under three different nutrient regimes; leaves were sampled as the plants grew. All three conditions resulted in the appearance of LIS-1 in the DNA extracted from leaves. Under two of these regimes, however, all the plants became homozygous for the insertion, and the inserted site was transmitted to all the progeny, whereas under the third regime, none of the progeny had LIS-1 inserted.

CONTROL OF THE GENERATION OF VARIATION

Within the flax genome there exists a set of regions that are particularly labile and able to be altered in response to environmental stresses.^[3] These sites vary frequently, and are therefore difficult to map by conventional genetic crosses, as they can vary in the generation in which they are scored.^[11] However, some flax varieties do not respond by destabilizing the genome when grown under these conditions. One of the crosses examined confirms that the loci controlling the response can also segregate, and can therefore be mapped and isolated. An understanding of the control of these genomic changes in flax will guide the search for similar mechanisms in other plants.

ARE THESE RAPID CHANGES ADAPTIVE?

What are the circumstances wherein such reorganization would confer a substantial advantage in an evolutionary context? First, it would need to be an inducible system so that when the organism is surviving well in a given environment there is no continuous generation of variation (although one could question whether any environment is really optimum). Ideally, the variation would only be

generated when the organism senses the need. The way in which such a sensory mechanism may work is not clear at present. Second, the regions of the genome that are targeted for restructuring need to be delineated. It appears unlikely that restructuring can occur at random. Random mutagenesis will mainly generate deleterious events rather than useful variation. Therefore, to have an advantageous mechanism, it is important to delineate regions of the genome that will be especially labile. The identification of these regions will be essential in understanding how the genomic reorganizations result in phenotypic variation. Third, the breeding system of the organism is also likely to be important. In the case of an inbreeding species, there will be little variation left when growth occurs in a favorable environment over an extended period. Thus, in such a circumstance, a significant change in the environment is likely to be disastrous, unless a mechanism is present by which either variation can be introduced or maintained. Therefore, it is likely that evolutionary selection will favor the presence of a controlled plasticity in those inbreeding species that have survived the slings and arrows of outrageous environments.

A question arises over the adaptive nature of any of these nuclear changes. In flax, it is clear that not all of the changes can be adaptive, as many of the variants are common to lines that have different phenotypes. The obligatory appearance of LIS-1 after some treatments, however, versus its complete absence after others indicates that it is likely to be of importance in the selection of that specific genomic variation under those conditions. It is therefore either one of the regions that confers adaptive advantage under those conditions, or is closely linked to the advantageous change. Because other heritable epigenetic changes such as imprinting can act at a distance from their chromosomal site, a characterization of the genomic context of this element may prove to be instructive.

CONCLUSION

These results in flax are the first demonstration that a series of genomic locations are labile and specifically responsive to particular environmental conditions. Within the set of variants, a particular combination of changes can be selected that are adaptive in those conditions. Under these circumstances the environment acts as an inducer of variation and then as the subsequent selective agent among the variants generated to genetically alter all or the majority of the population. These results have clear evolutionary implications for any organism in which the germline is not set aside very early in development, as this

mechanism can give rise to a coordinated set of variations under particular environmental conditions. The understanding of the control of these genomic changes in flax will be invaluable in the search for and understanding of the same processes in other species.

Plant Response to Stress: Mechanisms of Accommodation

H. R. Lerner

The Hebrew University, Jerusalem, Israel

INTRODUCTION

Whole plants and cultured plant cells have the capacity of increasing their tolerance to stress. This may occur through reversible, preexisting switches, as in phosphate starvation that induces a series of new enzymes. Other examples are the facultative halophytes that modify their carbon-fixing mechanism from C₃ to CAM under drought or saline stress. Other examples of overcoming stress are through irreversible changes, such as the effects on flax of imbalanced mineral nutrition or particular temperature regimes (discovered by Durrant in the late 1950s and further studied by Cullis); the discovery by McClintock that stress may cause nonrandom reorganization of the genome and chromosome aberrations in corn; and adaptation of sorghum to NaCl concentrations that are lethal for the unadapted plant. At the cultured plant cell level it has been shown that tobacco cells can be adapted to grow in 500 mM NaCl, and McCoy showed that exposure of cultured alfalfa cells to salt stress enhances dramatically the frequency of both chromosome aberrations and altered isozymes. This article discusses mechanisms of irreversible changes induced by stress.

THE PLANT'S DEVELOPMENTAL TRAJECTORY

The physiological response of a plant is modified as a function of its development. This change as a function of time is the developmental trajectory of the plant, often referred to as phasic development. Moreover, there are limited time periods—developmental windows—during which a plant's response is temporarily modified.^[1] The unfolding of internal developmental programs and external signals affect the developmental trajectory, which reflects the genetic makeup of the plant as well as its environmental history. All cells contain two types of information—the genetic information and the epigenetic system that is affected by environmental and developmental cues.^[2]

During the unfolding of the developmental trajectory the plant undergoes continuous modulation in its phytohormonal balance as well as in its sensitivity (its response) to phytohormones; in protein, posttranslational modifications such as phosphorylation/dephosphorylation; in

histone, modifications such as acetylation, methylation, phosphorylation, and probably DNA methylation. At the same time there is a reorganization of the genome that entails amplification and deletion of DNA (including A+T- and G+C-rich DNA) and DNA inversion.^[3,4] All these changes are mechanisms that modulate genome expression during development.

STRESS-RESPONSE MECHANISMS

Somaclonal Variations

Following plant regeneration from cultured cells, protein modifications and aberrations in chromosomes and DNA sequences are seen. These changes have been called somaclonal variations because they arise within clones of somatic cells. Modified phenotypes are sometimes, but not always, heritable.^[5] The number of aberrations increases with the length of time cells are maintained in culture and with intensity of stress conditions.^[5,6] Recurrence of similar types of somaclonal variations in cultured cells, which are sometimes similar to known heritable mutations in whole plants,^[5] indicates that there are hot spots for these changes; the phenomenon appears to be nonrandom. Observation of bridges at mitotic and meiotic anaphase suggests that a mechanism called breakage–fusion–bridge cycle (BFB) could be responsible for some of these mutations.^[5,7] The appearance of new isozymes and restriction fragment length polymorphism (RFLP) and rapid amplification of polymorphic DNA (RAPD) techniques are sensitive methods that reveal slight modifications in DNA sequences due to somaclonal variations.^[5,6] The mechanisms inducing somaclonal variations are unknown; however, several causes have been suggested, including imbalanced nutrient concentrations, phytohormones, leakage of cellular constituents, DNA amplification/deletion, chromosome breakage (including BFB), transposon movement, and 5-methylcytosine deamination.^[5]

Changes in Concentration of Phytohormone and Other Molecules Under Stress

Under stress, the concentration of abscisic acid and ethylene increases while the concentration of auxins,

cytokinins, and gibberellins decreases.^[8] Other molecules such as polyamines, brassinosteroid, methyl jasmonate/jasmonic acid, and salicylic acid are sometimes produced. Reactive oxygen species (ROS) such as superoxide radical, hydroxyl radical, and hydrogen peroxide are also produced under stress. See the contribution of A. Levine in this volume for the consequence of ROS on genome organization.

Genome Modifications Under Stress

For many plant species the haploid genome size (1C-value), in picograms (pg) or base pairs, has been reported in the literature;^[9,10] 1 pg = 965×10^6 bases. 1C-values for flowering plants range from <0.2 pg in *Arabidopsis thaliana* to 127.4 pg in *Fritillaria assyriaca*.^[10] From these values, the genome size varies by more than 600-fold, even though these plants express more or less similar genes, suggesting that the difference in chromatin content is due to noncoding DNA. Reasons for such differences could be changes in ploidy level, repetitive DNA such as tandemly repeated sequences that are grouped in one or a few sites (e.g., rDNA; satellite DNA that can be either A+T- or G+C-rich), or dispersed repeated sequences that are spread throughout the genome (e.g., amplification of transposable elements).

Growth of the inbred flax variety Stormont Cirrus in an inducing environment (such as imbalanced mineral nutrition or specific temperatures) causes stable and genetically altered plants after a single generation.^[11] The phenomenon is reproducible. Following similar treatment, identical changes are observed in plant height and weight at maturity and in the number of hairs on the false septa of the seed capsules. This is not due to selection because >90% of the seeds germinate and undergo the same changes. These phenotypic changes are accompanied by alterations in the number of repeats of repetitive DNA of both the tandem rDNA and in families of dispersed repeated sequences. These phenotypic/genotypic modifications are maintained for all generations tested.

The discovery that stress results in chromosome aberrations in the whole corn plant^[7] and in cultured alfalfa cells^[6] shows that stress modifies genome organization. This is also demonstrated by somaclonal variations^[5,6] because, for a plant cell, being cultured constitutes a stress. Adaptation of whole sorghum plants to NaCl^[1] is passed on to progenies for all generations tested (Amzalg personal communication). This suggests the inclusion of a genetic effect. Development of cultured cells from regenerated plants obtained from NaCl-adapted tobacco cells^[12] yields already adapted cells (Watad personal communication), also suggesting that this adaptation is a genetic effect. The course of accommodation to stress entails modifications in both genome organization and in

the process of modulation of genome expression. Another example of genome modification under stress has been shown for cold hardening.^[13]

Range of Stress-Response Process

Not all flax or sorghum varieties undergo the phenotype/genotype modifications described here; these changes are specific properties of particular varieties. Although the processes occurring in flax and sorghum seem similar, they are not identical. In flax all the plants submitted to an inducing condition undergo the same modification, whereas in sorghum there is an increase in the variability of parameters within the population (e.g., shoot height, shoot dry weight) following the adaptation treatment,^[14] indicating that each individual plant within the population undergoes its own stress-response pathway.

There is a wide range of plants' mechanisms of accommodation to stress—from reversible preexisting switches (e.g., phosphate starvation,^[15] facultative halophytes^[16]), to irreversible preexisting switches (e.g., flax^[11]), to the irreversible elaboration within a population of new patterns of modulations of genome expression (e.g., sorghum^[1]).

Nuclear Architecture

Using in situ radioactive DNA hybridization, the organization of parental chromosomes in plant hybrids is shown to occupy distinct, nonrandom, positions. Throughout the cell cycle, parental genomes are maintained in different domains, including during interphase (Ref. 9, Refs. 67,88 in Ref. 9). Moreover, using fluorescent in situ hybridization (FISH) on animal cells, it has been confirmed that the folding of DNA in chromatin is highly specific.^[17] It seems probable that nuclear organization may affect or be affected by gene expression.^[17]

CONCLUSION

The mechanisms of accommodation of plants to stress include all the mechanisms functioning during the plant's developmental trajectory, including changes in phytohormonal balance and sensitivity to phytohormones; protein posttranslational modification; DNA reorganization through amplification, deletion, and inversion; histone modification; DNA methylation; and movement of transposons. All these changes modulate genome organization and expression. The nucleus is a dynamic, plastic, highly organized organelle that, as described by McClintock, is capable of reorganizing itself to overcome adverse conditions. Although transformation is a very interesting and useful tool in plant research, for agriculture it is more

advantageous to allow crop plants to modify their genomes by themselves because they are better equipped than humans to do so.

Plant Response to Stress: Modifications of the Photosynthetic Apparatus

Eevi Rintamäki

University of Turku, Turku, Finland

INTRODUCTION

Because plants are sessile organisms, their growth and development greatly depend on abiotic and biotic environmental factors. Plants have developed efficient mechanisms for sensing changes in growth conditions and for induction of adaptive processes in order to cope with various kinds of environmental stress. Plants are ultimate harvesters of sunlight, and maintenance of a functional photosynthetic apparatus is fundamental for plant survival under unfavorable conditions. Light is the main environmental regulator in modifying the structure and function of plant photosystems. Other abiotic factors, e.g., extreme temperatures and oxidative stress, also induce changes in the photosynthetic machinery, but their action depends on light. Structural and functional modifications of Photosystem I and Photosystem II under abiotic stress conditions will be discussed in this article, with emphasis on protein phosphorylation, changes in subunit and pigment composition, and induction of protecting compounds.

PHOTOSYSTEM II

Photosystem II (PSII) functions as a light-driven water-plastoquinone-oxidoreductase in plant thylakoid membranes. PSII is composed of more than 25 proteins, including the subunits of the reaction center responsible for primary photochemistry, the oxygen evolving complex, and the polypeptides of chlorophyll *a/b* antenna.^[1] Functional PSII exists as a dimeric complex. In nature, plants experience continual short-term and long-term fluctuations in light intensity. PSII is a main regulated unit in the light reactions, and is thus also a primary target for modifications induced by environmental factors. The best-documented modifications of PSII are associated with photoinhibition of photosynthesis, including both the induction of photoprotective mechanisms and oxidative damage to PSII. Some of the changes are rapidly reversible on a time scale ranging from seconds to hours under transient changes of irradiance, whereas long-term exposure to new light conditions causes stable adjustments of the complex. Protein phosphorylation and changes in pigment composition belong to the reversible modifica-

tions occurring in PSII under variable environmental conditions. On the other hand, protein synthesis is required to cope with stress-induced photodamage to PSII, including the replacement of the oxidized protein with the new copy (see below) as well as the stimulation of the expression of protective proteins called ELIPs (early light inducible proteins) and a PSII subunit of 22 kDa (psbs).

Light-induced Protein Phosphorylation in Thylakoid Membranes

Light induces phosphorylation of a number of PSII proteins in thylakoid membranes. Four PSII core proteins—D1 and D2 reaction center proteins, 43-kDa chlorophyll *a*-binding protein (CP43), and the *psbH* gene product (psbH protein)—undergo reversible phosphorylation in thylakoid membranes.^[2] The PSII antenna consists of six pigment-binding proteins designated Lhcb1 to Lhcb6, from which three (Lhcb1, Lhcb2, and Lhcb4) have been shown to become reversibly phosphorylated in light-dark transitions.^[2,3] Light regulates this phosphorylation via the redox state of electron carriers between PSII and PSI.^[2] Reduction of plastoquinone activates serine/threonine protein kinase(s) that phosphorylate the PSII core phosphoproteins and Lhcb4 protein,^[3] whereas both the reduction of plastoquinone and subsequent binding of plastoquinol to the Q_o site of the cytochrome b_6f complex are required to initiate the phosphorylation of Lhcb1 and 2 proteins.^[2,3] Moreover, the kinase that phosphorylates the Lhcb1 and 2 proteins is specifically inhibited in the presence of thiol reductants.^[3] Significantly, thylakoid membranes contain several membrane-bound protein kinases with specific regulation mechanisms and at least partial substrate specificity for PSII phosphoproteins. Decreasing redox potential in the chloroplast, e.g., by shifting plants into darkness, induces the dephosphorylation of PSII phosphoproteins via protein phosphatases.^[2] Both soluble and membrane-bound phosphatases capable of dephosphorylating PSII phosphoproteins have been found in chloroplast. However, these enzymes are still poorly characterized.

Previously, the reversible phosphorylation of PSII proteins was assumed to be coupled to light stress of the chloroplast through prevention of the imbalance between

excitation rates of the photosystems under fluctuations in light intensity, and via protection of PSII from photoinhibition in high light (discussed later). This scheme presumes that an exposure to high light would induce the phosphorylation of PSII proteins. However, screening of the environmental conditions activating the phosphorylation of PSII proteins *in vivo* has indicated that maximal phosphorylation of the PSII core proteins occurs at light conditions prevailing during growth of plants without any evident symptoms of light stress.^[4] This maximal phosphorylation level, corresponding to 70–80% of PSII complexes with phosphorylated PSII core proteins, is maintained under conditions with redox potential equivalent to or higher than observed at growth light conditions.^[4] Moreover, the antenna proteins Lhcb1 and 2 are maximally phosphorylated only at low redox potential in the chloroplast, e.g., after a shift of the plant to a light intensity lower than experienced during growth, while high light strongly inhibits phosphorylation of these proteins.^[4] Only the phosphorylation of the Lhcb4 protein seems to be specifically stress-stimulated.^[3]

What are the physiological implications for the PSII complex modified by protein phosphorylation? A number of functional roles have been suggested for PSII core protein phosphorylation. Chlorophyll fluorescence and low temperature electron paramagnetic resonance (EPR) measurements have demonstrated that phosphorylation of D1, D2, and CP43 proteins does not influence the electron transfer capacity in PSII.^[3] Stabilization of a dimeric form of PSII—and direct protection of PSII from photoinhibition—have also been linked to the phosphorylation of PSII core proteins, but discrepancies in the experimental results mean that these hypotheses should still be questioned. A number of experimental data, however, support the hypothesis that phosphorylation of the PSII core proteins regulates the PSII photoinhibition repair cycle by controlling the timing and location of proteolytic degradation of the photodamaged D1 protein in thylakoid membranes.^[3] This regulation prevents a collapse and total proteolysis of the subunits of photodamaged PSII complex, especially under the stress conditions that cause deterioration of protein synthesis, e.g., low temperature combined with illumination of plant.

Phosphorylation of Lhcb1 and 2 proteins has been proposed to induce state transition that modulates energy distribution between PSII and photosystem I (PSI) in plant thylakoid membranes.^[2] Phosphorylation of these proteins results in partial dissociation of the phosphorylated Lhcb1 and 2 proteins from PSII, and subsequent association of these proteins with PSI.^[2] Originally, the state transition was thought to protect PSII from photoinactivation by reducing the antenna size of PSII, and thereby the excitation of PSII. However, this function is not supported by the finding that excessive light intensity strongly

inhibits the phosphorylation of these proteins.^[3] It has been proposed that Lhcb1 and 2 protein phosphorylation regulates the synthesis of Lhcb proteins during the long-term acclimation of plants to various light intensities.^[3] A putative role of this phosphorylation in the relay of signals between chloroplast and nucleus is based on the distinct positive correlation between the phosphorylation level of Lhcb1 and 2 proteins and the expression of *Lhcb* genes.

Phosphorylation of Lhcb4 protein has been attributed to the protection of PSII complex against photoinhibition, especially in chilling-sensitive plants at low temperatures. This protection may be attained by altered distribution of excitation energy between PSII and its antenna after phosphorylation of Lhcb4 protein.

The Xanthophyll Cycle and Photoprotection of Chloroplasts

Besides the photochemistry in thylakoid photosystems, light reactions also generate reactive intermediates and oxygen species that have a potential to damage the photosynthetic machinery, especially in excess light. To prevent their detrimental effect, plants have evolved a number of protection mechanisms—including antioxidant systems and processes for thermal dissipation of light energy.

The extent of the thermal dissipation in PSII can be measured as a quenching of chlorophyll fluorescence in PSII. The energy-dependent component (q_E) of non-photochemical quenching (NPQ) depends on the amount and composition of xanthophyll pigment in membranes, as well as the acidification stage of the thylakoid lumen.^[5] The xanthophyll cycle is a universal pigment-conversion mechanism in plants that is involved in the dissipation of excess light energy to heat in thylakoid membranes. In higher plants under light stress, zeaxanthin is formed from violaxanthin via antheraxanthin in the reactions catalyzed by violaxanthin de-epoxidase (VDE), which is activated through acidification of the thylakoid lumen.^[6] The cycle is reversible under low light conditions, resulting in the regeneration of violaxanthin via the action of zeaxanthin epoxidase.^[6] Xanthophylls bind to chlorophyll a/b binding proteins of both PSII and PSI antennae, but this cyclic conversion of pigments has been proposed to occur in a free form of the molecule, resulting in the reorganization of xanthophyll pigments in Lhcb proteins.^[5] Studies with *Arabidopsis* mutants with reduced levels of VDE have shown the involvement of zeaxanthin in thermal dissipation of excess light energy.^[6] However, the exact mechanism for this energy dissipation is still obscure. According to the direct model, chlorophyll transfers excitation energy to zeaxanthin, which dissipates it as heat. Alternatively, the production of zeaxanthin may stimulate the proton-dependent structural changes in Lhcb proteins (aggregation, protein–protein interactions) resulting in

the formation of dissipation centers in specific antenna complexes.^[5]

Recently, a new component involved in dissipation of thermal energy in PSII has been established. q_E was absent in a *psbS*-deletion mutant in Arabidopsis.^[7] *psbS* protein is a component of PSII with homology to chlorophyll *a/b* binding proteins. However, the chlorophyll-binding domains are not conserved, which excludes the possible role of *psbS* protein in light harvesting. Transgenic *Arabidopsis* plants overexpressing *psbS* gene had significantly increased q_E and enhanced resistance to PSII photoinhibition.^[8] Moreover, low-temperature stress increases the expression of *psbS* gene in illuminated potato leaves. These results strongly support the role of q_E in photoprotection and also the hypothesis that the key function of *psbS* protein is in the induction of energy-dependent thermal dissipation. The putative function of this protein is in sensing the luminal acidification, which induces a conformational modification of *psbS* protein and/or of Lhc *b* proteins, finally resulting in the stabilization of the dissipation centers in PSII.^[5]

Photoinhibition of Photosystem II

Despite the photoprotection mechanisms discussed above, irreversible inhibition of photosynthesis occurs in illuminated plants. Both PSII and PSI can be targets of

oxygen-dependent photodamage of the reaction center, but under different environmental conditions. Photodamage to PSII can be detected at all physiological light intensities; moreover, the absorption of light in excess of the capacity to utilize it in plants leads to the accumulation of inactive PSII complexes in thylakoid membranes.^[3] PSII photoinhibition is induced especially at low temperatures under moderate light intensities.^[9]

Irreversible photoinactivation of PSII ultimately results in oxidative damage to the reaction center protein D1 of PSII. To restore the activity of PSII, the photodamaged D1 protein is degraded by proteolysis and substituted by a newly synthesized D1 protein.^[3] Strict coordination of the degradation and synthesis of the D1 protein is necessary to prevent loss of other polypeptides in this multisubunit complex, which would lead to total collapse of the complex and thus to more severe damage to the photosynthetic machinery. This coordination is attained via regulation of the turnover of D1 protein by phosphorylation of PSII core proteins.^[3] The key feature in this regulation is that the phosphorylated form of the photodamaged D1 protein is not susceptible to proteolytic degradation. Inactivation of PSII takes place in grana lamellae, whereas the co-translational incorporation of the new D1 copy is spatially conceivable only in stroma-exposed thylakoid membranes (Fig. 1). Phosphorylation of PSII core proteins stabilizes the partially disassembled inactive PSII complex upon migration from the grana region to the stroma-exposed

Fig. 1 Phosphorylation of the PSII core proteins and photoinhibition repair cycle of Photosystem II in higher plant thylakoid membranes. (From Ref. 3.)

membranes of thylakoids, in which repair of the complex is induced by dephosphorylation of PSII core proteins, followed by degradation of photodamaged D1 and synthesis of a new copy of protein (Fig. 1).

PHOTOINHIBITION OF PHOTOSYSTEM I

Photosystem I is a light-driven plastocyanin-ferredoxin oxidoreductase involved in the production of NADPH in photosynthetic light reactions. The enzyme complex is composed of 14 subunits, from which the PsaA, PsaB, and PsaC proteins bind the electron carriers of PSI.^[1] PsaA-PsaB heterodimer functions also as a core antenna by binding approximately 90 chlorophyll a molecules and 10–15 β -carotenes per reaction center. The chlorophyll a/b-binding proteins of PSI antenna are encoded by four *Lhca* genes designated *Lhca1* to *Lhca4*.^[1]

PSI is not regarded as a rate-limiting component of the light reactions; thus, the dynamic and regulatory aspect of PSI has been investigated less extensively. Low temperature combined with light, however, inhibits PSI activity specifically—both in chilling-sensitive and tolerant plant species.^[9] This oxygen-dependent PSI inactivation results in the degradation of the psaA-psaB heterodimer of the PSI reaction center, but a loss of some extrinsic PSI proteins has also been reported.^[9] The unique features of PSI photoinhibition are that; 1) bleaching of chlorophyll is observed after return of plants to the growth temperature; 2) degradation of PSI proteins occurs several days after exposure to low temperature; 3) the recovery is much slower than in PSII photoinhibition; and 4) it can ultimately result in a definitive decrease in the amount of PSI complexes in leaves. This more severe photoinhibition of PSI under specific environmental conditions may be due to lack of control over the repair of photodamaged PSI reaction center proteins, compared to the mechanism that has evolved for PSII complexes.

EARLY LIGHT-INDUCED PROTEINS: A STRESS PROTEIN FAMILY IN THYLAKOID MEMBRANES

Originally, the early light-induced proteins (ELIPs) were found upon greening of etiolated seedlings. Expression of these proteins was induced very early after the shift of seedlings to light, although they were not present in mature leaves under ambient growth conditions. However, it was observed later that the expression of these proteins is induced under several different conditions of stress, in-

cluding light, cold, and salt stress, as well as during nutrient deprivation and desiccation.^[10] ELIPs and chlorophyll a/b-binding proteins have sequence similarity, but only binding of chlorophyll a and lutein has been detected in purified proteins.^[10] It is generally agreed that these proteins are not involved in energy transfer in photosynthesis. They are localized to the stroma-exposed membranes of thylakoids, probably in close vicinity to PSII complexes, but the direct interaction of ELIPs with the photosystems is still obscure. Furthermore, a number of protective roles of ELIPs under stress conditions has been suggested,^[10] although the exact function of these proteins remains to be elucidated. One tempting hypothesis is that ELIPs might bind pigments released from the photosystems during the reorganization of complexes (e.g., photoinhibition, the xanthophyll cycle) under different stress conditions.

CONCLUSION

Light is a key element in modifications of the photosynthetic apparatus that are induced by various abiotic stress factors. The molecular aspects of changes in the structure and function of photosystems are studied mainly by combining light with one of the environmental variables at a time. In nature, stresses can appear contemporaneously, compounding the symptoms and allowing the development of new modifications in plants. In the near future, the establishment of new technologies such as DNA microarray analysis, proteomics, and metabolomics will vastly increase our knowledge of the dynamic aspects of the photosynthetic apparatus, even under the complex environmental conditions that exist in nature.

Plant Response to Stress: Phosphatidic Acid As a Second Messenger

Christa Testerink
Teun Munnik

University of Amsterdam, Amsterdam, The Netherlands

INTRODUCTION

Phosphatidic acid (PA) is emerging as the most important lipid second messenger in plants. It is formed within minutes in response to a wide array of stress conditions, including ethylene, abscisic acid (ABA), cold, Nod factor, pathogen-derived elicitors, wounding, drought, salt, and hypoosmotic stress. PA and the enzymes that form and metabolize this molecule seem to play a key role in plant stress signaling.

FORMATION OF PA

Phospholipids maintain the integrity of biological membranes around cells and their organelles. Relatively new is the awareness that several of them play a crucial role in signal transduction.^[1,2] One of the latest additions to this field is the lipid second messenger PA, a minor lipid that occurs in different cellular membranes. When a plant cell is subjected to stress, two different phospholipases can be activated to hydrolyze structural membrane lipids, resulting in the production of PA. Phospholipase D (PLD) hydrolyzes phosphatidylcholine (PC) or phosphatidylethanolamine (PE) to release PA and a free headgroup (choline or ethanolamine), while phospholipase C (PLC) hydrolyzes phosphatidylinositol 4,5-bisphosphate (PIP₂) to generate inositol 1,4,5-trisphosphate (IP₃) and diacylglycerol (DAG), which is immediately phosphorylated by DAG kinase (DGK) to produce PA. The increase is transient because PA is rapidly converted to diacylglycerol pyrophosphate (DGPP) by PA kinase (Fig. 1).

Phospholipase D

Several genes encoding PLDs have been cloned from plants. In *Arabidopsis thaliana*, there are twelve members that have been grouped into five classes.^[3-5] Individual isoforms have different expression patterns and different biochemical properties. A recent discovery is the association of a PLD with microtubuli, where it could mediate

cytoskeletal rearrangements, which are known to occur in response to several stress treatments.^[6] When PLD hydrolyzes its substrate, it can use primary alcohols instead of water as an acceptor for the phosphatidyl group (transphosphatidylation). Thus, in the presence of *n*-butanol, phosphatidylbutanol is formed. This characteristic has been used to measure in vivo PLD activity, but also to inhibit PA production and to distinguish PLD-generated PA from PLC-generated PA.^[7]

Phospholipase C

In the *Arabidopsis* genome, there are nine PLCs, of which four have been cloned and characterized. The PA they generate together with DGK can be distinguished from that generated by PLD by a differential ³²P-labeling protocol and by using specific PLC inhibitors.^[7]

THE ROLE OF PHOSPHATIDIC ACID IN STRESS SIGNALING

PA formation has been linked to biotic and abiotic stress treatments, suggesting it is a general stress signal. In support, inhibiting or silencing PLD in plants reduces stress responses, while exogenous application of PA induces stress responses. Some of the best characterised PA responses are discussed here.

ABA and Osmotic Stress

The phytohormone ABA is involved in aging, seed development, germination, and the responses to cold and water stress. It induces the formation of PA in stomatal guard cells and aleurone cells. Osmotic stress, in the form of salt or drought, also increases the level of PA. Both PLC and PLD pathways are activated in response to osmotic stress and ABA. Moreover, in plants in which PLD expression is suppressed, ethylene and ABA-induced senescence, as well as other ABA- and osmotic stress-related responses,

Fig. 1 PA signaling cascades. Different stress treatments activate phospholipid signaling pathways. PLC hydrolyzes PIP₂ into IP₃ and DAG. IP₃ diffuses into the cytosol, where it induces calcium release from intracellular stores. DAG remains in the membrane and is phosphorylated by DGK to PA. PLD hydrolyzes structural phospholipids, thereby generating PA directly. PA formation affects targets such as PDK1, MAPK, CDPK, ion channels, and NADPH oxidase. The PA signal is attenuated by conversion to DGPP. (R = receptor. Solid arrows indicate metabolic conversions; dashed arrows indicate activation (either directly or indirectly) of downstream targets.) (View this art in color at www.dekker.com.)

are reduced. Interestingly, exogenously applied PA mimics ABA action in guard cells; it inhibits ion channel activity and induces stomatal closure.^[5]

Defense Against Pathogens

A well-studied mechanism of plant defense against pathogens are pathogen-derived elicitors, which activate the plant's defense responses. Several elicitors, such as xylanase, chitinase, flagellin, and the *Cladosporium fulvum* race-specific elicitor Avr4, induce PA formation within minutes.^[8] Interestingly, Nod factors that are signal molecules of symbiotic *Rhizobium* bacteria also induce the formation of PA in leguminous plants. Wounding a plant triggers PA accumulation, as well, both locally and systemically.^[5]

The PA produced in response to pathogen elicitors and Nod factor is mainly due to PLC activation. Blocking PLC enzyme activity inhibits activation of several defense responses, including the formation of reactive oxygen species. Conversely, exogenously applied PA induces an

oxidative burst and triggers a MAP kinase pathway, showing that PA is involved in the early response to pathogen attack. PLD is involved in the response to some elicitors and to wounding. When rice is infected by *Xanthomonas oryzae*, PLD is recruited to the site of infection on the plasma membrane. Silencing PLD reduces the wound-induced accumulation of jasmonic acid.^[5,8]

PA ACTION AND SPECIFICITY

It is becoming clear that PA plays a major role in cell signaling even though little is known about its working mechanism. Presumably, the formation of PA creates docking sites in the membrane to which specific proteins bind (Fig. 2). Membrane recruitment then leads to activation, either directly by PA or indirectly by other proteins.^[8] In addition, PA's shape and negative charge could affect membrane properties, promoting curvature and vesicle formation.

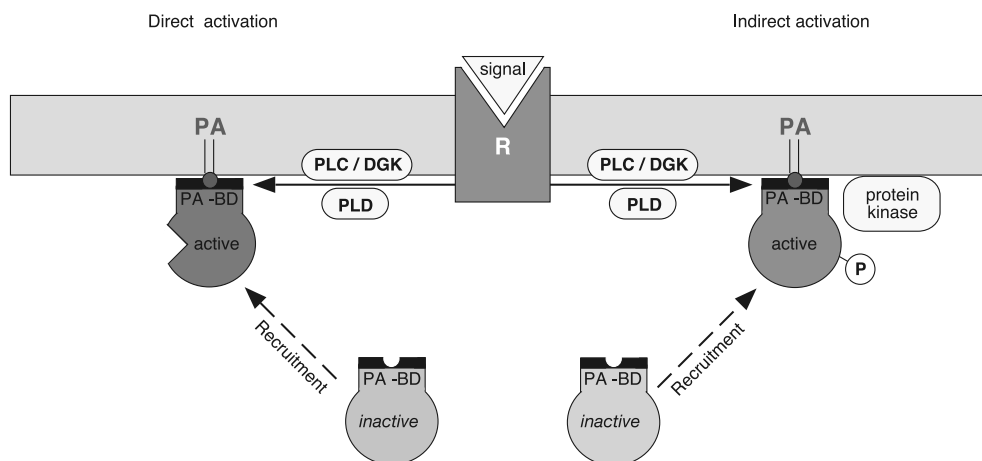

Fig. 2 Possible mechanisms for activation of PA targets. PA is generated locally via PLD and/or PLC/DGK activation. Proteins that are able to bind PA via their PA-binding domain are recruited to the membrane. This can activate them directly by inducing a conformational change, or indirectly, by promoting their activation by other proteins, e.g., a protein kinase. In the latter case, PA acts by increasing the local concentration of target protein(s), bringing it in close vicinity to its activator, thus allowing signaling to occur. (Adapted from Ref. 8, with permission.) (View this art in color at www.dekker.com.)

Another major question regards the specificity of the PA signal. Since a variety of environmental conditions induce the formation of PA, one must ask how response specificity is maintained. Of course, first there will be a level of tissue and developmental information that determines the final response to environmental cues, the hard wiring of the cell. And every stress treatment will activate both specific and general signaling pathways. Thus, PA may represent a general, multifunctional stress signal that integrates different pathways, similar to the action of calcium and MAP kinases.^[9]

PA Targets

Several mammalian proteins that directly interact with PA have been identified. These so-called PA targets are involved in various cellular processes, such as mitogenic signaling, vesicular trafficking, and the oxidative burst, and include protein kinases and phosphatases, lipid kinases, cAMP-phosphodiesterases, small G-proteins, mTOR, and NADPH oxidase. PA-binding regions in some of them have been identified by deletion studies, but their sequences do not show significant homology to each other.^[10]

Few PA targets have been identified in plants. PA affects ion-channel and MAP-kinase activity *in vivo*, but it is not known whether this is due to direct binding. Phosphoinositide-dependent protein kinase 1 (PDK1) binds PA and a calcium-dependent protein kinase (CDPK) is activated by PA *in vitro* but clearly more targets must be identified to distinguish a general PA-binding domain and to understand how PA signals stress (Fig. 1).

CONCLUSION AND PERSPECTIVES

PA is a secondary messenger that has all the qualities of a general stress-signaling molecule in plants. It is formed in response to stress conditions and it induces downstream responses typically related to stress, while prevention of PA formation reduces these responses. One of the major challenges will be to find the molecular targets for PA.

Other main goals in this field are to find the upstream regulators of the PA-generating enzymes, and to localize PA in the living cell, using fusion constructs of PA-binding domains with green fluorescent protein. Over-expression of a PA-binding domain can be used to inhibit PA signaling, and knocking out individual PLC and PLD isoforms will establish their contribution to the PA signal under different conditions. These type of approaches will help us to understand what the role of PA is in stress and other responses.

INTRODUCTION

Plant growth is greatly affected by water deficit. Plants respond and adapt to dehydration in order to survive under drought stress by the induction of various biochemical and physiological responses. Various genes are induced in response to drought at the transcriptional level. Their gene products are thought to function in response to drought and in tolerance to drought. It is important to analyze functions of stress-inducible genes not only to understand higher plants' molecular mechanisms of stress response but also to improve the stress tolerance of transgenic plants. The expression and functions of stress-inducible genes have been studied at the molecular level. Complex mechanisms seem to be involved in gene expression and signal transduction in response to drought stress. This article describes recent progress on *cis*- and *trans*-acting factors involved in drought-inducible gene expression.

EXPRESSION PROFILES OF DROUGHT-INDUCIBLE GENES USING MICORARRAY TECHNOLOGY

Microarray technology has been developed extensively and has become a powerful tool for the global analysis of expression profiles of many genes. This microarray technology allows the large-scale comparative analysis of gene expression under various stress conditions. Recently, many drought-inducible genes have been identified in *Arabidopsis*.^[1] Microarray analysis has revealed the existence of strong cross talk between drought and high salinity responses, and moderate cross talk between drought and cold stress responses. Various kinds of genes with different functions are involved in stress tolerance and stress response.^[1] Among the stress-inducible genes, many transcription factor genes have been identified, suggesting that various transcriptional regulatory machineries function in drought-inducible gene expression.

ABA-DEPENDENT AND ABA-INDEPENDENT GENE EXPRESSION IN RESPONSE TO DROUGHT STRESS

Dehydration triggers the production of abscisic acid (ABA), which in turn, not only causes stomata closure but also induces various genes. As shown in Fig. 1, it is hypothesized that at least four independent signal pathways function in the activation of stress-inducible genes under dehydration conditions: Two are ABA-dependent (pathways I and II) and two are ABA-independent (pathways III and IV).^[2] One of the ABA-dependent pathways requires protein biosynthesis (pathway I). ABA-independent regulatory systems are thought to function in the early process of drought-stress signaling before the accumulation of ABA.

ABA-INDEPENDENT GENE EXPRESSION

One of the ABA-independent pathways of drought-stress response overlaps with that of cold-stress response (pathway IV). Promoter analysis of drought-inducible *rd29A* gene reveals that a *cis*-acting element including A/GCCGAC, named the Dehydration Responsive Element (DRE) and C-Repeat (CRT), is essential for regulation of the induction of *rd29A* under drought, low-temperature, and high-salt stress conditions in an ABA-independent pathway.^[3] All the DRE/CRT-binding proteins (DREBs and CBFs) contain a conserved DNA-binding motif (AP2/ERF motif).^[4,5] These five cDNA clones that encode DRE/CRT-binding proteins are classified into two groups, DREB1/CBF and DREB2. Expression of the *DREB1A* (*CBF3*) gene and its two homologues (*DREB1B* = *CBF1*, *DREB1C* = *CBF2*) is induced by low-temperature stress, whereas expression of the *DREB2A* gene and its single homologue (*DREB2B*) was induced by dehydration. These results indicate that two independent families of DREB proteins, DREB1/CBF and DREB2, function as *trans*-acting factors in two separate signal transduction pathways under low temperature and dehydration conditions,

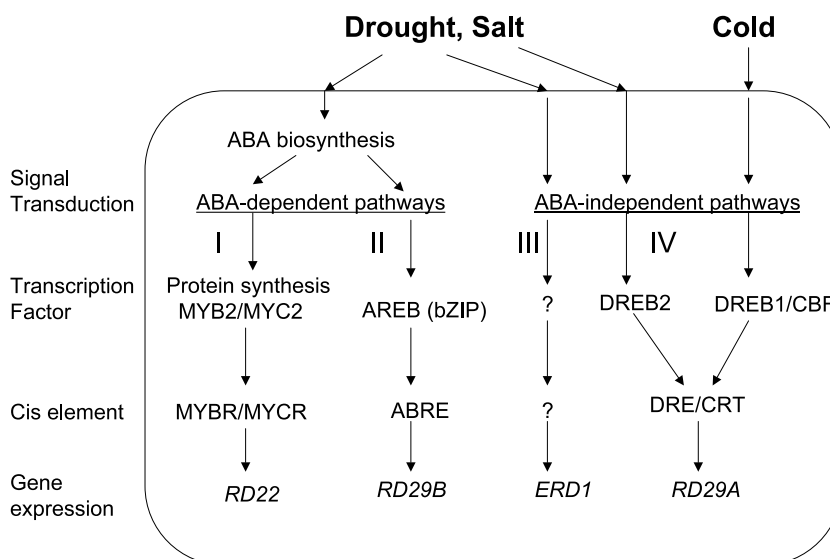

Fig. 1 Signal transduction pathways between initial drought-stress signal and gene expression in *Arabidopsis*. There are at least four signal transduction pathways: Two are ABA-dependent and two are ABA-independent. Stress-inducible genes *RD29A/COR78/LTI78*, *RD29B/LTI65*, *RD22*, and *ERD1* are used for the analysis of each signaling process. (From Ref. 2.)

respectively.^[5] Overproduction of the DREB1A/CBF3 and CBF1/DREB1B cDNAs in transgenic plants significantly improves stress tolerance to drought and freezing.^[5–7] Microarray analysis identifies many genes with various functions as DREB/CBF target genes.^[8,9]

Several drought-inducible genes including *erd1* do not respond to either cold or ABA treatment, which suggests the existence of an additional ABA-independent pathway in dehydration stress response (pathway III). Promoter analysis of these genes will give us more information on pathway III.

ABA-DEPENDENT GENE EXPRESSION

Endogenous ABA increases significantly under drought and high salinity conditions. Many drought-inducible genes are upregulated by exogenous ABA treatment. In one of the ABA-dependent pathways (Fig. 1, pathway II), drought-inducible genes do not require protein biosynthesis for their expression. These dehydration-inducible genes contain potential ABA-responsive elements (ABREs; PyACGTGGC) in their promoter regions. ABRE functions as a *cis*-acting DNA element involved in ABA-regulated gene expression. ABRE was first identified in wheat *Em* and rice *rab* genes, and its DNA-binding protein EmBP1 was shown to encode a bZIP protein.^[2] Two ABREs function in the ABA-dependent gene expression of *rd29B*. Two ABRE-binding proteins (AREB1 and AREB2) are involved in ABA-responsive gene expression and contain the bZIP structure.^[10] AREB1 and AREB2 genes are induced by drought; their gene

products seem to be activated by phosphorylation. AREB1 and AREB2 function downstream from *abi1/abi2* and *eral* in ABA signal transduction pathways. Similar ABRE-binding proteins have been identified and named as ABFs that function in stress tolerance.^[11,12]

Biosynthesis of novel protein factors is necessary for the expression of ABA-inducible genes in one of the ABA-dependent pathways (pathway I). The induction of an *Arabidopsis* drought-inducible gene, *rd22*, is mediated by ABA, and requires protein biosynthesis for its ABA-dependent expression. MYC and MYB recognition sequences are essential for the ABA- and drought-responsive expression of *rd22*. Transcription factors—MYB (ATMYB2) and MYC (*rd22BP1*)—are thought to function in the regulation of slowly stress-inducible genes after the production of ABA-inducible transcription factors (pathway I).^[13]

Many drought- and ABA-inducible genes encoding various transcription factors have been reported. These contain conserved DNA-binding motifs, such as zinc finger, homeo box, and WRKY motif. Among them, ATHB6 (containing the homeodomain) functions as a negative regulator downstream of ABI1 protein phosphatase in the ABA signal transduction pathway.^[14]

GENETIC ANALYSIS OF DROUGHT-STRESS SIGNAL TRANSDUCTION

Genetic analysis of *Arabidopsis* mutants with the *rd29A* promoter::luciferase transgene reveals complex cross talk among signaling pathways in drought-, salt-, and

cold-stress responses, and suggests that stress-signaling pathways, (including ABA-independent and ABA-dependent pathways) are not completely independent.^[15] Recently, many genes have been identified using map-based cloning, some of which encode putative transcription factors.^[16] Genetic analysis of these mutants is thought to provide more information on drought-stress signal transduction.

CONCLUSION

Many genes are induced by drought stress. Analyses of stress-inducible gene expression have revealed the presence of multiple signal-transduction pathways between the perception of drought-stress signal and gene expression. At least four different transcription systems function in the regulation of dehydration-inducible genes; two are ABA-responsive and two are ABA-independent. This explains the complex stress response observed after the exposure of plants to drought stress. Some genes are rapidly induced by drought stress, whereas others are slowly induced after the accumulation of endogenous ABA. Genetic analysis of Arabidopsis mutants also suggests complex signaling pathways in drought-, salt-, and cold-stress responses. Functional genomics has become a powerful approach to elucidate complex stress-signaling cascades.

Plant Response to Stress: Role of Molecular Chaperones

Barbara Despres

Pierre Goloubinoff

University of Lausanne, Lausanne, Switzerland

INTRODUCTION

Unlike algae, terrestrial plants do not benefit from a well-buffered environment provided by large water bodies. The atmosphere cannot as efficiently attenuate sudden changes in the environment, and land plants—notably desert plants—are exposed to a plethora of combined environmental stresses: heat-shock, water loss, excess light, accumulation of oxygen radicals, osmotic shock, freezing, mechanical stress, etc. Unlike animals, plants have limited motility and cannot seek shelter to escape damage from daily and seasonal variations in the environment. One powerful defense mechanism involves a network of molecular chaperones, which can prevent stress-induced protein aggregation and actively scavenge and refold stable aggregates into functional native proteins.

PROTEIN AGGREGATES AND ACQUIRED STRESS RESISTANCE

Because proteins maintain a delicate equilibrium between structural rigidity and functional flexibility, external stresses may cause them to lose their native conformation and seek alternatively stable inactive structures, called aggregates. Because of their insoluble hydrophobic nature, aggregates may interfere with membrane functions such as photosynthesis and occupy vital cellular space. Some protein aggregates from mammals, the amyloids and prions, cause neural degeneration. Deleterious properties of stress-induced protein aggregates in plants are unknown. Yet the fact that high levels of heat shock proteins (Hsps), which prevent stress-induced aggregation and regulate plant development, are induced in stressed plants strongly suggests that Hsps act to minimize interference with vital cellular processes by protein aggregates.

Most organisms, including plants, have evolved defense mechanisms that can react to various mild doses of stress and build up responses in anticipation of more extreme stresses to come.^[1] Although more economical than maintaining various defense mechanisms at all times, acquired resistance is transient by nature. Hence, an abrupt, unannounced stress may not allow enough time to estab-

lish proper defense mechanisms, while as time passes, previously induced defense mechanisms may subside and lose their ability to withstand a renewed challenge.

MAJOR MOLECULAR CHAPERONES IN PLANTS AND THEIR ROLES UNDER HEAT STRESS

The effect of heat shock has been extensively studied as a paradigm of other types of environmental stresses. Nearly all organisms, including plants, arrest protein synthesis during mild, nonlethal heat shock, except for a subset of proteins termed heat shock proteins (Hsps), which are produced in large amounts. Induction of heat shock genes in response to heat stress is mediated by transcriptional activator proteins (HSF) that trimerize and bind to cis-regulatory promoter elements (HSEs) conserved in all eukaryotes.^[2] Molecular chaperones, many of which are Hsps, belong to several classes of proteins initially classified according to their molecular weight: Hsp110, Hsp100, Hsp90, Hsp70, Hsp60, and small Hsps. Hsp chaperones have also constitutively expressed cognates (Hsc), which are sequence-related and carry housekeeping chaperone functions under nonstressed conditions.

Hsp70

Hsp70 is a highly conserved molecular chaperone present in all living organisms (with the exception of some archaeobacteria). In the model plant *Arabidopsis thaliana*, about 14 highly homologous (>45% identity) Hsp70 members are expressed constitutively (Hsc70), or in a stress-dependent manner (Hsp70). The encoded proteins are localized to the cytosol, endoplasmic reticulum (ER), mitochondria, and chloroplasts (Table 1). In addition, there are four members of the Hsp110 family, which is sequence-related to the Hsp70 family. In neuronal cells, Hsp110 prevents stress-induced apoptosis and may regulate the Hsp70/40 chaperone system.

Hsp70 (DnaK in *E. coli*) is composed of a 40-kDa ATPase domain and a 30-kDa protein-binding domain. DnaK collaborates with two co-chaperones, DnaJ (Hsp40)

(From Ref. 11.)

and GrpE. DnaJ is thought to bind locally to hydrophobic regions in loops of misfolded proteins. DnaJ-bound loops are then transferred to the protein-binding pocket of DnaK, triggering ATP hydrolysis. Release of the bound polypeptide from DnaK requires GrpE, which accelerates nucleotide exchange in DnaK. Reiteration of such local binding/release events likely leads to a gradual disentanglement of the polypeptides from the aggregates and correct refolding of the polypeptide.^[3] Hsp70 collaborates with other molecular chaperones and can be considered as the core element of the chaperone network in the cell, toward which are funneled various forms of misfolded proteins for disaggregation (Fig. 1).

The *Arabidopsis* genome expresses a plethora of Hsp40-like proteins, which because of their DnaJ-like domains are suspected to interact with the various members of Hsp70s in the cell and drive specific chaperone reactions. Plant genomes contain several prokaryotic-like GrpE genes, likely in the chloroplasts and mitochondria. Hip (Hsp70 interacting protein) proteins have also been identified in plants and might regulate Hsp70 activity, as in animals, by stabilizing Hsp70 in an ADP-conformation with high affinity for the polypeptidic substrate.^[4] In *Arabidopsis* and various other organisms, Hsp70 seems to act as a negative feedback regulator of HSF activity.

Indeed, when excess Hsp70 (and other Hsps) is synthesized under heat stress, its interaction with heat shock factors could repress transcription of heat shock genes.^[5]

Hsp100

Hsp100 proteins from prokaryotes and eukaryotes are also termed Clp (for caseinolytic protease) because the first member described was *E. coli* ClpA/P protease, which can hydrolyze casein in vitro. Hsp100/Clp proteins are divided in two major classes: ClpA/B/C/D containing two ATP-binding domains, and ClpM/N/X/Y containing only one ATP-binding domain.^[6] Most ClpB proteins are Hsps, which, together with Hsp70, carry the solubilization and refolding of large protein aggregates.^[3]

Several Hsp100s have been isolated in different plant species. They are found in the cytosol, in mitochondria, and in chloroplasts. In plants, expression of Hsp100 is developmentally regulated.^[7] *Arabidopsis* Hsp100s present four ClpB-like, three ClpA-like, and eight related proteins whose functions cannot be predicted by sequence analysis (Table 2). Plant ClpB-like Hsp101 (At1g74310) plays a crucial role in the acquisition of thermotolerance, but it is dispensable for development and germination in

Fig. 1 Functional hierarchy of the chaperone network: Stress unfolds native proteins, which form intermediates that associate into insoluble aggregates. Hsp60, Hsp90, Hsp40, Hsp70, or sHsps can bind small aggregates to prevent further aggregation. Hsp70 is the core of the chaperone network, to which are funneled early intermediates stabilized by Hsp90 or Hsp40, small aggregates stabilized by small Hsps, or large aggregates processed by Hsp100. Following unfolding of misfolded structures by Hsp70, individual polypeptides may refold into the native state. (From Ref. 11.) (View this art in color at www.dekker.com.)

(From Ref. 11.)

the absence of stress.^[7] It will be interesting to address the protein-refolding and/or proteolytic functions of the many Clp-like genes in *Arabidopsis* and their contribution to various stress resistances.

Small Hsps

In most prokaryotes and eukaryotes, various stresses induce low-molecular-weight (small) 10–30 kDa heat shock proteins (sHsps), which all share a conserved C-terminal domain similar to mammalian α -crystallin. They often form loose, hollowed, oligomeric structures comprising 9 to 32 subunits.

In plants, sHsps are most abundantly expressed under various stresses in the cytosol, endoplasmic reticulum, mitochondria, and chloroplasts. The *Arabidopsis* genome encodes for at least 50 proteins that include a crystallinlike domain. While it is not yet clear which among them are stress-related proteins, about two dozen fall into two groups of cytoplasmic and organellar sHsps, respectively. In the chaperone network, small Hsps complement Hsp100 by presenting aggregates to Hsp70 for disaggregation.

sHsps prevent the formation of large aggregates in the first place, and thus ensure optimal interaction with Hsp70.

A remarkable property of the sHsps in vitro, in *Chlamydomonas* chloroplasts and in *Synechocystis*, is their ability to transiently bind membranes during stress and confer membrane stability against thermally or chemically induced hyperfluidity.^[8] Thus, sHsps may also provide a mechanism for short-term adaptation of membranes to heat shock.

Hsp60

Hsp60 belongs to the chaperone subfamily named chaperonins. Its prokaryotic homologue, GroEL, mediates polypeptide folding by a well-described cage-sequestering mechanism. Unlike Hsp70 and Hsp100, it cannot act upon large complexes of misfolded protein and cannot solubilize aggregates. Rather, Hsp60 can assist Hsp70-mediated protein disaggregation by accelerating the final refolding steps.^[3] GroEL-like Hsp60 can be found in chloroplasts and mitochondria, but not in other compartments of the plant cell, suggesting that it

primarily contributes to the stress protection of these organelles.^[11]

Hsp90

Hsp90 is a highly conserved ATPase chaperone, very abundant in the cytoplasm of eukaryotic and prokaryotic cells, even under nonstressed conditions. Like many chaperones, Hsp90 can minimize stress-induced protein aggregation and, together with Hsp70 and ATP, assist the correct refolding of stress-induced misfolded proteins. Under nonstress conditions, mammalian Hsp90 acts as the central component of a supercomplex involved in signal transduction via interaction with steroid hormone receptors or protein kinases. Plant cells also contain similar complexes composed of Hsp90, Hsp70, and FKBP-type prolyl-isomerase.^[9] Hsp90 controls the morphology and development of complex eukaryotes. In *Arabidopsis* are present four highly homologous cytoplasmic Hsp90 genes (>90%) and one form in each organelle: ER, chloroplasts, and mitochondria (Table 2). Hsp90 is the only chaperone for which there are specific inhibitors (geldanamycin, radicicol) that reveal a central role for Hsp90 in the mechanism of evolution.^[10]

CONCLUSION

We describe here a coherent molecular mechanism by which Hsp chaperones can limit damages and actively repair lesions in proteins of plants subjected to rapid and extreme variations of temperature. sHsps may also limit stress damage in membranes. Because chemically modified unrefoldable proteins may occur as a result of other stresses, such as oxidative stress, chaperones may not always act in refolding, but may serve to recognize misfolded proteins that need to be targeted to proteases for degradation.

Chaperones Link Stress with Evolution

The mechanism of evolution implies a balance between accumulation of mutations in a population and their selection by environmental stress. It is thought that protein stabilization by molecular chaperones allows numerous mild mutations to accumulate in unstressed organisms, including plants.^[10] During prolonged environmental stresses, the housekeeping and mutant-buffering functions of chaperones are affected by their recruitment for aggregate prevention/repair duties. Thus, environmental stresses may reveal large arrays of new alleles and of corresponding phenotypes, some of which may better

fit the new, extreme environmental conditions. Hence, alongside providing efficient short-term protection against environmental stresses, molecular chaperones can also mediate the long-term evolutionary adaptation of plants to ever more extreme and challenging terrestrial climates.

Plant Response to Stress: Role of the Jasmonate Signal Transduction Pathway

Mirna Atallah
Johan Memelink

Leiden University, Wassenaarseweg, Leiden, The Netherlands

INTRODUCTION

Plants differentially activate distinct defense pathways in response to stress. Depending on the type of stress, plants synthesize the signaling molecules jasmonic acid (JA), salicylic acid (SA), or ethylene, which regulate the defense response.

Jasmonates (JAs) are fatty acid derivatives synthesized via the octadecanoid (ODA) pathway. They play pivotal roles in wound and defense responses, and in anther and pollen development. The defense JA pathway comprises several signal transduction events: the perception of the primary stress stimulus and transduction of the signal locally and systemically; the perception of this signal and induction of JA biosynthesis; the perception of JA and expression of responsive genes; and finally, integration of JA signaling with outputs from other signaling pathways.

STRESS-INDUCED JA BIOSYNTHESIS

How stress signals affect JA biosynthesis is largely unknown. In *Catharanthus roseus* cells, elicitor-induced JA biosynthesis depends on an increase in cytoplasmic Ca^{2+} concentration and protein phosphorylation^[2] (Fig. 1). In tobacco, wound-induced JA biosynthesis depends on the mitogen-activated protein kinase WIPK.^[1]

More is known about the JA biosynthetic pathway itself.^[1] The biosynthesis of JAs, which include the biologically active intermediates in the ODA pathway and derivatives of jasmonic acid, begins in the plastids with phospholipase (PL)-mediated release of α -linolenic acid (LA) from membrane lipids.^[1] LA is then converted by lipoxygenase (LOX), allene oxide synthase (AOS), and allene oxide cyclase (AOC) into the intermediate 12-oxo-phytodienoic acid (OPDA). This compound is converted in the peroxisomes into JA by OPDA reductase 3 (OPR3), and by three rounds of β -oxidation. JA can be methylated in the cytoplasm to its volatile derivative methyl-jasmonate (MeJA) by *S*-adenosyl-L-methionine: jasmonic acid carboxyl methyltransferase (JMT) (Fig. 2).

Wounding induces the expression of several JA biosynthesis genes. Therefore, one possible mechanism for stress-induced JA biosynthesis is de novo synthesis of biosynthetic enzymes. In addition, the expression of JA biosynthesis genes is induced by JAs themselves, indicating that JA signaling is amplified by a positive feedback mechanism.

Several mutants in *Arabidopsis thaliana* affected in JA biosynthesis have been isolated.^[1] The *fad3-2fad7-2fad8* triple mutant, lacking the fatty acid desaturases necessary to synthesize the JA precursor linolenate, contains negligible amounts of LA and JAs. The *opr3* mutant (also known as *dde1: delayed dehiscence1*) lacks the OPDA reductase isoform required for JA biosynthesis, but accumulates OPDA when wounded.

JA SIGNAL TRANSDUCTION

How JAs are perceived by plant cells is unknown. The mechanisms whereby JA signaling triggers gene expression are just starting to be elucidated. A JA- and elicitor-responsive element (JERE) in the promoter of the terpenoid indole alkaloid (TIA) biosynthetic gene *Strictosidine synthase (Str)* from *C. roseus* interacts with two transcription factors called Octadecanoid-Responsive *Catharanthus* AP Σ Γ Σ LA2/Ethylene Response Factor (AP2/ERF)-domain proteins (ORCAs).^[3,4] ORCA2 was isolated by yeast one hybrid screening using the JERE as bait^[3] and ORCA3 was isolated by a genetic T-DNA activation tagging approach.^[2] Both belong to the AP2/ERF family of transcription factors, which are unique to plants and are characterized by the AP2/ERF DNA-binding domain.

Significantly, ORCA gene expression is rapidly induced by (Me)JA. In addition, evidence suggests that JA activates preexisting ORCA transcription factors by inducing a posttranslational modification, for example, phosphorylation.^[4] Activated ORCA proteins may autoregulate ORCA gene expression as well as regulating TIA biosynthetic gene expression. Alternatively, JA-induced ORCA gene expression can occur via a transcriptional cascade, including a yet unidentified transcription-activating factor

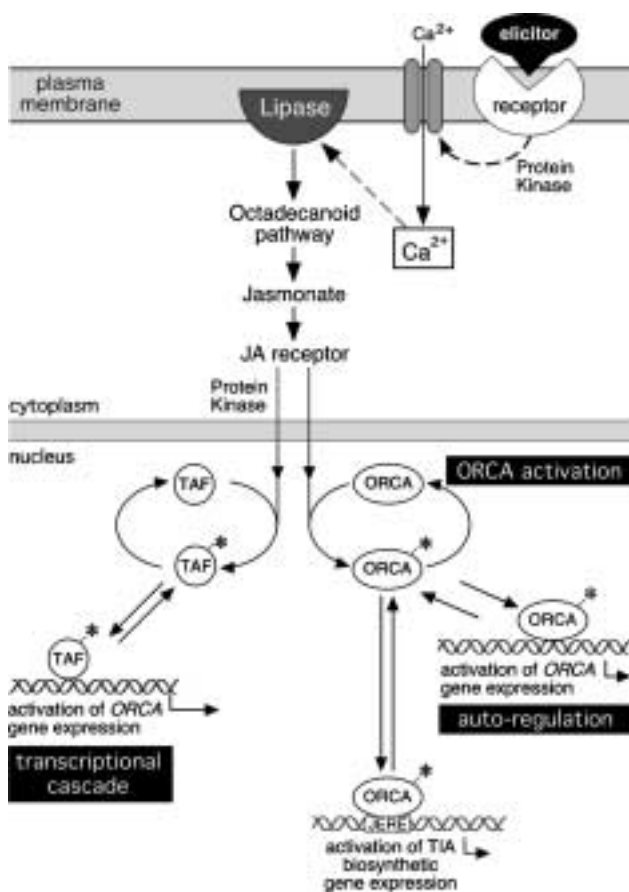

Fig. 1 Model for elicitor signal transduction leading to TIA biosynthetic gene expression in *C. roseus*.

(TAF), which is activated via posttranslational modification (Fig. 1).

In *Arabidopsis*, the AP2/ERF-domain transcription factor ETHYLENE RESPONSE FACTOR 1 (ERF1) was shown to be involved in JA signal transduction as well as in ethylene signaling.^[5] Constitutive expression of ERF1 leads to increased expression levels of defense-related genes that are synergistically induced by a combination of ethylene and JA (including *PDF1.2*), and confers resistance to several necrotrophic fungi.^[5] Therefore, it appears that *Arabidopsis* also uses a subset of its 124 AP2/ERF-domain transcription factors (including ERF1) to regulate JA-responsive gene expression.

Several JA-insensitive *Arabidopsis* mutants have been found by screening for a reduction in the inhibition of root growth caused by MeJA or by the bacterial toxin coronatine, a structural analogue of JA and OPDA.^[1] The *coronatine-insensitive 1* (*coi1*) mutant is affected in a gene encoding a protein with 16 leucine-rich repeats and an F-box motif. The COI1 F-box protein associates with

Skp1-like proteins (S) and cullin (C) to form SCF^{COI1} ubiquitin-ligase complexes.^[6] F-box proteins are the components of SCF complexes, which recognize substrate proteins and target them for degradation via the ubiquitin-proteasome pathway. Therefore, COI1 seems to recruit one or more repressors of JA responses for degradation.^[1,6]

The JA-insensitive mutant *mpk4* was identified by its dwarf phenotype, and is affected in the gene encoding the mitogen-activated protein kinase 4.^[7]

JA RESPONSES

A key role for JAs in defense of tomato against insect herbivores and microbial pathogens was proposed in 1992 by Farmer and Ryan, who showed that intermediates and end products of the octadecanoid pathway (but not other closely related lipids) induce proteinase inhibitors that deter insect feeding.^[1]

JA is the physiological signal for several wound- and pathogen-induced responses in plants, and it is essential for pollen development in *Arabidopsis*.^[1] Exogenously applied (Me)JA results in major reprogramming of gene expression, including defense-related genes that are activated by wounding and pathogen attack. The JA-responsive

Fig. 2 Schematic representation of the JA biosynthetic pathway. A mutant blocked in a biosynthesis step is in italics.

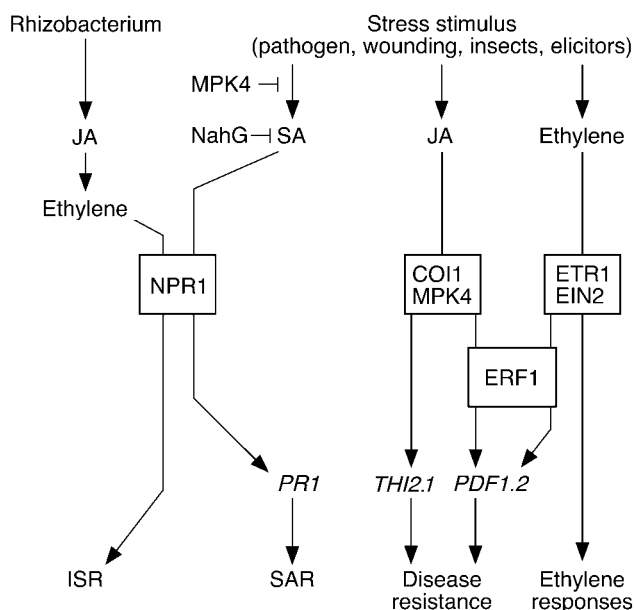

Fig. 3 Model showing signaling in stress responses in *Arabidopsis*.

PDF1.2 and *THI2.1* genes encode antimicrobial plant defensin and thionin proteins, respectively.^[1] JAs also induce the expression of biosynthesis genes leading to the accumulation of antimicrobial secondary metabolites, including alkaloids, terpenoids, flavonoids, anthraquinones, and glucosinolates in different plant species.^[2,8]

Arabidopsis mutants defective in JA biosynthesis or perception are deficient in certain defense responses and are male-sterile. The *coi1* mutant is defective in its resistance to insects and certain pathogens, and fails to express JA-regulated genes, including *PDF1.2* and *THI2.1*.^[1] A single amino acid substitution in COI1, which disrupts SCF^{COI1} complex formation, results in loss of the JA response.^[6] The *mpk4* mutant is blocked in the induction of JA-inducible *PDF1.2* and *THI2.1* genes and has reduced fertility^[7] (Fig. 3). The *fad* triple mutant shows enhanced sensitivity to the fungus *Pythium irregulare* and the dipteran insect *Bradysia impatiens*.^[1] The *opr3* mutant is male-sterile, indicating that pollen development uniquely requires JA and not OPDA. Fertility is restored in the *opr3* mutant and the *fad* triple mutant by application of JA. OPDA plays a major role as a stress signal, because its synthesis in the *opr3* mutant is sufficient to trigger a defense response against *B. impatiens* and the fungus *Alternaria brassicicola*.^[9]

JAs play an important role in ISR, a form of induced systemic resistance elicited by nonpathogenic strains of the root-colonizing bacterium *Pseudomonas fluorescens*^[10] (Fig. 3).

CROSS TALK BETWEEN DEFENSE SIGNALING PATHWAYS

The JA signaling pathway interacts cooperatively and antagonistically with the ethylene and SA pathways in a variety of responses, leading to fine-tuning of the complex defense response. Together with JA, ethylene plays a crucial role in defense against necrotrophic microbes, in expression of *PDF1.2* and other defense genes, and in ISR (Fig. 3). Mutants affected in ethylene signal transduction (including the ethylene receptor mutant *ethylene-resistant1* (*etr1*) and the *ethylene-insensitive2* (*ein2*) mutant) also have reduced expression of certain JA-responsive genes,^[5] are more susceptible to certain microbial pathogens, and cannot mount ISR (Fig. 3). A subset of AP2/ERF-domain transcription factors (including Arabidopsis ERF1)^[5] may serve as the platform to integrate the input from the JA and ethylene signaling pathways (Fig. 3).

Systemic acquired resistance (SAR) is a defense response in which, in contrast to ISR, SA is the key regulatory signal. Transgenic *Arabidopsis* NahG plants expressing the bacterial SA-degrading enzyme salicylate hydroxylase cannot mount SAR. SAR provides protection in uninfected plant parts against pathogens and is correlated with the expression of pathogenesis-related (PR) proteins with antimicrobial activity (Fig. 3). The NPR1 (Nonexpressor of PR genes 1) protein has a dual role in systemic resistance mechanisms mediated by either SA (SAR) or JA and ethylene (ISR)^[1,10] (Fig. 3). The *mpk4* mutant, blocked in JA signaling, exhibits elevated levels of SA and constitutive SAR.^[7]

CONCLUSION

The role of JAs in development, defense responses, and gene expression is currently being delineated through the analysis of additional gain-of-function and loss-of-function *Arabidopsis* mutants,^[1,11] and through the analysis of JA-responsive promoters and transcription factors. Future work will focus on the regulation of JA synthesis, the identification of JA receptors, the identification of JA-responsive transcription factors in different plant species and of other signal transduction steps that regulate transcription factor activity, and on the mechanisms of cross talk between different defense signaling pathways.

Plant Response to Stress: Source-Sink Regulation by Stress

Thomas Roitsch

Universität Würzburg, Würzburg, Germany

INTRODUCTION

Plants are challenged by a variety of biotic and abiotic stress factors. Due to their sessile form of life, higher plants have evolved an enormous metabolic flexibility to cope with adverse stimuli by substantial changes in primary and secondary metabolism. One key target of plant metabolism is the partitioning of assimilates between the autotrophic source tissues and the heterotrophic sink tissues. This results in profound effects on many aspects of growth and development, thereby also affecting crop yield. This article reviews the current knowledge of the underlying regulatory mechanism and discusses possible agricultural and biotechnological implications.

CARBOHYDRATE PARTITIONING IN HIGHER PLANTS

Higher plants are physiological mosaics of source tissues. Their mature leaves, e.g., export carbohydrates to photosynthetically less active or inactive sink tissues such as roots, fruits, and tubers, characterized by net import of sugars. The supply of the transport sugar sucrose is a limiting step for the metabolism and growth of sink tissues. By generating a sucrose gradient to support the unloading of sucrose from phloem, the sucrose-cleaving enzymes invertase and sucrose-synthase are important determinants of sink capacity.^[1] Thus they are critical links between photosynthate production in source leaves and growth capacity of sink organs.^[2,3] Carbohydrate partitioning between source and sink tissues—competing for a common pool of carbohydrates—is a highly dynamic process that accompanies all stages of the growth and development of higher plants and is influenced by environmental stimuli.

EFFECT OF PATHOGENS ON SOURCE-SINK RELATIONS

Plants may be challenged by a variety of biotic stress factors such as pests and pathogens that result in substantial harvest losses. Fungi and bacteria may act as biotrophic symbionts that utilize carbohydrates synthe-

sized by the host plant. Fungi in particular have evolved sophisticated structures and mechanisms to create an additional strong sink that drains assimilates from the infected plant. In contrast, necrotrophic pathogens (which may include fungi, bacteria, and viruses) grow on the biomass of the infected plant and ultimately result in the death of the host organism.

Activation of defense responses upon pathogen infection is usually accompanied by a fast induction of sink metabolism, possibly to satisfy the increased demand for carbohydrates as an energy source to activate the cascade of direct defense responses and further mediate physiological adaptations (Fig. 1). The source metabolism is generally inversely regulated.^[4] Two mechanisms may account for the observed suppression of photosynthesis in response to pathogens: 1) the direct effect of the pathogen on the expression of photosynthetic genes; and 2) the indirect effect due to induction of sink metabolism mediated via sugar repression of photosynthetic genes (Fig. 1). In addition to the localized source-sink transition, the pathogen infection will also affect whole plant carbon partitioning by creating a new sink that competes with other sinks for the common pool of carbohydrates. During the initial defense response, transient effects on source-sink relations are observed. In addition, biotrophic pathogens will establish persistent changes in assimilate allocations by the permanent establishment of a new sink.^[5] The pathogen-induced modulation of the carbohydrate status will also affect the susceptibility of the plant, which is evident from the phenomenon of high sugar resistance, the finding that various key pathogenesis-related genes are sugar inducible, and the finding that overexpression of a yeast invertase in the plant apoplast results in increased resistance to virus infection.^[6] The effects of a systemic viral infection on photosynthesis, carbohydrate accumulation, and assimilate partitioning seem to be mediated by the viral movement proteins.^[7]

REGULATION OF SOURCE-SINK RELATIONS BY ABIOTIC STRESS

Plants are exposed to a wide range of different abiotic stimuli including irradiance, ozone, temperature, osmotic

factors, wind, water deficiency and mechanical wounding. Drought and salinity are the two major abiotic stresses that limit plant productivity. Although these two stresses are clearly different in their physical nature, they activate some common reactions in plants.^[2] A high root:shoot ratio is an important adaptive response to drought and salinity that, by alleviating stress, permits the plant to recover functional equilibrium.^[8] This dry matter redistribution is closely associated with carbohydrate allocation to the roots. Therefore, modulation of the processes involved in carbon metabolism and energy production seems to be a promising approach to the engineering of plants with greater adaptability to water and saline stress.

The photoassimilates produced under salt stress are used to support crucial, mutual processes such as growth and osmotic adjustment. The competition of sink organs for the limited carbon supplies under salinity significantly affects overall plant growth, dry matter distribution, and crop yield. As a consequence, the different growth responses to salinity can be interpreted as resulting from changes in the allocation and partitioning of photoassimilates. In general, salinity causes a reduction in sink enzyme activities, leading to an increase in sucrose in source leaves and a decrease in photosynthesis rate by feedback inhibition. Extracellular invertase activity seems to be particularly involved in salt stress response: The enzyme activity correlates with the redistribution of dry matter and is much higher in the roots of salt-tolerant species. An increase in extracellular invertase activity in transgenic plants improves salt tolerance.^[2]

Water deficits in plants lead to physiological modifications such as photosynthesis reduction and osmolyte biosynthesis.^[9] Large alterations in source-sink relations with source limitations are induced that result in decreased export of assimilates and decreased crop load. It has been shown that an effect of water stress on phloem unloading (via a decline in invertase activity) correlates with male sterility in cereals and blocks pollination and early kernel development in maize.^[7]

INTERACTIONS AND SIGNAL INTEGRATION

Under natural conditions plants are simultaneously affected by a variety of both biotic and abiotic stress-related stimuli. Although this fact is neglected when the effect of a single stress is analysed (as is usual), a few studies indicate that naturally occurring multistress situations will differentially affect source-sink relations. For example, it has been shown that elevated levels of CO₂ modulate the effect of powdery mildew infection on carbon partitioning

in barley and ameliorate ozone effects on biomass and leaf area.^[7]

It is becoming evident that complex regulatory networks operate in plants that link endogenous and exogenous stimuli.^[10] The finding that specific subsets of mitogen-activated protein (MAP) kinases are activated in response to different stimuli could provide a molecular mechanism suggesting how diverse signals may be integrated to result in the observed coordinated

Fig. 1 Model for the inverse regulation of sink metabolism/defense responses and photosynthesis by stress-related stimuli. Abiotic and biotic stress-related stimuli activate different signal transduction pathways that are ultimately integrated to coordinately regulate gene expression. Activation of different subsets of MAP-kinases provides a mechanism to integrate different signals, and results in coordinated and signal-specific gene regulation. Any signal that upregulates extracellular invertase will be amplified and maintained via the sugar-induced expression of this enzyme as outlined in Roitsch et al. (From Ref. 4.)

responses, while simultaneously maintaining the possibility for unique signal-specific downstream effects (Fig. 1; Refs. 11,12).

EXTRACELLULAR INVERTASE: KEY METABOLIC ENZYME AND MODULATOR OF STRESS RESPONSES

Supplying carbohydrates to sink tissues via an apoplastic pathway involves the release of the transport sugar sucrose into the apoplast by a sucrose transporter, cleavage of the disaccharide by an extracellular invertase, and uptake of the hexose monomers by monosaccharide transporters. Experimental data demonstrate not only that the extracellular invertase is crucial in supplying carbohydrates to symplastically isolated sink tissues and actively growing tissues, but that this sucrose-cleaving enzyme also plays a crucial role in mediating stress responses. As outlined by Roitsch et al.,^[3] the function of extracellular invertase in stress responses includes the regulation of source-sink transition and the integration of signals that regulate source-sink relations and defense responses. In addition, the sugar inducible expression of extracellular invertase and defense-related genes provides a feed-forward mechanism for maintaining or amplifying the effect of stress-related stimuli: Upregulation of extracellular invertase by any stimulus enhances sink strength and thus results in an elevated sugar concentration. This metabolic signal further induces extracellular invertase for signal amplification and also results in induction of defense-related genes as depicted in Fig. 1.

CONCLUSION

Evidence is accumulating that both biotic and abiotic stress-related stimuli are important exogenous factors that affect source-sink relations (Fig. 1). This interaction modulates plant growth and development and harvest yield, and thus has profound effects on many aspects of the plant life cycle, and also interferes with productivity in agriculture.

Determination of photosynthetic parameters by in vivo fluorescence imaging^[13] could be a valuable noninvasive technique to detect effects of pathogen infection on source-sink relations at early stages, for practical applications and to elucidate the underlying regulatory mechanisms in planta.^[12] It will be important to further study the effect of the naturally occurring interactions of various signals to determine possible additive, synergistic and

compensating effects between stress-related stimuli and endogenous factors on source-sink relations.

Only scattered information is available about the intracellular transduction of stress-related signals and molecular and cellular mechanisms that contribute to the physiological responses. Numerous attempts in many laboratories to modify carbon fluxes by modifying individual enzymatic steps have been essentially unsuccessful.^[6] The challenge remains therefore to unravel the underlying sophisticated network of highly flexible regulatory circuits (with complex interactions and crosstalk) for insight into source-sink regulation at the molecular level.^[10] This will allow the predictable genetic engineering of resistant plants by manipulating signal transduction pathways to increase the partitioning of fixed carbon into harvestable sinks despite the ubiquitous presence of biotic and abiotic stresses.

ACKNOWLEDGMENTS

Due to space limitations, the author apologizes for not being able to cite the many important original publications that have contributed to rapid progress in the field of plant response to stress. The great effort of all past and current co-workers, stimulating discussions in weekly Laborseminars, and helpful comments on the manuscript by M. Hofmann and S. Berger are gratefully acknowledged.

Plant Responses to Stress: Nematode Infection

Godielieve Gheysen

Ghent University, Ghent, Belgium

INTRODUCTION

Plant-parasitic nematodes are cosmopolitan pests that have evolved various feeding strategies to obtain nutrients from their host plants. These nematodes possess a stylet capable of penetrating plant cell walls and are all obligate biotrophs, that is, they need to feed on living cytoplasm. Some nematodes do this by just withdrawing the plant cell contents, usually causing cell death, after which they move to another cell. In contrast to this “hit-and-run” strategy, other types of nematodes carefully puncture selected plant cells and transform them into elaborate feeding cells. According to their lifestyle, nematodes are considered migratory or sedentary, and endo- or ectoparasites. Most research to date has been focused on root-parasitic nematodes.^[1] Here, we will focus on the sedentary endoparasitic species from the family Heteroderidae: the cyst nematodes (*Globodera* and *Heterodera*) and the root-knot nematodes (*Meloidogyne*). The infective stage is the motile second-stage juvenile that penetrates the plant root, usually close to the tip, and moves to the vascular cylinder. Upon initiation of feeding, the nematode loses motility and becomes sedentary. These are the most damaging plant-parasitic nematodes, and they evoke complicated cellular responses in the infected roots.

SYMPTOMS OF NEMATODE-INFECTED PLANTS

Root-parasitic nematodes are called hidden enemies because the above-ground symptoms are not often visible before major damage has been done. Endoparasitic nematodes either destroy root tissues (migratory species) or distort the vascular tissue (sedentary species). In addition, heavily infected plants usually have a less developed root system than normal. An obvious effect of deficient water transport is wilting of the plants in dry weather conditions. Heavily infected plants are stunted and exhibit symptoms of nutritional deficiencies. Lower infection levels often stay undetected because the resulting symptoms are more subtle: lower yields due to a decreased water transport, a reduction in photosynthesis, and nutrient removal by the nematodes.

Although plant-parasitic nematodes are microscopically small and usually inside the roots, their effects can often be seen on the outside (Fig. 1). Root-knot nematodes are named after the characteristic root knots or galls they induce on susceptible plants. In severe cases, the roots become stunted and completely deformed. Mature cyst nematode females transform into cysts that protect hundreds of eggs against adverse environmental conditions. Depending on the species, these cysts are visible as golden to brown globular or lemon-shaped structures loosely attached to the root. The induction of additional lateral roots is another typical symptom seen after infection with certain nematodes (such as *Heterodera avenae*, *H. schachtii*, *Meloidogyne hapla*), which gives a bearded appearance to taproots.

WOUND AND DEFENSE RESPONSES OF INFECTED PLANTS

Nematode infection always causes wounding of plant tissues, especially during the migration step. In the case of migratory nematodes, this leads to massive necrosis throughout the infection process. Root-knot nematodes circumvent strong plant responses during migration because they move between the cells by separating them at the middle lamella.^[2] The juveniles usually move down in the cortex to the root tip, where they turn 180° to migrate up in the vascular cylinder. At this point, the root meristem can be severely damaged if several juveniles pass through the same tip and try to find their way up. Cyst nematodes take a shorter route to the vascular tissue: they go straight through the cells toward the center of the root, causing strong necrosis from their point of entry to the place where they settle down.^[2]

Plants are usually able to recognize and react to these parasites by switching on defense responses.^[3] When the response is too weak or too late, a successful infection (compatible interaction) will result. A rapid and strong defense response (e.g., due to the presence of a resistance gene) will result in a resistant (incompatible) interaction. An incompatible interaction is often characterized by a hypersensitive reaction (cell death and necrosis), that impedes induction of feeding cells or further migration of the nematode.

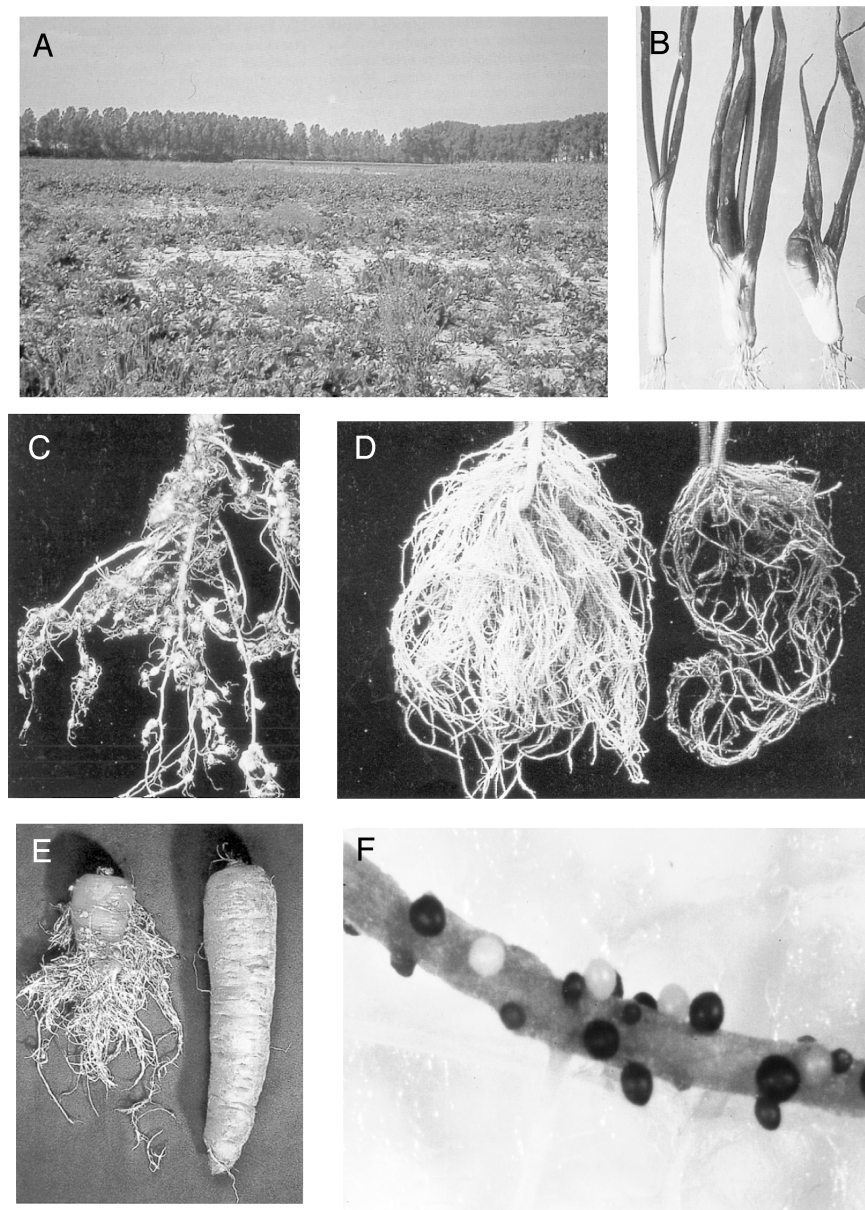

Fig. 1 Symptoms of nematode-infected plants. A. A field of sugarbeets infested with the beet cyst nematode *Heterodera schachtii*. Spots with infection are clearly visible as open spaces because of poor growth of plants. B. Onion plants affected by the stem nematode *Ditylenchus* show thickening (plant at the left is the uninfected control). C. Root galls caused by the root-knot nematode *Meloidogyne*. D. Strong necrosis (browning) in potato roots (right) due to infection by the migratory root-lesion nematode *Pratylenchus penetrans* (healthy plant at left). E. Bearded root effect on carrot caused by northern root-knot nematode (*Meloidogyne hapla*) (left: infected; right: control). F. Microscopic picture of cysts (*G. pallida*) on potato roots. [Photos (A)–(E) courtesy of A. F. Van der Wal (Wageningen).] (View this art in color at www.dekker.com.)

Changes in gene expression correlated with wound or defense response have been studied in several plant–nematode interactions.^[3] For example, the wound-inducible *wun1* promoter was rapidly induced by cyst nematodes in potato but only weakly responded to root-knot nematode infection. Induction of pathogenesis-related proteins has been detected in leaves and roots of potato plants infected with different pathotypes of *Globodera pallida*. Analysis of tomato roots 12 hours after infection with root-knot nematodes identified several defense genes to be upregulated. Most of these were induced in the compatible as well as in the incompatible interaction, although with differences in levels and timing.^[3] Examples of activated defense genes include per-

oxidase, chitinase, lipoxygenase, extensin, and proteinase inhibitors. Induced defenses against nematodes are not limited to upregulation of defense proteins; they also include pathways resulting in phytoalexin biosynthesis (such as glyceollin in soybean) and deposition of callose or lignin as a physical barrier.

DEVELOPMENT OF LARGE FEEDING CELLS IN RESPONSE TO SEDENTARY NEMATODES

Nematodes that feed for a prolonged period from the same cell(s) induce cytological modifications to increase

Fig. 2 Cellular alterations induced by sedentary endoparasitic nematodes. A. Section through an uninfected *Arabidopsis thaliana* root. The root tip is shown, as well as the region above the tip where sedentary nematodes induce feeding cells. B. Section through syncytium (S) induced by *Heterodera schachtii* in *A. thaliana*. The large cell in the middle is the syncytium that originated from fusion of neighbouring cells. Pieces of cell wall remnants can be seen as dashed lines inside the syncytium. C. Section through root gall induced by *Meloidogyne incognita* in *A. thaliana*. The nematode (n) is visible in the middle of the gall, feeding from one of the giant cells (*). About six giant cells are seen, as well as the increased number of cell layers that cause the gall. D. Electron microscopy picture of a section through a giant cell, showing typical features: multiple large-lobed nuclei (N), granular cytoplasm, small vacuoles (V), many organelles, and endoplasmic reticulum (E) membranes. (Bars: 50 μ m in A–C, 5 μ m in D). (Photo courtesy of J. de Almeida-Engler.) (View this art in color at www.dekker.com.)

the metabolic and transport capacities of that cell.^[1] *Criconebella xenoplax* is a sedentary ectoparasite that feeds for up to eight days from a single cortical cell. The nematode uses its stylet to withdraw nutrients from this cell via a zone of modified cytoplasm. Plasmodesmata between the food cell and surrounding cells are modified in a special way to facilitate solute transport. The ectoparasites *Xiphinema index* and *X. diversicaudatum* feed on root tips and transform them into terminal galls. The galls contain enlarged multinucleate cells that arise from repeated mitosis without cell division. The best studied and most pronounced cellular modifications are induced by the sedentary endoparasitic nematodes (Fig. 2). The successful induction of an elaborate feeding site is essential for the survival of these nematodes, because once they become sedentary they are unable to move to another cell. Probably in response to salivary secretions from the nematode, alterations of the nuclei, the cytoplasm, and the cell walls turn normal root cells into huge multinucleate feeding cells. A syncytium (induced by cyst nematodes) is formed by the breakdown of plant cell walls and subsequent fusion of neighbouring cells.

Giant cells (induced by root-knot nematodes) are formed as the result of repeated nuclear divisions without cell division.^[4]

NUCLEAR AND CYTOPLASMIC CHANGES IN FEEDING CELLS

Aberrant cell cycles that lead to a higher DNA content are typical for plant tissues that have a nutritional function, such as endosperm and tapetum. This phenomenon also occurs in developing feeding cells, although under a different form in giant cells and syncytia.^[5] The first sign of giant cell development is the formation of binucleate cells.^[6] Cell plate vesicles initially line up between the two daughter nuclei but then disperse, resulting in the abortion of the new cell plate. Additional mitoses uncoupled from cell division result in multinucleate large cells. The mean number of nuclei per mature giant cell is between 30 and 60 in most studied plant hosts, and the nuclei are also larger than normal. In sharp contrast to

giant cells, no mitosis has been seen in syncytia induced by cyst nematodes. The enlargement of nuclei indicates that DNA synthesis (uncoupled from mitosis) is taking

place within the syncytial tissue during and after the incorporation of new cells through cell wall dissolution.^[7] Both types of feeding cells thus contain many large nuclei, and since the transcriptional and translational activity increases at each doubling of the DNA, these cells are functionally equivalent to hundreds of diploid cells. The resulting high metabolism is reflected in a dense granular cytoplasm with many mitochondria, an increase in rough endoplasmic reticulum, and small vacuoles.

CELL WALL REMODELING IN FEEDING CELLS

When a cyst nematode selects an initial syncytial cell, the plant cell responds by gradually widening some plasmodesmata to neighbouring cells.^[2] The protoplasts of adjacent cells then fuse through the developing wall openings. At later stages, cell wall openings are formed de novo and the syncytium continues to grow by integrating neighboring cells. Giant cell and syncytium cell walls adjacent to the xylem increase their thickness by fingerlike cell wall invaginations that are followed by the plasma membrane.^[7] These invaginations enlarge the surface for water transport from the xylem into the feeding cell.

GENES EXPRESSED IN FEEDING CELLS

Various strategies have been used to identify plant genes that are upregulated in feeding cells and could thus be important in feeding-cell development or functioning^[8] (Fig. 3). Many different plant genes have been found to be activated in feeding cells; the challenge now is to elucidate the role and the importance of these genes in the infection process. Examples include genes for metabolic enzymes, cell wall-modifying enzymes, a water channel protein, cytoskeleton proteins, and genes that are putatively involved in early feeding-cell development, such as cell cycle genes and transcription factors.^[9] With the ongoing application of genomics tools to the study of plant–nematode interactions, the number of known plant genes involved in plant–nematode interactions will increase dramatically.

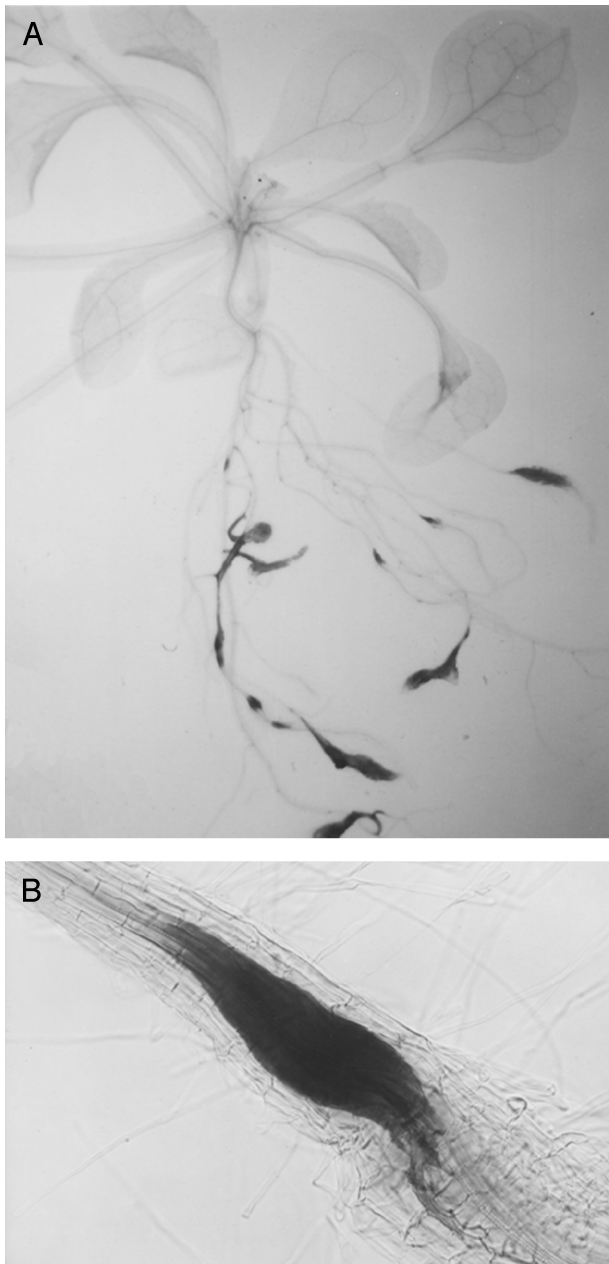

Fig. 3 Gene expression in nematode feeding sites. Promoter trapping is based on the random integration of a promoterless-glucuronidase (*gus*) gene in the DNA of a plant species, often *Arabidopsis thaliana*.^[10] When inserted downstream from a plant promoter that is inducible by nematode infection, a higher GUS activity (blue color) can be seen at the infection site. The elegance of this method lies in the ability to directly visualize induced expression in nematode feeding sites at various stages of the interaction, while analyzing the specificity of expression using uninfected parts of the same plant and control plants. A. GUS-assay on *A. thaliana* plant tagged with a promoterless *gus*-construct. The analysis was performed 3 days after inoculation with *Meloidogyne incognita*. Galls turn blue because of local promoter activity. B. Detail of a gall, the nematode has been counterstained with acid fuchsin. (Photo courtesy of Mansour Karimi.) Plant Responses to Stress: Ultraviolet-B Light

Brian R. Jordan

Lincoln University, Canterbury, New Zealand

INTRODUCTION

Ultraviolet-B radiation (UV-B: 280–320 nm) is highly energetic and can cause damage to a wide range of cellular components, such as DNA, amino acids, and lipids. Plants, because of their sessile nature, are potentially very susceptible to UV-B exposure, and the increase in UV-B as a result of ozone depletion could have severe consequences. Over the last few decades there has been a substantial amount of research on the effects of UV-B on plants.^[1,2] These studies show a large number of responses including changes in growth and development, increase in protective pigment biosynthesis, effects on photosynthesis, DNA damage, etc. These responses are also very variable, both between species and even within varieties of the same species. Most of these studies, however, have been carried out in controlled environment cabinets. Unfortunately, while providing experimental control, this approach does not provide a realistic comparison to the natural environment and consequently over-states the damaging influence of UV-B. Despite this disadvantage, controlled environment cabinets have provided valuable insight into the cellular changes induced by UV-B exposure, e.g., changes in gene expression. Recently more environmentally significant data is being generated on UV-B stress and a complex picture is emerging of multiple impacts at the physiological and ecological level.^[2,3] This short review will focus on changes at the molecular level as a result of UV-B-induced stress.^[1,4]

MOLECULAR RESPONSE TO UV-B STRESS

Gene Activation

It is now apparent that many of the UV-B induced responses require gene activation. Initial studies showed that genes that were required for protection against UV-B were activated, while those for photosynthesis, primary metabolism, etc, were down-regulated. To change gene expression, UV-B, unlike other wavelengths of light, can be absorbed directly by DNA and nonspecifically inhibit

DNA transcription. Alternatively, UV-B could be perceived by a specific photoreceptor or in some nonspecific manner (e.g., increased oxidative stress) that subsequently leads to gene regulation. Although no UV-B photoreceptor has been identified, there is some limited evidence that UV-B perception may operate through such a mechanism.^[5] After perception of the UV-B radiation, a signal transduction pathway(s) must be initiated that eventually changes gene activity. Recent studies on UV-B-induced gene activation has unveiled a complex response involving numerous signal transduction pathways.^[4,6] These responses are similar in some ways to other stress responses, e.g, to pathogens,^[7] but differ in various details such as the chemical components of the transduction pathway. At present, a number of characteristics of UV-B-induced signal transduction pathways have been described, with a variety of different components, which include ROS (reactive oxygen species), jasmonate, salicylate, and ethylene (Fig. 1). ROS is generated through a variety of mechanisms, including NADPH oxidase and peroxidase. Changes in ROS appear to be important in the early stages of signal transduction for many but not all genes.^[8] Although these pathways are specific for the activation of a particular gene, “cross-talk” between transduction pathways induced by other stress factors must also take place.

Irrespective of the pathway there must eventually be an interaction with the gene involving transcription factors and cis-acting elements within the gene promoter. UV-B-inducible promoter elements and candidate transcription factors have now been identified in plants.^[1,4] The cis-acting elements for light responsive *chs* in parsley are called ACE (ACGT-containing elements that recognize common plant regulatory factors) and MRE (Myb recognition elements). Although some differences exist, consistent structural similarities are found in *chs* promoters between species. A number of other UV-B-inducible transcription factors have recently been identified, including a novel 11-bp, GC-rich sequence identified in the pea *sadA* and *C* genes. The *sad* genes are particularly interesting as they are up regulated rapidly by UV-B and at a relatively low irradiance level. The *sad* genes are also affected by other environmental stresses, and, therefore, elements in the promoter must be a point of convergence

Fig. 1 UV-B-induced signal transduction pathways. (From Ref. 15) (View this art in color at www.dekker.com.)

for multiple environmental signals.^[9] This is supported by an inversely regulated promoter unit that has been identified and responds positively to UV and negatively to a pathogen-derived elicitor.^[10] This promoter unit could function as a convergence for largely distinct signal pathways and may also operate through common plant regulatory factors. These and similar studies are being further advanced by the application of rapid throughput screening techniques such as DNA array analysis^[11] and suppression subtractive hybridization^[12] that can identify UV-B-specific changes in gene activity.

UV-B Defense Mechanisms

Plants have a wide range of protective mechanisms that they use to defend themselves against UV-B radiation (Table 1). One of the first changes that take place in response to UV-B stress is an enhancement in secondary metabolism, particularly in phenylpropanoid-metabolism. This change produces predominantly water-soluble polyphenolic compounds that are synthesized in the epidermal cells. The biosynthetic enzymes are regulated by transcription factors and these may respond to UV-B levels.^[13] In addition, in some desert plants hydrophobic derivatives may also be localized in the cuticle. Studies have shown that these compounds are very effective in absorbing UV-B.^[1,4] However, there are substantial differences between species in the degree of UV-B penetration into the underlying mesophyll and palisade tissue. This seems to depend upon a lack of UV-B-absorbing pigments allowing passage through the anticlinal cell walls.^[1]

One of the main consequences of UV-B exposure is the generation of free oxygen radicals (e.g., from polyunsaturated fatty acids), leading to a cascade of cellular damage (see the previous section on signal transduction). The plant defense response is to synthesize a number of antioxidants or antioxidant enzymes, such as SOD, catalase, glutathione, ascorbate, flavonoids, or carotenoids. This response is a similar cellular response to that stimulated by many other biotic and abiotic stresses.^[7] A more specific change, however, that occurs during UV-B stress is that dihydroxylated flavonoid production is enhanced as they are stronger antioxidants.^[4]

A significant difference of UV-B to other stresses, is that UV-B radiation directly impinges on and is absorbed by the DNA of the cell. Many types of DNA lesion are created, but the most common are cyclobutane pyrimidine dimers (CPD) and 6–4 photoproducts.^[11] These lesions would have severe consequences for cellular function if not repaired. Most plants have a very effective DNA repair system with light-activated photolyase as the major repair mechanism, dark excision repair enzyme activity also being present. In most studies, DNA damage by exposure to UV-B can be detected, but the repair mechanisms seem to remove the lesions very efficiently.^[4]

Overall, the plant defense against UV-B stress depends on protective pigments, antioxidants, and DNA repair mechanisms. Each of these approaches relies on the biosynthesis of enzymes and consequently is dependent on UV-B-induced gene activation. It is apparent that UV-B protection comes at a substantial cost in terms of conversion from primary to secondary metabolism and production of antioxidant systems and repair enzymes. UV-B light appears to stimulate extensive reprogramming of cellular metabolism. This however, is, not as extensive as is the reprogramming induced by pathogens and indicates a clear hierarchy of stress responses with pathogen defense overriding UV-B by selective transcriptional modification of one or more metabolic pathways.^[10]

Table 1 UV-B-induced defense mechanisms

- Reflectance by cuticular layer and surface structures.
- Synthesis of UV-B absorbing pigments, primarily in the epidermal layers.
- Changes in gene expression to produce enzymes involved in UV-B defense.
- Production of antioxidant systems to protect against free radical damage.
- DNA repair enzymes activated to remove UV-B-induced DNA lesions.
- Amelioration mechanisms stimulated by other environmental parameters, e.g., high PAR.

INTERACTION BETWEEN UV-B AND OTHER ENVIRONMENTAL FACTORS

The response of plants to UV-B is significantly influenced by the interaction with other environmental factors. There are many examples in the literature^[1] and a few examples will be illustrated here. A unique response of plants to UV-B radiation relates to the property of high photosynthetically active radiation (PAR) to ameliorate the damaging impact of UV-B on plants. This was initially discovered at the physiological level, and later molecular studies noted that the down-regulation of gene expression was also reduced by high PAR. This “protection” did not involve synthesis of protective pigments, but was related to the function of the photosynthetic apparatus itself, probably associated with electron transport and photophosphorylation.^[4] The ability of different wavelengths to modulate the photosynthetic system to sense the external environment and act as a photoreceptor has been documented and can in some instances change chloroplast gene expression.^[4] Another important aspect of UV-B-induced changes in gene expression is that it varies depending upon the developmental stage of the tissue. UV-B does not appear to down-regulate genes for photosynthetic proteins in etiolated tissue.^[1] Thus, etiolated tissue exposed to light will strongly express genes for chloroplast protein biosynthesis. This expression continues even in the presence of supplementary UV-B radiation. This result is indicative of a strong link between the development of the photosynthetic apparatus and UV-B-induced gene expression. In addition to light quantity, light quality has a strong influence, both at the molecular and the physiological level.

The impact of UV-B stress is also modified by the drought status of the plants. Although some studies show additive effects, most show ameliorating antagonistic interactions. The growth of plants under no-water stress can be severely inhibited by UV-B. However, the same plants exposed to water stress will not be as severely affected. The reduced impact may be due to the drought limiting growth and cell division, consequently limiting the potential of UV-B to damage cellular processes. Other drought stress responses, such as increased levels of osmoprotectants (e.g., proline, GABA, etc.) may also play a role in reducing the impact of UV-B damage. Studies show that the effect will vary on the duration of exposure to both UV-B and drought. In addition, the plant's genetic background will influence the response. For instance, slow growing ecotypes exposed to these stresses are likely to be more tolerant.

Another interactive stress that has not been extensively investigated is that between UV-B and pathogens/herbivores. Studies have indicated that UV-B-induced changes

in plant chemistry can have an impact on pathogens or herbivores. Changes may take place in primary or secondary metabolism to alter the chemical constituents. Such changes could have subtle, but substantial impact on the interactions between a number of trophic levels.^[2,3]

SUMMARY

Although substantial progress has been made over the last decade to elucidate the molecular mechanisms involved in UV-B-induced stress responses^[1,4,6,14] this area still lags behind comparable areas of plant biology. Through greater knowledge at the molecular level the variation in responses at the whole plant level, plant pathogen/herbivore interactions level, and even at the ecological community level will be understood more fully.

John Innes Centre, Colney, Norwich, U.K.

INTRODUCTION

Plant viruses are widespread and economically important plant pathogens. Virtually all plants that humans grow for food and fiber are affected by at least one virus; depending on the plant species, geographic location, growing season, etc., virus disease(s) can preclude the ability to grow specific crops in certain locations. Hence, significant time and monetary resources are invested in efforts to control plant virus diseases. About 80% of the approximately 1000 currently recognized plant-infecting viruses have ribonucleic acid (RNA) as their genetic material. This contrasts with viruses affecting animals and prokaryotes, in which the most common type of genetic material is deoxyribonucleic acid (DNA). This article discusses RNA plant viruses and diseases, factors affecting disease development, and approaches for controlling these diseases.

VIRUS DISEASES IN PLANTS

The natural host ranges of RNA viruses vary from very wide (e.g., *Cucumber mosaic cucumovirus* (CMV) infects more than 800 species in 85 families) to very narrow, infecting one or a few species (e.g., *Apple stem grooving capillovirus*). Virus infection results in symptoms that range from no or mild symptoms (latent or cryptic infection) to death of the plant. The symptom type is usually characteristic of the virus, the most common being a mottle or mosaic pattern of light and dark green areas on the leaves delimited by the vein structure; in monocotyledonous plants this results in chlorotic or light green stripes. Mosaic in flowers can give color breaking. Other common symptoms include chlorosis of the leaves, vein clearing, and chlorotic or necrotic ringspots. The most common growth abnormality is stunting; viruses can also cause deformation of leaves, swelling of the stem, and even outgrowths on the underside of leaves. All of these result in reduced yield quality or quantity.^[1]

At the cellular level virus infection often causes perturbation of chloroplasts (associated with mosaic symptoms) and disruption or proliferation of membrane

systems such as the endoplasmic reticulum. Virus gene products often accumulate to give characteristic inclusion bodies (e.g., the pinwheel structures of infections with *Potato virus Y potyvirus* (PVY) and related viruses).

DIVERSITY, COMPOSITION, AND REPLICATION

Most RNA viruses have positive-sense single-stranded genomes ((+)-sense ssRNA) (Table 1); the remainder have either negative-sense single-stranded ((-)-sense ssRNA) or double-stranded RNA (ds-RNA). These viruses are classified into genera based on their genome properties, together with characters such as particle shape and biological vectors. Some of the genera with important characters in common are grouped into families. The (-)-sense RNA and dsRNA viruses are closely related to groups of viruses that infect insects and vertebrates.

The particles of most (+)-sense ssRNA viruses are simple, comprising the RNA genome surrounded by subunits of usually a single species of coat protein. There are two basic particle types. In rod-shaped particles, the coat protein subunits are arranged in a helix with the RNA embedded between them. The particles can be either rigid or flexible with a length and diameter characteristic of the genus or family. Rigid particles (e.g., *Tobacco mosaic virus* (TMV) (300 × 18 nm)) range from less than 100 nm to a few hundred nm in length and flexuous particles from a few hundred to almost 2 microns (e.g., PVY (750 × 13 nm) and *Citrus tristeza closterovirus* (CTV, 2000 × 12 nm)). The structure of isometric spherical particles is based on icosahedral symmetry, with particles usually comprising 180 protein subunits and having a diameter of 25–30 nm (e.g., CMV); the particles of some viruses, e.g., *Tobacco necrosis satellite virus*, are smaller (ca. 18 nm) and comprise 60 subunits. Some viruses, e.g., *Alfalfa mosaic alfamovirus*, have bacilliform particles (25–60 × 18 nm), the structure of which is based on the principles of icosahedral symmetry. The RNA in isometric particles is usually associated with the inner part of the subunits or even with the inner cavity of the particle.

Table 1 Genomes of RNA plant viruses

Genome	No. of species	No. of genera	No. of families
+ -sense ss RNA	635	49	7
- -sense ss RNA	100	5	2
Ds RNA	45	6	2

The plant (–)-sense ssRNA viruses have more complex particles made up of protein and lipid and are either spherical (genus *Tospovirus*) or bacilliform (family *Rhabdoviridae*) in shape. The dsRNA viruses also have complex isometric particles comprising two or more layers of different coat protein species.

Many (+)-strand ssRNA viruses, e.g., TMV and PVY, have undivided genomes. However, one unusual feature of other (+)-strand ssRNA viruses is that the genome required for full infection is divided between two and five segments that are packaged into different particles. Thus, the genome of CMV is divided into three segments, each packaged in a separate isometric particle, and that of *Beet necrotic yellow vein benyvirus* (BNYVV) is divided between five rod-shaped particles. The genomes of many (–)-sense ss and ds RNA viruses are divided between several segments, but these are all packaged in the same particle.

RNA viruses replicate by transcribing RNA from RNA. Thus, (+)-strand ssRNA viruses transcribe a (–) strand from the viral template, which in turn is transcribed to give progeny (+) strands. Similarly, (–)-strand ssRNA and dsRNA viruses replicate via a (+)-strand intermediate. Replication is effected by a virus-coded RNA-dependent RNA polymerase (RdRP). The replicase complex comprises RdRP and often a helicase that unwinds double-stranded intermediates and a methyltransferase that caps the 5' end of the (+) strand.

The genomes of RNA viruses encode the information for virus replication and contain genes for usually five to seven proteins. Those viruses with undivided genomes are faced with the problem of eukaryotic translation systems being able to express only the 5' open reading frame (ORF). The input RNA of (+)-strand ssRNA viruses acts as an mRNA expressing the genetic information of the virus and giving early virus products such as the RdRP and associated enzymes, the ORFs of which are usually at the 5' end of the genomic RNA. Downstream ORFs are expressed by processes such as readthrough of stop codons, frameshift from the reading frame of the 5' ORF, and formation of subgenomic mRNAs during RNA replication. These subgenomic RNAs usually encode late products, e.g., coat protein. The segmentation of the RNAs in divided genome viruses results in most of the

ORFs being 5', thus overcoming the eukaryotic translational constraints.

mRNAs must be transcribed from the viral genomes for expression of the viruses with (–)-strand and ds RNA genomes. The particles of these viruses contain RdRP, which is used in the early stages of infection to produce mRNAs.

RNA PLANT VIRUS TRANSMISSION

Plant viruses must spread among sedentary plant hosts. As viruses lack self-motility, they are dependent on other means for moving from plant to plant; virus movement is effected in several specific ways. By far, the majority of plant viruses are spread by specific, plant-feeding arthropod vectors, mainly Homopteran insects, in particular, aphids; others include leafhoppers, planthoppers, and whiteflies. Some viruses are transmitted by non-Homopterans such as mites, thrips, and beetles. Whereas dispersal by insect vectors is the most common means, a few plant viruses are soilborne, being transmitted by root-feeding nematodes or unicellular, root-infecting fungi.

The ability of a virus to be vector transmitted is determined by specific interactions between the virus and the corresponding vector. However, even among the aphid-transmitted viruses a number of types of interactions exist and significantly affect disease epidemiology. For example, rapid short-distance virus spread is typical for noncirculative aphid-transmitted viruses, whereas circulative viruses that are borne internally within the vector can sometimes be transmitted for the life of the vector. Thus, for the latter, long-distance spread is quite possible.

CONTROLLING RNA VIRUS INFECTIONS OF PLANTS

Viruses are molecular intracellular obligate parasites. As such, they are dependent on their hosts' normal cellular machinery for aspects of their replication and gene expression. Because virus activities are so intimately associated with those of the host cell, opportunities are not readily available for using chemicals (viricides) to interfere with virus infections without also adversely affecting normal host cell metabolism. The most effective approaches for controlling RNA plant virus infections are to avoid or prevent infections.

Avoiding or eliminating sources of virus inoculum is essential for virus disease control, especially if the virus is contained within propagation materials, including seeds or vegetative cuttings. Most woody species (e.g., grapes, roses, fruit trees) are propagated vegetatively and thus, the

simple approach of ensuring that propagation sources are virus-free can provide effective disease control. Many RNA plant viruses such as CTV have been disseminated worldwide by using virus-infected propagation materials. Some viruses are seedborne in crop hosts or in weeds. Both types of host plants can be important for dissemination and subsequent disease development, but if seedborne virus in the crop host is an important source of primary inoculum, then planting seed that is virus-free can provide effective disease control (e.g., lettuce seeds free of *Lettuce mosaic potyvirus* (LMV)). Although eliminating virus inoculum can be very effective, it is not this simple for most plant virus diseases.

Because most plant viruses are transmitted to plants by specific vectors, vector control can also be useful. However, vector control is often expensive and inefficient and may adversely affect non-target organisms. Also, because many RNA plant viruses (particularly those in the genus *Potyvirus*) can be inoculated to plants by their aphid vectors in as little as a few seconds, protective insecticide applications cannot kill aphids before viruses are transmitted, thereby failing to provide disease control.

Host plant resistance (HPR) is a common and often most desirable means for controlling virus diseases in plants. Several important sources of genetic resistance have been identified and are used in crop plants, including beans, tobacco, potatoes, and tomatoes. Although HPR is very desirable and can be very effective (i.e., *N* gene resistance in *Nicotiana* spp. to viruses in the genus *Tobamovirus*), there are limits to its usefulness. For example, *N* gene resistance is specific, and thus effective against most tobamoviruses but not against unrelated viruses. Although the *N* gene can be transferred among related *Nicotiana* spp. by conventional plant breeding, it cannot be similarly transferred to unrelated species lacking effective resistance genes (i.e., cowpeas (*Vigna unguiculata*) for *Sunnehemp mosaic tobamovirus*). In other instances, HPR may be multigenic, and can be very difficult to effectively manipulate.

In recent years genetically engineered resistance has been shown to be a powerful, and potentially very useful, alternative strategy that can complement other approaches to controlling virus diseases in plants. A good source of antiviral resistance genes has proven to be the viruses themselves. By expressing in plants, genes, or gene

fragments derived from RNA virus genomes, very high levels of resistance against the donor virus have been obtained. This approach has worked experimentally for many different viruses in several plant species, although only a few genetically engineered virus-resistant plants have been used so far in commercial agriculture. One good example is resistance in papaya (*Carica papaya*) to *Papaya ringspot potyvirus* (PRV) in Hawaii.^[2] The use of genetically engineered resistance so far appears very promising for complementing other approaches to virus disease control in plants.

CONCLUSION

Virus infections continue to be a serious constraint on crop production in spite of the wide range of control measures in use. The application of new technologies such as genetic manipulation and genomics should lead to more successful ways of controlling viruses. These will be of particular importance in developing countries where losses due to viruses are relatively great.

The study of the interaction of plant viruses with their hosts has already led to greater understanding of how plants function at the molecular level. With the increasing sophistication of molecular technologies, it is likely this will continue at an ever increasing rate. RNA viruses will play a major role in this, especially in understanding defense systems against foreign RNAs.^[3]

Plant Variety Protection in the United States

Janice M. Strachan

*Plant Variety Protection Office, United States Department of Agriculture,
Beltsville, Maryland, U.S.A.*

INTRODUCTION

The U.S.A. has several types of intellectual property rights that apply to plant cultivars or varieties. Plant Variety Protection (PVP) is handled by the U.S. Department of Agriculture (USDA), PVP Office. A PVP is similar to plant breeders' rights in other International Union for the Protection of New Varieties of Plants [known by its French acronym (UPOV)] countries; however, in U.S.A., eligibility for PVP is limited to seed- or tuber-reproduced plant varieties. Varieties need to be new, distinct, uniform, and stable to be granted a PVP Certificate. Once granted, the breeder has exclusive marketing rights for a limited time. This allows breeders to recover the costs of research and development, and encourages them to reinvest in agricultural breeding work.

APPLICATION FOR PVP

Plant breeders may take 10–15 yr to develop a new plant variety, but the variety's market life can be as short as 2–5 yr. Breeders, and the companies they work for, use intellectual property rights protection to control the marketing of their new varieties. This extends the period in which the owner can benefit from having developed the variety, thus allowing for potential recovery of their research and development costs.

If the variety is sexually reproduced or tuber propagated, the breeder may apply for PVP. "Tuber" is used in its most strict botanical sense, examples of which include potato, anemone, caladium, and oxalis. Inbred lines, open-pollinated or self-pollinated varieties, synthetic populations, hybrids, and genetically modified plants are eligible for PVP, but bacteria and fungi are excluded.^[1] For vegetatively reproduced plant species, there are other means of protection such as plant patents administered by the U.S. Patent and Trademark Office. Please read elsewhere for information about other forms of protection.

In the application, the applicant must demonstrate that the variety is new, distinct, uniform, and stable. These are the same standards used by UPOV.^[2] The applicant is responsible for conducting the tests for distinctness, uniformity, and stability (DUS), analyzing

the data, and reporting information to the PVP Office. Examiners base their decisions on the information contained within the application. Unlike some other UPOV member countries, no site visits or government testing are performed in U.S.A. Therefore, the completeness and quality of the application is important to the decision-making process.

An application consists of three parts: paperwork, fees, and a voucher seed sample.^[3] The paperwork has six sections. Necessary forms can be obtained from the PVP Office, which also can offer advice and guidance in preparation of an application. The application form serves as a cover sheet for the application. The form requests such information as name of the applicant, whom to contact during processing, the identity of the crop and variety, administrative details, and whether the variety is new. To establish that the variety is new, the applicant must indicate that the variety, or a hybrid produced from it, has not been exploited for more than one year in U.S.A. or more than four years in a foreign country (or six years in a foreign country in the case of a vine or tree). The applicant signs at the bottom of the form to attest to the truthfulness of all reported information.

Exhibit A contains a full description of the breeding history of the variety. The variety should be "finished" when the applicant applies for protection. There should be no further need for cleaning up the variety, doing further generations of selections, or otherwise changing the genetic composition of the variety.

Toward the end of the Exhibit A, the applicant needs to state whether the variety is uniform and stable, and how this was determined. Uniformity must be considered for the variety as a whole, not just for the traits of interest. For example, being uniform for herbicide tolerance would not be acceptable if all other traits of the plants were excessively variable. A finished variety should be stable over the course of maintaining the variety through repeated generations of reproduction. So, stability should be tested by maintaining the finished variety through three or more generations.

In the Exhibit A, applicants are required to include a statement about known or expected genetic variants. There should be no off-types, other species, or other varieties contaminating the seed stock, because these should have been removed during the breeding and

cleaning processes. There should be very few genetic variants expected when the variety is reproduced over time, and the level of purity that is acceptable depends on the specific breeding method that was used. Some breeding methods can produce almost homozygous seeds, given enough generations of selfing and selection. Other methods cannot attain such a high level of purity, and perhaps as much as 5% genetic variants may be considered acceptable in these cases.

In addition to the statements made in the Exhibit A concerning uniformity, stability, and variants, the examiner will study the rest of the application to determine whether the variety is sufficiently uniform and stable for the reproductive method used to create the variety and maintain it over time. Mixtures and blends, by their very nature, are not uniform or stable. Special circumstances govern the uniformity of hybrids and synthetic varieties, for which there is not sufficient space in this entry to describe adequately.

Exhibit B contains the claims and supporting evidence for the distinctness of this variety. Several formats for this document are acceptable, but the easiest format is one in which the new variety is compared to one or a few most similar comparison varieties. The applicant then states how the application variety differs from the most similar varieties, using objective data to support the claims. Supporting data may include statistical analyses for quantitative differences; color chart values for color differences; photographs for qualitative differences; biomolecular assays showing presence or absence of genes, proteins, or enzymes; laboratory test results; genetic fingerprints; or other types of verifiable test results. The claims and data contained in Exhibit B are heavily scrutinized, because this document provides much of the evidence used to make a final decision about DUS for the application variety.

The Exhibit C form is used to objectively describe the application variety. The PVP Office has created over 100 crop-specific objective description forms. New forms are created if the form is expected to be used regularly in the future. A general form for use with any species has been developed to accommodate first applications in crops that are new to the PVP Office.

Exhibit D is an optional document used for additional description of the variety. Applicants have used this section of the application to report extensive statistical analyses, genetic fingerprinting, or agronomic performance information.

The Exhibit E form guides the applicant in attesting to the breeder's ownership and eligibility to apply for PVP. If the rights to the variety have been transferred to another person or company, the ownership changes need to be explained. Eligibility requirements include the nationality of the applicant. US citizens, residents, and companies, or citizens, residents and companies of

other UPOV member countries are eligible to apply for PVP in U.S.A. Applicants from countries that are not UPOV members may apply; however, they must first demonstrate reciprocity with a *sui generis* law which grants intellectual property rights to plant varieties. Ninety percent of applicants are from U.S.A., of which 15% are from US public institutions such as universities or government agencies (Fig. 1). Only 10% of applications are received from foreign applicants.

The PVP Office is completely user-fee funded. Fees collected from applicants and other users of services are used to pay salaries, rent, supplies, and other costs of doing business. The fee schedule is available in the PVP Act's Regulations^[4] or on the PVP Web site.^[5] The fees for filing and examining the application must accompany the application packet.

A voucher seed sample is required for all seed-reproduced application varieties at the time of filing the application. There is a new procedure for direct deposit of the seeds in the approved seed repository. When using the direct deposit option, applicants will be asked to supply the seed sample within 3 mo after the filing date of the application. Tissue cultures for tuber-propagated varieties need to be provided at the time of issuance of the PVP Certificate. The seeds and cultures are stored at the National Center for Genetic Resources Preservation in Fort Collins, Colorado, U.S.A.^[6] A phytosanitary certificate is required for samples that are imported into U.S.A.

Processing of Applications

Applications are reviewed for completeness and internal consistency. Descriptive data is entered into crop-specific data tables to allow examiners to search for previously existing varieties that may prevent issuance of the certificate. The examiner will correspond with the applicant to clarify information contained in

Fig. 1 Nationality of Plant Variety Protection applicants. Most applicants (75%) are US companies or individuals, often referred to as the private sector. The public sector (universities and government) accounts for 15% of applications. (From PVP Office data). (View this art in color at www.informaworld.com.)

the application or acquire missing information. Once the applicant has demonstrated that the variety is new, distinct, uniform, and stable, the examiner writes a report, which includes a recommendation that a certificate of protection be issued. The work of the examiner is reviewed and approved by the PVP Commissioner. Certificates are signed by the PVP Commissioner and the Secretary of Agriculture (Fig. 2).

Essentially derived varieties were given legal status in the 1991 UPOV Convention. PVP examiners do not consider whether a variety is essentially derived from another variety when making their decisions to grant PVP Certificates. The only criteria considered are whether the variety is new, distinct, uniform, and stable.

A PVP Certificate grants the owner exclusive marketing rights for 20 yr (25 yr in the case of trees and vines). These rights cover harvested material of the variety, varieties that are indistinct or essentially derived from the variety, and varieties that require

repeated use of the protected variety. There are two exemptions to these rights: one allows farmers to save seed of the protected variety for use in their own farm; the second allows researchers to use the protected variety in plant breeding or other research.

The PVP Office receives approximately 300 new applications a year. The majority of applications are for agricultural crops such as soybean, maize, and wheat (Fig. 3). Applications are assigned to one of seven examiners, who have expertise in their assigned crops and who make the decisions whether to grant PVP Certificates. They are assisted by three support persons, who handle data entry and routine correspondence, and a computer specialist, who maintains the computer resources. The office is supervised by the PVP Commissioner who has responsibility for the quality and completeness of the examiners' decisions.

The total time needed to process an application depends on the quality and completeness of the application, and the amount of time needed for literature research and updates to the data tables. Seventy-seven percent of applications are processed in less than 36 mo. Applications of higher quality can be processed faster, and poorer quality applications take more time (as much as 10 yr). The longer times often indicate multiple opportunities when the applicant was asked to amend the application to establish that the variety was new, distinct, uniform, and/or stable.

Typically, 84% of applications result in the grant of a PVP Certificate (Fig. 4). Most of the remaining applications are either abandoned or withdrawn by the applicant. Rarely is an application denied (18 applications; average processing time was 61 mo) or declared ineligible (75 applications; average processing time was 19 mo). Ineligibility is often based on the variety not being new or the applicant not being eligible. Denial is usually based on the variety being indistinct from previously existing varieties. A few denials were based on non-uniformity or instability of the variety.

Fig. 2 An issued PVP Certificate. The certificate includes copies of the application paperwork permanently affixed inside the folder with rivets. Signatures of the PVP Commissioner and the U.S. Secretary of Agriculture are evident behind the green ribbon and gold seal. (Photo Courtesy of Dr. Paul Zankowski, PVP Commissioner.) (View this art in color at www.informaworld.com.)

Fig. 3 Types of crops that are filed for PVP. Agricultural crops, such as maize, soybeans, and wheat, account for 75% of PVP applications of the 300 applications received each year. Tubers became eligible for PVP in 1995. (From PVP Office data.) (View this art in color at www.informaworld.com.)

Fig. 4 Final disposition of PVP applications. Most PVP applications are issued a certificate of protection. Nineteen percent of applicants decide to abandon or withdraw their applications. Only 1% of applications are denied or declared ineligible. No PVP Certificate has been overturned in a court of law. (From PVP Office data.) (View this art in color at www.informaworld.com.)

CONCLUSIONS

PVP provides a unique form of intellectual property rights specifically designed for plants. It incorporates the legal criteria established by UPOV, and the examination process mimics patent examinations. The technical review of applications focuses on the scientific details of the development and description of the variety, which makes the application preparation meaningful for plant breeders and scientists. The rights granted

by a PVP Certificate allow the owner of the plant variety to recover research and development costs by controlling the marketing of the variety.

Plant Viral Synergisms

John L. Sherwood

University of Georgia, Athens, Georgia, U.S.A.

INTRODUCTION

Synergism is one of the many interactions that may occur between viruses that affects both the expression of disease and the replication of the viruses involved. In medical virology the occurrence of synergism is relatively rare, as the occurrence of two viruses in vertebrate cells is rather uncommon outside of laboratory cell culture. With plant viruses, however, the phenomenon of synergism has been noted since the early days of plant virus research in the 1920s. Synergism was intermittently studied until the tools of molecular biology became available to dissect this interesting virus interaction. Posttranscriptional gene silencing is now thought to modulate the virus replication and accumulation resulting in a synergistic interaction between plant viruses.

INTERACTIONS BETWEEN PLANT VIRUSES

A number of interactions may occur between plant viruses.^[2] Cross-protection refers to the protection of a plant by a mild strain of a virus from a related severe strain. When plant viruses are inoculated concurrently, a protection may ensue that results from the reduction of replication rate or final quantity of the challenge virus. Satellite viruses or satellite RNAs require a helper virus to replicate, but generally satellites do not have much sequence homology with the helper virus. The symptomatic outcome is usually a reduced severity of disease, although there are many exceptions involving satellites where in more severe disease symptoms are expressed. The outcome of a synergistic interaction between plant viruses, however, is by definition a more severe expression of disease than either virus alone or the expected additive effect produced by the infection of two viruses. In addition, the increase in symptom severity is usually associated with an increased accumulation of one or both of the coinfecting viruses.

SYNERGISTIC INTERACTIONS ARE NOT LIMITED TO A FEW VIRUSES

The literature is replete with examples of synergism between different plant viruses that include viruses with

genomes of RNA or DNA.^[3] Some interactions that have been noted are significant in the field, resulting in severe and recurring losses to producers; others are limited to the greenhouse; and some are laboratory oddities that have been produced by inoculation with viruses that normally would not be found in the same host plant. The model system that has been most frequently investigated is the interaction that occurs between *Potato X virus* (PVX), a species in the *Potexvirus* genus, and *Potato Y virus* (PVY), a species in the *Potyvirus* genus, family *Potyviridae* (Fig. 1). PVX and PVY were noted to cause a severe symptom in potato coined “crinkle,” “rugose mosaic,” and “streak.”^[4] Initial investigations of this system elucidated that both viruses replicated in the same cells, and an increase in the amount of PVX detected was likely due to an increase in the amount of virus produced.^[5] PVX has no allegiance to PVY in producing a synergistic interaction, and coinfection with a number of Potyvirus species (including *Tobacco vein mottling virus* (TVMV), *Tobacco etch virus* (TEV), or *Pepper mottle virus*) all result in a synergistic manifestation of disease.

A CONVERGENCE OF IDEAS LEADS TO INSIGHT INTO THE MECHANISM OF SYNERGISM

Gene Silencing

With the advent and common availability of methodology and reagents for gene cloning and plant transformation, a myriad of transgenic plants was produced with a variety of virus gene constructs, with the goal of overexpression of the gene of interest. In many of the experiments, however, the outcome was the opposite of what was anticipated, and gene expression was suppressed. A number of terms have been used in the literature to describe this phenomenon, including cosuppression, RNA interference (RNAi), post-transcriptional gene silencing (PTGS), sense suppression, quelling, and virus-induced gene silencing (VIGS).^[6] Double-stranded RNA (dsRNA) is a key component of the proposed pathway by which RNA silencing occurs, and dsRNA is a key component during replication of RNA plant viruses. RNA silencing has been extensively reviewed^[6,7] and will therefore be only briefly treated

Fig. 1 Synergism between *Potato X virus* (PVX), a species in the *Potexvirus* genus, and *Potato Y virus* (PVY), a species in the *Potyvirus* genus, family *Potyviridae*. Leaf at left was inoculated with PVY; leaf at right was inoculated with PVX; middle leaf was inoculated with both PVY and PVX. Photo taken 12 days after inoculation. (Photo by A. F. Ross, courtesy of R. M. Goodman.) (View this art in color at www.dekker.com.)

here. RNA silencing is a naturally occurring mechanism of genetic regulation in eukaryotes that is directly targeted at nucleic acid. It can be induced by viruses, transgenes, or the transcripts normally produced in the plant that result in the formation of dsRNA. The dsRNA is acted upon by an enzyme coined DICER that processes the dsRNAs into short (approximately 25-nucleotide) RNAs. The small interfering RNAs (siRNA) derived from the processing of the dsRNA enters into a RNase complex, RISC (RNA interference specificity complex), that further mediates sequence-specific RNA degradation. Associated with gene silencing is a mobile signal that may move throughout the host plant and hence act as the systemic signal in gene silencing. It has also been noted in plants that methylation of the transcribed region is

associated with gene silencing, a state that may be recurring in subsequent generations of an affected organism and may be the basis for maintaining the gene silencing.

This system is of great interest because the silencing signal can function in other points in the plant wherein the cascade of events was initiated. The unfolding understanding of the parameters that modulate RNA silencing provides an exciting avenue for the regulation of gene expression, from transgenes or endogenous genes.

***Potyvirus* and *Potexvirus* Genomes**

Virions of the members of the Family *Potyviridae* are a long, flexuous particle whose size ranges from 650–900 nm in length and 11–15 nm in diameter. Most have a single-stranded plus-sense RNA that codes for one polyprotein that is cleaved into a number of proteins. The replication strategy and viral genome are well characterized, as the order of the proteins in the polyprotein and their function have been extensively studied.^[2] The 5' terminus encodes protease-1 (P1, molecular weight 35K), helper component protease (HC-Pro, molecular weight 52K), and protein-3 (P3, molecular weight 50K). P1 is involved in the processing of the polyprotein, as is HC-Pro, which is also involved in transmission of the virus by aphids. Virions of the genus *Potexvirus* have flexuous particles about 470–580 nm long and 13 nm in diameter. The viral RNA is a single-stranded plus-sense RNA. However, unlike members of the Family *Potyviridae*, one protein—the replicase—is produced from the genomic RNA for members of the genus *Potexvirus*; other proteins are produced from subgenomic RNAs that are produced during virus replication.

Synergism

To elucidate the nature of interaction between PVX and members of the *Potyviridae* that result in a synergistic interaction, tobacco was transformed to express a variety of portions of the genome if TVMV or TEV were challenge-inoculated with PVX. Transgenic plants expressing the 5'-proximal region of the TVMV genome that included the P1, HC-Pro, and P3 genes were challenged with PVX, resulting in symptoms typical of the PVX-*Potyviridae* synergism. Typical synergistic symptoms were also observed when transgenic tobacco plants expressing the similar 5'-proximal region of the TEV genome were inoculated with PVX. Hence, the interaction was linked to the 5'-proximal end of the potyvirus genome. Subsequent investigations showed that the P1 and P3 regions were not necessary for the synergistic symptoms to be produced, as expression of HC-Pro alone could facilitate the synergistic interaction.^[8] In addition, expression of HC-Pro was found to enhance the

accumulation of *Cucumber mosaic virus* and *Tobacco mosaic virus*. These viruses are unrelated to PVX; thus HC-Pro appears to act to enhance virus replication irrespective of the infecting virus.

The enhancement of virus replication in the synergistic interaction appears to result from the suppression of gene silencing. During unaltered virus replication as dsRNA is produced, the natural defense mechanisms of plants likely modulate the accumulation of virus through PTGS as briefly outlined in the foregoing. As the dsRNA are not processed, resulting in the production of the siRNAs necessary for the degradation complex, the resulting accumulation of PVX appears to result in the synergistic interaction and severe symptoms.^[9] Grafting experiments indicate that the mobile silencing signal continued to be produced, and thus is not dependent on the production of the small RNAs.

CONCLUSION

Although the possible basis of synergism has been partially unveiled, there remains much to understand about the applied aspects mitigating the effects of synergism in the field. The epidemiological consequences synergism has been modeled, and viruses sharing an infected host may be in a perplexing ecological dilemma.^[10] Increased symptom severity can result in reduced availability of the host, whereas increased replication and increase in virus titer may represent greater opportunity for subsequent transmission. In regard to disease management, severe symptom expression is generally accompanied by loss of plant yield and quality. Hence, the basis of synergism must be determined so that it can be effectively managed to address recurring problems.

Plant Virus Nomenclature and Taxonomy

Edward P. Rybicki

Department of Molecular and Cell Biology, University of Cape Town,
Cape Town, South Africa

INTRODUCTION

Plant virus taxonomy has been perhaps the only area of the science of virus systematics where most of the rules of the International Committee on Taxonomy of Viruses (ICTV) are followed. In fact, plant virologists have led the way a number of times in the last 40 years in establishing and testing criteria for virus systematics as a result of that cohesion, and the trend continues with the latest proposals for nomenclature. The result is a more or less uniform set of descriptive virus names, and an essentially unified set of criteria for determining familial, generic, and species membership. Inasmuch as taxonomy consists of classification plus nomenclature, the core criteria for assigning new plant viruses to a taxon, the latest consensus on nomenclature and orthography, and problems in plant virus taxonomy are described in this entry.

PLANT VIRUS CLASSIFICATION

Viruses are classified into taxonomic orders (suffix: *virales*), families (suffix: *viridae*), subfamilies (suffix: *virinae*), genera (suffix: *virus*), and species. The official publication of the ICTV on virus taxonomy—now the eighth report—lists 3 orders of viruses, 73 families, 9 subfamilies, 287 genera, and 1938 virus species. Of these, only 16 families (and no orders or subfamilies) contain plant-infecting viruses; 61 genera in these families, together with viruses from 17 unassigned genera, give a total of 797 recognized species of plant viruses. There are also two official families of the circular ssRNA viroids, with 7 genera and 28 species, as well as 4 satellite virus species. While there are no officially recognized satellite nucleic acid species, there are two ssDNA and ssRNA entities grouped into four distinct categories. The currently accepted list of plant virus families and genera, satellite viruses and viroids, as well as satellite nucleic acids are illustrated in [Table 1](#).^[1,2]

Families and Genera of Plant Viruses

The ICTV website (<http://www.ncbi.nlm.nih.gov/ICTV/>) lists the following as the criteria defining taxonomic families and genera.

Family: common properties between several genera including

- Biochemical composition.
- Virus replication strategy.
- Nature of the particle structure.
- Genome organization.

Genus: common properties within a genus including

- Virus replication strategy.
- Genome size, organization, and/or number of segments.
- Sequence homologies (hybridization properties).
- Vector transmission.

More detailed familial criteria are given at the ICTV website; these include many more specific properties such as type and strandedness of genome, number of genome segments, and number and size of proteins (<http://www.ncbi.nlm.nih.gov/ICTV/Descriptors.html>).

The exact criteria for any given genus are operationally defined on the basis of observations made by members of the defined ICTV Plant Virus Subcommittee Study Groups. For example, the study groups have had to make decisions on whether the number of genome components is more important than the type of vector which transmits the viruses, or, where there is a known vector, how much of a taxonomic criterion this is. While the number of genome components is a major criterion for potyviruses, for example, only generic bymoviruses have two components, while all other potyvirus genera have only one, there are several generic begomoviruses in family *Geminiviridae* which have one genome component while the rest have two.^[1]

Species of Plant Viruses

The concept of a viral species has long bedeviled the taxonomic virology community, largely because of the fact that viruses do not replicate like cellular organisms, and classical definitions simply did not fit. However, it is now accepted that “A virus species is a polythetic class of viruses that constitute a replicating lineage and occupy a particular ecological niche.”^[3] Operationally, defining a virus species is probably even more a family and genus-specific process than for

(Data from Dr. M. J. Adams, ICTV Plant Virus Subcommittee, Rothamsted Experiment Station, BBSRC, U.K.)

defining genera. For example, in the *Geminiviridae* species demarcation criteria are as follows:

- Different numbers of genome components.
- Different organization of genes in the genome.
- No transcomplementation of gene products.
- No pseudorecombination between components.
- Nucleotide sequence identity (<75% for mastreviruses, <80% for curtoviruses, and <90% for begomoviruses).
- Virions react differently with key antibodies.
- <90% coat protein gene sequence identity.
- Different vector species.
- Different host range/pathogenicity.^[4]

Note that in genus *Begomovirus*, a viral species is defined as a virus having at most 89% total DNA sequence similarity to any other defined species, whereas in genus *Mastrevirus*, the difference in a species may be as large as 25%, given a more similar biology between these viruses than between begomoviruses, and greater potential for *trans*-replication across the sequence divide. Thus, the same criteria are not rigidly applied across genera, and a balance may be struck between sequence-defined and biologically defined properties.

PLANT VIRUS NOMENCLATURE AND ORTHOGRAPHY

Rule 3.40 of the International Code of Virus Classification and Nomenclature reads: “Species names are printed in italics and have the first letter of the first word capitalised. Other words are not capitalised unless they are proper nouns, or parts of proper nouns.”^[3] This format is, however, used only when referring to an official taxonomic entity, or taxon—otherwise one would refer to, for example, “tobacco mosaic virus replicase,” or “purification of cucumber mosaic virus.”^[5] When writing a paper, it has become a convention to initially define the viruses one works with by familial, generic, and species definitions, and thereafter by acronym or by common name. As an example, a particular geminivirus would first be referred to in text as belonging to species *Bean golden mosaic virus-Puerto Rico* (BGMV-PR; genus: *Begomovirus*, family: *Geminiviridae*), and thereafter called BGMV-PR or simply BGMV. A comprehensive list of plant virus names and abbreviations is given in Refs.^[1,6]

PROBLEMS IN PLANT VIRUS TAXONOMY

With the increasing ease of DNA sequencing have come an explosion in complete genome sequencing of plant viruses and an increase in reliance on the use of sequence rather than on more classical properties to classify them.

The use of sequence has allowed genetic distinctions to be made between viruses that otherwise apparently share biological properties, to the point of being almost indistinguishable. Among begomoviruses in the species *Tomato yellow leaf curl virus* (TYLCV), for example, *Tomato yellow leaf curl Sardinia virus* (TYLCSV) and *Tomato yellow leaf curl Thailand virus* (TYLCTV), all cause similar disease, but are genetically distinct, and, in the case of TYLCTV, have two genome components rather than one.^[4] This has led to a problem of naming viruses that may have been called the same thing or strains of one species, but are later shown to be distinct species. For example, *East African cassava mosaic virus* (EACMV) was so named to distinguish it from *African cassava mosaic virus* (ACMV) after sequencing revealed the distinction; later, a necessity arose to similarly distinguish *East African cassava mosaic Tanzania virus* and *EACM Malawi virus* from each other and from EACMV.^[4] This may prove difficult to do in future, and new rules may be needed for naming of species.

CONCLUSIONS

As with all virus taxonomy, plant virus systematics is a work in progress: it will change from year to year, and may change radically without warning. However, it remains a system of rules which is amenable to suggestion, while at the same time striving to offer logical ways to order a very varied group of organisms.

Plant Virus Replication

M. Shanks

G. P. Lomonosoff

John Innes Centre, Norwich, United Kingdom

INTRODUCTION

Viruses are important causative agents of plant disease. Although crop losses due to viruses are difficult to quantify, it has been estimated that damage caused by a single viral disease, the “Tungro” disease of rice, costs in the region of US\$1.5 billion per year in Southeast Asia alone. In plants, as in prokaryotes and animals, there is a wide diversity of viruses in terms of the host range, their mode of infection, morphology, etc. Although it is possible to classify viruses according to these characteristics, it has become increasingly apparent that the fundamental nature of a virus is best described in terms of its mode of replication rather than its phenotypic properties. In this section we review the replication strategy of all currently known plant viruses and highlight their classification based on the “Baltimore scheme.”

THE BALTIMORE CLASSIFICATION SCHEME OF VIRUSES

A virus is an organism that contains genetic material surrounded by a protein shell and, in some cases, a lipid envelope. All viruses are intracellular parasites and have an absolute dependence on the host. Whereas host cells exclusively have double-stranded DNA as their genetic material, viruses can have genomes consisting of either DNA or RNA, and this, in turn, can be either single- or double-stranded. This variation has led to a scheme, known as the “Baltimore scheme” (after its originator David Baltimore). This scheme classifies all viruses, regardless of host or particle morphology, according to their genome structure and mode of replication. The basis of the classification scheme is that it attaches central importance to the stage in the viral replication cycle where messenger RNA (mRNA) is synthesized. In its original form, the Baltimore scheme recognized six classes of viruses, but this has been subsequently revised to include a seventh. Classes 1 and 2 consist of viruses which have DNA genomes and which replicate through DNA intermediates. Classes 3, 4, and 5 consist of viruses with RNA genomes which replicate through RNA intermediates, while classes 6 and 7 contain viruses which

incorporate both DNA and RNA stages in their replication cycles.

Table 1 lists the families and genera of plant viruses classified according to the revised Baltimore scheme. All the names used are as agreed by the seventh report of The International Committee on Taxonomy of Viruses (ICTV^[2]).

REPLICATION STRATEGIES USED BY PLANT VIRUSES

Class 1

Class 1 consists of viruses that have double-stranded (ds) DNA genomes and which replicate via the classic semiconservative method. Somewhat surprisingly there are no plant viruses within this class, although over 20% of plant virus genera have genomes based on DNA rather than RNA. By contrast, class 1 accounts for over 75% of the virus genera found in bacteria (including the T-even and lambda phages of *Escherichia coli*) and 26.5% of viruses in higher animals (e.g., the pox and herpes viruses^[3]). Under the original Baltimore classification scheme, the *Caulimoviridae* family was assigned to class 1. However, it was subsequently found that this family of viruses, although encapsidating ds DNA, replicates through a mechanism involving an RNA intermediate and a new class had to be created to accommodate them (class 7, see below).

Class 2

Class 2 encompasses those viruses which encapsidate single-stranded (ss) DNA. The replication of these viruses requires the formation of a “replicative-form” (RF) ds DNA intermediate soon after infection. It is from the RF DNA that the virus-specific mRNA is transcribed (Fig. 1). There are two families of class 2 type virus which contain plant-infecting genera, the *Geminiviridae* and the *Circoviridae*. The *Geminiviridae* have circular ss DNA genomes of a total size of 2.7–5.4 kb depending on whether they are mono- or bicomponent viruses. The DNA is replicated by the rolling-circle mechanism. The

Table 1 Viruses that multiply in plants classified according to the Baltimore scheme

Class 1: Viruses with ds DNA genomes
None

Class 2: Viruses with ss DNA genomes
Family: *Circoviridae*; genus: *Nanovirus*
Family: *Geminiviridae*; genera: *Curtovirus*, *Masterovirus*, *Begomovirus*

Class 3: Viruses with ds RNA genomes with a virion-associated RNA-dependent RNA polymerase
Family: *Partitiviridae*; genera: *Alphacryptovirus* and *Betacryptovirus*
Family: *Reoviridae*; genera: *Fijivirus*, *Oryzavirus*, *Phytoreovirus*
Genus: *Varicosavirus* (not assigned to a family)

Class 4: Viruses with positive-sense ss RNA genomes

a) Isometric particles
Family: *Comoviridae*; genera: *Comovirus*, *Fabavirus*, *Nepovirus*
Family: *Luteoviridae*; genera: *Enamovirus*, *Luteovirus*, *Polerovirus*
Family: *Sequiviridae*; genera: *Sequivirus*, *Waikavirus*
Family: *Tombusviridae*; genera: *Aureusvirus*, *Avenavirus*, *Carmovirus*, *Dianthovirus*, *Machlomovirus*, *Necrovirus*, *Panicovirus*, *Tombusvirus*
Genera not assigned to a family: *Idaeovirus*, *Marafivirus*, *Sobemovirus*, *Tymovirus*, *Umbravirus*
Family: *Bromoviridae*; genera: *Alfamovirus*, *Ilarvirus*, *Bromovirus*, *Cucumovirus*, *Oleavirus*

b) Rod-shaped particles
Genera (not assigned to a family): *Benyvirus*, *Furovirus*, *Hordeivirus*, *Ourmiavirus* (bacilliform), *Pecluvirus*, *Pomovirus*, *Tobamovirus*, *Tobravirus*

c) Flexuous rods
Family: *Closteroviridae*; genera: *Closterovirus*, *Crinivirus*
Family: *Potyviridae*; genera: *Potyvirus*, *Ipomovirus*, *Macluravirus*, *Rymovirus*, *Tritimovirus*, *Bymovirus*
Genera not assigned to a family: *Allexivirus*, *Capillovirus*, *Carlavirus*, *Foveavirus*, *Potexvirus*, *Trichovirus*, *Vitivirus*

Class 5: Viruses with negative-sense/ambisense ss RNA genomes with a virion-associated RNA-dependant RNA polymerase
Family: *Bunyaviridae*; genus: *Tospovirus*, *Nucleorhabdovirus*
Family: *Rhabdoviridae*; genus: *Cytorhabdovirus*
Genera not assigned to a family: *Ophiovirus*, *Tenuivirus*

Class 6: Viruses with RNA genomes that replicate through an DNA intermediate
None

Class 7: Viruses with DNA genomes that replicate through an RNA intermediate
Family: *Caulimoviridae*; genera: *Caulimovirus*, *Badnavirus*

Adapted from Ref. [1].

family *Circoviridae* contains genera which infect both animals (circoviruses) and plants (nanoviruses). The nanoviruses have genomes that consist of 6–10 segments

of circular ss DNA, each of approximately 1 kb in size and encoding a single protein. The precise number of segments that make up a complete nanovirus genome is not clear.

Class 3

Class 3 consists of viruses that have ds RNA genomes. The process of transcription to produce the viral mRNAs is analogous to that from ds DNA. However, the enzymes necessary to carry out this process from an RNA template are missing in an uninfected cell. Thus this group of viruses must encode an RNA-dependent RNA polymerase (RdRp), which is packaged within the virion and is introduced into the host cell at the same time as the genome. There are two families of plant-infecting class 3 viruses, the *Partitiviridae* and the *Reoviridae*. Members of the *Partitiviridae* family have genomes consisting of two segments of linear ds RNA of 1.4–3.0 kb and exclusively infect plants. *Reoviridae* have multicomponent genomes (typically 10–12 segments of ds RNA) with all segments being encapsidated in a single shell. The total genome size is approximately 18–30 kbp. There are genera of the family *Reoviridae* which infect either animals or plants. The plant-infecting genera are able to replicate in their insect vectors.

Class 4

Class 4 viruses have genomes that consist of one or more segments of ss RNA of positive-strand (mRNA-sense) RNA. By far the largest proportion of plant viruses (65%) falls within this class. This class also has members which infect animals and bacteria. The RNA within the particles can immediately act as mRNA upon infection, and provided it can be delivered to appropriate cells, RNA isolated from virus particles is directly infectious. Upon uncoating, translation of the viral RNA using the host-encoded translation machinery rapidly ensues. One of the earliest products produced is the viral RdRp, which synthesizes complementary sense (so-called “minus-strand”) RNA using the viral (“positive-strand”) RNA as a template. A replication complex is then produced which maintains a balance between minus-strand, positive-strand, and double-stranded (i.e., – and + strand) RNA molecules. A bias in the complex favors the production of positive-strand molecules and synthesis of the viral structural proteins. The coat protein(s) and positive-strand RNA assemble, and mature virions are produced. At present 48 genera of plant viruses are classified as class 4. These include viruses which have either one or several genome segments, and particles which have either isometric or rod-shaped morphologies.

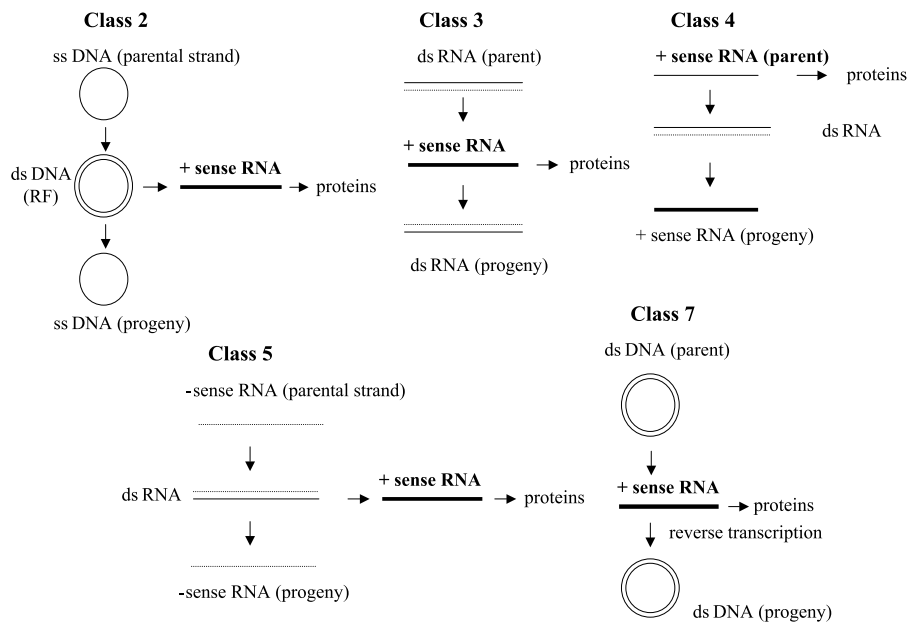

Fig. 1 Replication strategies used by plant viruses. The viruses are classified according to the revised Baltimore scheme, which attaches particular significance to the stage at which mRNA (thick line) is synthesized in the replication cycle. Only those classes that have plant-infecting members are shown.

Class 5

Class 5 viruses have genomes that consist of one or more segments of ss RNA that is of the complementary sense to the mRNA. RNA extracted from such “negative-strand” viruses is not directly infectious. On entry into a host cell, the virion RNA is transcribed by a virus-derived RdRp to give the mRNAs which can be translated to give the virus-specific proteins. In a manner similar to that found with class 4 viruses, a replication complex is formed, but in this case there is probably a bias for production of full-length positive-sense RNA and subsequent generation of genomic (negative-strand) RNA. There are two families (the *Bunyaviridae* and *Rhabdoviridae*) as well as some unassigned genera which infect plants. Both families also contain genera that infect animals. Members of the tospoviruses, the plant-infecting genus of *Bunyaviridae*, have tripartite genomes, whereas members of the *Rhabdoviridae* family are nonsegmented.

Class 6

This group contains viruses which encapsidate ss RNA molecules of positive (mRNA sense) polarity. However, unlike class 4 viruses, the RNA replicates via a ds DNA intermediate which becomes integrated into the host genome. While viruses of the family *Retroviridae* are extremely important animal pathogens, there are currently no class 6 plant viruses recognized.

Class 7

Viruses in class 7 encapsidate ds or partially ds DNA molecules and replicate via an RNA intermediate. They are known as “pararetroviruses” to distinguish them from retroviruses which encapsidate RNA. There are two families in this class, the *Hepadnaviridae* (which infect animals) and the *Caulimoviridae* (which infect plants). In the case of the *Caulimoviridae*, the ds circular genomic DNA is about 8 kb and is directly infectious. Once inside the nucleus of the host cells, the DNA is transcribed by a host-encoded RNA polymerase to produce positive-sense RNA. These molecules act as mRNAs for the synthesis of the virus-specific proteins and also as a substrate for the virus-encoded reverse transcriptase, to produce new copies of the genomic ds DNA. For many years it was believed that the genomes of the family *Caulimoviridae* did not integrate into the host genome. However, more recent work with the members of the genus *Badnavirus* has shown that integration does indeed occur and may play a significant part in the spread of the viruses.

CONCLUSION

This article has discussed the replication of plant viruses in terms of the “Baltimore scheme.” This is a simplified and unified approach which stresses the similarity between different viruses rather than their differences. It

has not been the purpose of this review to cover in great detail the genome structures or taxonomy of the various virus families and genera, which is comprehensively covered by the seventh report of the ITCV.^[2] Similarly, for further information relating to the general description of the plant viruses the reader is referred to the web-based databases that are available.^[4,5]

Plant Virus Transmission

Rose C. Gergerich

University of Arkansas, Fayetteville, Arkansas, U.S.A.

INTRODUCTION

In order for plant viruses to survive in nature, they must spread from infected plants to susceptible plants. Because plant viruses are unable to penetrate the protective layer (cuticle), viruses must be deposited into plant cells before infection can occur. Viruses may be introduced through a wound or from an infected plant through seed or pollen from the infected plant. The use of plant parts, such as tubers or stem pieces, from infected plants for vegetative propagation or grafting results in the spread of viruses to progeny and grafted plants. Many plant viruses depend on another organism, called a vector, which penetrates the cuticle of plants and acquires and transmits the virus during feeding. Vectors for plant viruses include invertebrates, such as aphids, whiteflies, leafhoppers, beetles, mites, and thrips, and nematodes and fungi. Viruses usually have only one type of vector under natural conditions, but a virus may spread by several means, e.g., by seed and aphid transmission. Transmission of plant viruses by various means is important to their dispersal and survival and plays a critical role in their epidemiology. Determining the means by which a plant virus spreads in the field is essential for development of effective disease management strategies.

MECHANICAL TRANSMISSION

Transmission of viruses by contact between infected and healthy plants is relatively rare in nature and occurs with only a few very stable viruses that reach high concentrations in plant cells. When an infected plant rubs against a healthy plant and causes a wound, sap from the infected plant can enter the wound and infect the healthy plant. *Tobacco mosaic virus* is readily transmitted from infected tomato plant debris to healthy tomato seedlings when the roots of seedlings are wounded during transplanting or as they grow in the soil. This stable virus is also readily transmitted on equipment and the hands of workers that have been in contact with virus-infected plants. Management of this type of transmission is through the use of clean soil and equipment and thorough hand washing.^[1]

SEED TRANSMISSION

Virus transmission through seed is an effective means for virus survival while a crop is not being grown and for establishment of virus-infected seedlings randomly throughout a field early in the season. Seed transmission of viruses is relatively rare in that only about 15% of plant viruses have been reported to be seed-transmitted in one of their hosts.^[2] The percentage of seeds from infected plants that give rise to virus-infected seedlings is usually small, although in some cases, 100% seed transmission has been reported. Even with low levels of seed transmission, extensive crop infection and economic loss may result if natural transmission by another means, such as with an insect vector, occurs during the growing season. Seed transmission is also a potential problem in the international spread of viruses through commerce of infected commercial seed.

Seed may become infected with virus through an infected mother plant or through pollen from a virus-infected plant. Seedlings from infected seed become infected in one of two ways: 1) the virus is found within the tissues of the embryo that gives rise to the seedling; 2) the virus is transmitted on or in the seed coat, and the growing embryo becomes infected during germination or transplanting. When infection of the seedling occurs from virus contamination of the seed coat, the virus can be eliminated by seed treatment with hydrochloric acid or trisodium orthophosphate.^[3] For viruses found in the embryo, the production and use of virus-free seed is an effective management strategy when seed transmission is the main or only source of the virus for the crop. A good example of the effectiveness of this strategy is the use of virus-free seed to control *Lettuce mosaic virus* in lettuce in California.^[4] Programs such as these require strict guidelines for seed production and sensitive assays to test for the presence of virus in batches of seed.

VECTOR TRANSMISSION

Plant virus vectors are the main means by which many economically important viruses are spread in the field.^[2] A diverse group of organisms is capable of transmitting

Genus <i>Olpidium</i>

plant viruses (Table 1). An important characteristic of all plant virus vectors is that they break the cuticle and cell wall of the plant and introduce virus into the cytoplasm of plant cells. Some vectors, such as aphids, nematodes, and whiteflies, accomplish this through a specialized feeding apparatus called a stylet that is used to penetrate the plant cuticle and cell wall. The viruses are acquired from infected cells during feeding when the vector ingests cell contents through the stylet, and subsequently, the viruses are deposited into a plant cell as vectors insert their stylet and salivate into the cell during feeding. Viruses that are transmitted by fungi are introduced into root cells when virus-carrying zoospores penetrate the cuticle and cell wall during fungal infection.

Plant viruses have developed unique relationships with the organisms that transmit them from plant to plant. Generally, one type of virus is transmitted by one type of vector. For example, the *Nepovirus* genera of viruses are transmitted only by nematodes in the genera *Xiphinema* and *Longidorus* in the nematode family Longidoridae^[2] and not by other nematodes or other virus vectors such as aphids, beetles, and whiteflies. The interaction between plant viruses and their vectors ranges from a superficial and short-lived attachment to vector mouthparts to a very intimate, long-term interaction in which the virus replicates within the cells of the vector.

The length of time required for a vector to acquire virus from an infected plant and the time that a vector continues to transmit the virus to healthy plants are determined by the interaction between the virus, the plant, and the vector. For example, the aphid-transmitted *Potyvirus*es are attached superficially to the aphid stylet, and the virus is

acquired and released within minutes during short feeding probes when the aphid inserts the stylet through the plant cuticle into the cytoplasm of epidermal leaf cells.^[5] In contrast, the aphid-transmitted *Luteovirus*es require several days for transmission. *Luteovirus*es are acquired by aphids during extended feeding periods from the phloem of the plant (these viruses only multiply in the phloem of infected plants) and can be transmitted to healthy plants only after the ingested virus moves through the gut wall of the aphid into the circulatory system and then from the circulatory system into the salivary glands from which the virus is transmitted in the saliva during feeding.^[6] Several *Rhabdovirus*es replicate in their aphid vectors after they are acquired during feeding, and the aphids transmit the virus for the rest of their lives. These examples of the types of interactions between aphid-transmitted plant viruses and their aphid vectors illustrate the wide variety of associations that can occur between vectors and the viruses they transmit.

TRANSMISSION THROUGH VEGETATIVE PROPAGATION AND GRAFTING

Many horticultural crops are propagated vegetatively, and this results in a very efficient method of virus spread through the use of tubers, runners, cuttings, corms, and bulbs from virus-infected plants. Virus spreads to nearly all organs and tissues of an infected plant, and vegetative propagation from plant parts gives rise to infected plants without the need to establish infection in a new plant.

Grafting of a plant part from one plant onto a different plant to produce a new plant with characteristics of both is a common horticultural practice that is employed to take advantage of the desirable characteristics of the parent plants. For example, many commercial apple and grape plants have roots derived from selected plants and shoots that are from a different plant. If one part of the grafted plant contains virus, the virus usually moves into the healthy part of the plant and establishes infection. Management of virus diseases in vegetatively propagated crops or crop plants that are produced by grafting is accomplished by regulatory schemes for the establishment and maintenance of virus-free ‘‘mother’’ plants that are used as the source for plant production.^[7]

CONCLUSION

As discussed in this article, there are many possible routes through which a plant may become infected with a virus. Development of effective management strategies for plant diseases caused by viruses often depends on identifying and understanding all the means by which a particular virus is introduced into a plant host.

Plant Virus: Structure and Assembly

A. L. N. Rao

University of California, Riverside, California, U.S.A.

INTRODUCTION

The structure of coat protein (CP) had been thought to protect its infectious genome from the adverse conditions of the intra- and extracellular milieu. Advances made possible by recombinant DNA technologies have established that the viral CP is multifunctional and, most important, that the architecture of mature virions is critical for the survival of the virus, insect transmission, and disease. Knowledge of virion structure is an important prerequisite for understanding the overall biology of plant viruses.^[1] One way to elucidate the final structure of stable virions is to dissect the assembly process through in vitro and in vivo studies.

INTERACTIONS PROMOTING VIRUS ASSEMBLY

The assembly of mature virions, which involves nucleic acid–protein interactions, is an important phase in the virus life cycle.^[2] This process has been shown to be obligatory for several plant viruses to move from cell to cell, be transported over long distances within a plant through the phloem, and be acquired by insect vectors for dissemination to new hosts. The following interactions involving protein and RNA influence the assembly process: 1) Protein–protein interactions play a major role in virion assembly, although their contribution relative to RNA–protein interactions varies among different plant virus groups (e.g., *Tymovirus* and *Comovirus* virions are predominantly stabilized by protein–protein interactions and can therefore form empty capsid shells without the cognate genomic RNA); 2) RNA–protein interactions predominate in guiding the assembly for viruses such as *Tobamoviruses*, *Alfamoviruses*, and *Bromoviruses*. In these viruses capsid formation requires RNA and empty virions are therefore not formed in vivo; 3) Sequence-independent RNA–protein interactions are typically theorized as stabilizing encapsidated RNAs. Basic N-terminal arms found in the CPs of several RNA viruses are implicated in the interaction with RNA phosphates, facilitating the assembly of infectious virions;^[3] 4) Finally, sequence-dependent RNA–protein interactions are often critical in initiating the viral assembly process.

Because viral RNA and CP subunits are localized in the same compartment of the cell as cellular tRNA, mRNAs, or rRNA, these species could potentially be copackaged with viral genomic RNAs. Specific sequence and structure–dependent interactions between RNA and CP are thought to ensure that the majority of assembled virions exclusively contain viral RNA.

PATHWAYS

Tobacco mosaic tobamovirus (TMV) is a helical plant virus in which assembly is initiated by specific interaction between a disk of structural protein subunits and an internal sequence in the RNA genome (Fig. 1A). The study of virus assembly using TMV was pioneered by Frankel-Conrat, who reconstituted TMV particles in vitro from dissociated protein and RNA.

The first experimental evidence that purified RNA and CP of an icosahedral virus (*Cowpea chlorotic mottle virus*, CCMV, a species in the *Bromovirus* genus) can reassemble in vitro to produce infectious particles was provided as early as 1967 by Bancroft and Hiebert.^[4] *Bromovirus* virions are predominantly stabilized by RNA–protein interactions; RNA is therefore required for the formation of icosahedral capsids in vivo. RNA–protein interactions are thought to neutralize the negative charge of the RNA and allow condensation of the nucleic acid within the virus particle. The assembly process is independent of the virus replication complex; there is no indication of the involvement of any other virus-encoded proteins. Bromoviruses assemble into icosahedral particles with T=3 quasisymmetry (Fig. 1B). The structure of CCMV has been determined by X-ray crystallography to have 3.3 Å resolution.^[5] Based on polymerization kinetics observed by light scattering and gel filtration assays, it has been suggested that capsid assembly in CCMV is nucleated by the formation of a pentamer of dimers.^[6] Recent in vitro assembly studies with *brome mosaic virus* (BMV), the prototype Bromovirus, indicated that assembly of infectious virions requires a highly conserved 3' coterminal tRNA-like structure (TLS).^[7] The transient yet critical involvement of the TLS or tRNAs in BMV assembly suggests a role in the formation of CP dimers that serve as intermediaries in the encapsidation pathway.^[6]

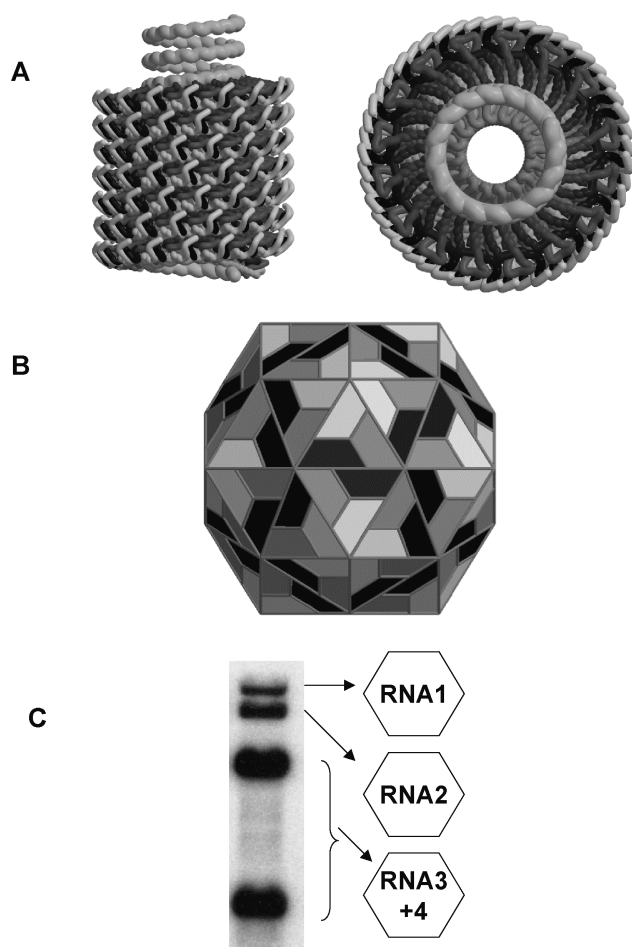

Fig. 1 A. An artistic illustration of TMV based on the structure determined by Pattanayek and Stubbs (23). Shown on the left is a view perpendicular to the helix axis and on the right is a view down the helix axis. The TMV subunits are shown in a tube representation with a color gradient going from black to light gray. The spiral in the middle shown as a thick gray tube corresponds to +ss RNA. B. Schematic representation of the T=3 icosahedral lattice of BMV. Each trapezoid corresponds to a subunit. The chemically identical subunits (same gene products) occupy three structurally distinct environments in the T=3 capsids, shown in different colors, light gray, dark gray and black. C. Packing schematic for four BMV RNAs into three morphologically indistinguishable virions.

GENOME PACKAGING

Genome packaging is considered to be a highly specific process. During packaging, viral nucleic acids must be distinguished from other cellular RNA molecules present in the compartment in which assembly takes place. Such discrimination is thought to result from specific recognition of sequences or structures unique to viral nucleic acids, termed origin of assembly sequences (OAS) or

packaging signals. These signals are often represented by small stretches of RNA that fold into unique secondary or tertiary structures specifically recognized only by the cognate CP. Although these specific sequences might promote packaging of viral genomic RNAs, their presence does not guarantee packaging, because several other parameters also govern the encapsidation process. For example, the fixed dimensions of icosahedral capsids impose an upper limit on the size of viral nucleic acid that can be accommodated. Consequently, nucleic acids substantially larger than a wild-type genome cannot be packaged, even if appropriate packaging signals are present. In contrast to viruses having one genomic segment (e.g., TMV, TCV, SBMV), those with a genome divided among multiple nucleic acid species have evolved mechanism(s) to balance distribution of the genome segments into either a single virion or among multiple virions. The genomes of plant viruses belonging to the *Bromo* (icosahedral), *Cucumo* (icosahedral), *Hordei* (rigid rods), and *Alfamovirus* (bacilliform) genera are divided among three RNA segments. In each of these genera, the genomic and subgenomic RNAs are distributed into separate particles, and their size and the number vary with genera. For example, in bromo- and cucumoviruses, the largest two genomic RNAs are packaged individually into two virions and the third genomic RNA and its subgenomic RNA are hypothesized to copackage into a third virion (Fig. 1C).^[8] These virions do not display any physical heterogeneity in either size or appearance. In hordeiviruses, the three genomic RNAs are encapsidated into three distinct-sized rods. Whether the subgenomic is packaged or not is unknown because of its low concentration. In members of the genus *Alfamovirus*, the three genomic RNAs and the subgenomic RNA are packaged individually into four distinctly sized virions. The mechanism(s) involved in maintaining a high degree of precision in distributing the four RNAs into three or four individual capsids is currently obscure.

WHY STUDY VIRUS STRUCTURE?

Structural information on viruses has provided inspiration for many novel approaches in biology, such as development of viruses as epitope carriers for gene therapy and for nanoengineering of materials. Two RNA plant viruses—TMV and *cowpea mosaic virus* (CPMV)—accumulate in very high concentrations in their hosts, and large quantities of highly purified virions can be obtained in less than 48 hours. Because the CP structure of these two viruses is known in detail, they have been used as vectors for the insertion and presentation of foreign peptides on the virion surface.^[9,10]

The structure of a given virus must be flexible enough to disassemble in order to release its contents upon entry to a healthy host cell. Structural transitions are therefore thought to occur for many virions due to defined chemical switches resulting in unique gating mechanisms that control the containment and release of the contents. Thus, knowledge gained from understanding the principles of the architecture has helped in using viruses as protein cages for material synthesis and molecular entrapment.^[10,11]

Finally, structure has been implicated in playing an important role in controlling many virus–host interactions. In several viruses, experimental evidence has indicated that virion structure assembled from mutated CP subunits has failed to optimally interact with host machinery, resulting in defective local and long-distance movement, and in altered symptom expression in susceptible hosts.

CONCLUSION

Despite many advances, knowledge of the mechanism by which plant viruses package their genomes is still in its infancy. Most of the progress in this direction is limited to viruses containing RNA genomes rather than DNA genomes. Understanding assembly and disassembly mechanisms will likely shed light on the development of novel strategies for virus disease control.

ACKNOWLEDGMENTS

Plant Viruses: Initiation of Infection

James N. Culver

University of Maryland Biotechnology Institute, College Park, Maryland, U.S.A.

INTRODUCTION

Initiation of plant virus infection is a complex process involving the entry and disassembly of the virus particle. Specifically, a virus particle must remain stable within the extracellular environment to protect its genome. However, upon entry into a host cell the particle must destabilize and disassemble in order to initiate the infection process. The mechanisms responsible for shifting particle stability in response to changing environmental conditions have been identified for a number of plant viruses. Furthermore, methods to prevent disassembly have been investigated as a means to develop disease resistance. In this article, the processes that contribute to the initiation of a plant viral infection will be discussed.

VIRUS ENTRY

Unlike animal viruses, which utilize cell surface receptors to gain entry into a cell, plant viruses typically gain access to a new host via nondestructive cellular wounds that penetrate the cell wall and plasmamembrane.^[1] Wounding and subsequent infection can occur by mechanical means; for example, through wind-driven rubbing of infected on healthy plants or by damage from contaminated farm implements. Although not of major economic importance, mechanical transmission using some type of abrasive, such as carborundum or celite, has been an important experimental method used in the study of numerous plant viruses. In comparison to mechanical transmission, the majority of economically important plant viruses are vector transmitted. Invertebrates that feed by sucking on plants, for example, aphids and whiteflies, make up the majority of plant virus vectors. However, other invertebrates such as nematodes and beetles as well as fungi—including members in the genera *Olpidium* and *Polymyxa*—also are capable of vectoring plant viruses. Generally, interactions between viruses and their vectors are highly specific, with a vector species transmitting only specific types of viruses.^[1] However, all of these vectors provide a direct method of entry for the virus into the cell cytoplasm.

VIRUS DISSASSEMBLY

In general, virus particles are stable macromolecules that function to protect their genomes from degradation. However, once inside a cell, the virus particle must disassemble in order to initiate virus replication and spread. Cellular entry therefore requires the normally stable virus particle to destabilize to permit the virus genome access to the host's molecular machinery. The process of switching from a stable to an unstable particle requires a sophisticated mechanism for sensing changes in the surrounding environment. For many viruses this switching mechanism is thought to involve clusters of negatively charged carboxylate groups that reside at the interfaces between adjacent coat protein subunits (Fig. 1).^[2] In the extracellular environment, the repulsive negative charges of the carboxylate groups are neutralized by divalent cations (such as Ca^{++}) or protons. However, upon entry into a cell the lower concentration of cations and the higher pH of the surrounding environment result in the loss of stabilizing cations and protons, allowing the negatively charged carboxylate groups to directly interact. The repulsive electrostatic charges of these groups then function to destabilize the virus particle.

For rod-shaped viruses such as *Tobacco mosaic virus* (TMV), the role of interacting carboxylate residues has been well studied. For each of the approximately 2140 coat protein subunits that make up a TMV particle, there are three known carboxylate groups: one interacting axially, one interacting laterally, and one interacting between the coat protein and the viral RNA (Fig. 1).^[3] All of these interacting carboxylate groups have a role in controlling the stability of the TMV particle.^[4] Interestingly, destabilization does not happen evenly along the axis of the rod-shaped TMV particle, but occurs predominantly at the 5' end of viral RNA. The polar nature of virion disassembly is due to instabilities in interactions between the TMV coat protein and the viral RNA. Each TMV coat protein binds three nucleotides of the viral RNA with the strongest binding occurring when a guanine residue is present in the third position.^[3] Although there is a preponderance of guanine residues in the third position throughout the viral genome, there are none in the 5' leader sequence of the viral RNA. This added instability,

Fig. 1 Model for the cotranslational disassembly of TMV. Expanded circle depicts a carboxylate interaction between aspartate 77 on one coat protein subunit and glutamate 50 on an adjacent coat protein subunit.

along with the repulsive interactions derived from the carboxylate groups, leads to the loss of coat protein subunits from the 5' end of the viral RNA.

The repulsive interactions of carboxylate groups identified within icosahedral viruses such as *Cowpea chlorotic mottle virus* (CCMV) have been shown to control particle swelling.^[5] Particle swelling by as much as 10–15% has been postulated to open channels that allow the release of the viral genome. However, swelling of the virus particle by itself does not always correlate with disassembly because a CCMV mutant deficient in virion swelling readily disassembles *in vivo*.^[6] In addition, some other icosahedral viruses, such as *Cucumber mosaic virus*, do not display particle swelling.^[5] Based on these and other findings, it has been proposed that the N termini of CCMV coat proteins, located at the pentameric vertices of the virus particle, undergo a major structural transition from the interior to the exterior of the virus particle.^[6] This structural transition likely provides a channel for the release of the viral RNA into the cellular environment. Interestingly, this structural transition is still induced by changes in pH and cation concentration, factors that suggest the involvement of a carboxylate interaction.

TRANSLATION- AND REPLICASE-MEDIATED DISASSEMBLY

Instability mediated by carboxylate interactions does not result in the complete disassembly of either icosahedral or rod-shaped viruses. Instead, the induced instability results in the partial release of the viral genome. For viruses with positive-strand RNA genomes such as TMV and CCMV, this leads to the exposure of ribosome binding sites on the genomic RNA and results in the initiation of protein translation. Ribosome translocation along the length of the genomic RNA results in the removal of the viral RNA from the remaining coat protein/virus particle. The linking of disassembly with translation of the viral genome has been termed cotranslational disassembly, and has the advantage of allowing the viral RNA to remain protected in the cytoplasm until replication is initiated.^[7] A similar process, termed replicase-mediated disassembly, also may contribute to the uncoating of the virus particle.^[8] For TMV, genome binding and transcription by the viral replicase proteins appear to result in the removal of coat protein subunits from the 3' non-translated region of the genomic RNA. Thus, complete disassembly of an RNA viral genome may involve both

translation- and replicase-mediated removal of coat protein subunits from the viral RNA.

CROSS PROTECTION: DISRUPTING VIRUS DISASSEMBLY

Cross-protection, defined as the ability of one virus to prevent or delay the infection of a subsequent virus, has been studied as a means to generate novel forms of virus resistance. More recently, plant transformation technologies have significantly expanded our abilities to investigate this phenomenon. In general, cross-protection mechanisms have been linked to either RNA-mediated mechanisms—such as the activation of host-derived gene-silencing—or to protein-mediated mechanisms that disrupt the virus life cycle. The coat protein of TMV has been shown conclusively to play a role in conferring protection in both classical cross-protection and transgenic coat protein-mediated resistance.^[9] Specifically, studies have demonstrated that protection can be overcome using infectious uncoated viral RNA as inoculum. Structural studies have also demonstrated that protection is dependent upon the capability of the protecting TMV coat protein to bind the viral RNA and assemble into a virus particle.^[10] Mutant coat proteins deficient in assembly cannot confer protection. More important, coat proteins with enhanced abilities to assemble significantly enhance observed levels of protection.^[9,10] Together these findings support a recoating protection model in which the presence of the protecting coat protein functions to block the disassembly of the infecting virus particle.

CONCLUSION

The ability of a plant virus to initiate an infection clearly is dependent upon a complex set of mechanisms. These mechanisms also may affect virus movement, disease development, and host resistance.^[9] For example, TMV moves systemically within its host's vascular tissues as an assembled virus particle; hence, upon exiting the vascular tissues the virus particle must undergo disassembly in order to initiate a systemic infection. Thus, understanding the processes involved in the initiation of a plant virus

infection will enhance our overall knowledge of the entire infection process. Unfortunately, for most viruses our understanding of these processes is minimal. One major limitation is the lack of structural information available for the majority of plant viruses. Thus, there is a need for more information regarding the structure and function of virus particles during the infection process.

Plasticity of Root Architecture: Developmental and Nutritional Aspects

Wolfgang Schmidt

Margarete Müller

Humboldt University Berlin, Berlin, Germany

INTRODUCTION

Nonmotile organisms such as plants require a high plasticity in their developmental programs to changing environmental conditions. In general, developmental pathways of plants are more flexible than those of animals because of the continuous production of new meristems. Roots display a wide array of adaptations to spatial and temporal fluctuations in the availability of edaphic resources, resulting in changes in growth rate, diameter, growth angle, the formation of adventitious roots, and anatomical acclimations such as the formation of apoplasmic barriers or aerenchyma. The availability of nitrate, phosphate, sulfate, iron, and even micronutrients such as zinc and manganese can dramatically alter the development of the root system. This article is restricted to those changes that have attracted the most interest during the last decade: the development of lateral roots and the differentiation of epidermal cells in response to the availability of nitrate, phosphate, and iron. Transgenic and genetic approaches have allowed to discover the first components that come into play when the availability of or the demand for nutrients necessitates changes in the developmental program. Recent progress concerning the signaling pathways that control these changes is considered as a further aspect.

LATERAL ROOTS

The formation of lateral roots can dramatically change the architecture of the root system, leading, in general, to an increase in the volume of soil that is explored by the plant. This process shows high plasticity and is responsive to the environment, both being determined by developmental programs and external signals. Lateral roots are initiated in an acropetal sequence from the outermost layer of the stele, the pericycle, in the differentiation zone of the parent root.^[1] Pericycle cells opposite to the xylem poles are primed for the formation of laterals, as indicated by a separately regulated cell cycle.^[2] A dome-like structure of already differentiated cells is formed by sequential

periclinal divisions. Some of these cells form an active meristem that start to function as initials after the primordium has emerged from the parent root, a process driven by cell expansion rather than cell division. The anatomy of lateral and primary roots is highly similar, suggesting that embryonic and postembryonic root developments share some common mechanisms. This is supported by some, but not all, root developmental mutants, indicating that, besides some general similarities in the development, aspects in the organization differ between both root types.

The number and placement of lateral root primordia along the main axis are strongly affected by environmental signals, particularly by the availability and distribution of nitrate and phosphate. In general, high nitrate and phosphate levels suppress the development of lateral roots, while low concentrations of these nutrients favor lateral root growth.^[3,4] When plants were grown at low nitrate or phosphate levels, local nutrient-rich spots led to localized proliferation of lateral roots. Thus both local and systemic signals are integrated to allow for efficient foraging of limited resources. Depending on species and growth conditions, the effect of nitrate is either to elongate or both to initiate and elongate lateral roots. While the response to nitrate is primarily advantageous in relation to interspecies competition, the increase in lateral root elongation triggered by P is thought to enhance phosphate acquisition in addition to increasing competitive strength.

CLUSTER ROOTS: A SPECIAL CASE

Some terrestrial vascular sporophytes produce tight groupings of determinate lateral roots in a small region of the parent root, referred to as cluster roots or proteoid roots. These closely spaced laterals form a bottlebrush-like cluster and emerge synchronously on the same plant (Ref. [5], Fig. 1). Similar to ordinary lateral roots, rootlet primordia arise from the pericycle. Within the cluster, rootlets emerge opposite every protoxylem pole, leading to the typical structure of cluster roots. In some species, a rootlet can become the axis for another cluster, resulting

Fig. 1 Different states of cluster root formation in *Lupinus albus*. A. Growing rootlets with active meristems. B. Differentiation of root cells; formation of root hairs. C. Final state of cluster root formation: the entire root tip is covered with root hairs. (View this art in color at www.dekker.com.)

in complex clusters. The development of cluster roots is followed by an exudative burst, during which a disparate array of root exudates is released into the rhizosphere, facilitating the mobilization and diffusion of nutrients, mainly P and Fe.^[5] The development of the morphological structures appears to be separately regulated from the export of organic acids. The number of root clusters is greatly enhanced by P starvation. The formation of cluster roots is suppressed by a high P status, indicating that their development is controlled by internal signals and not by the local presence of phosphate.^[6] Because cluster roots are formed by nonmycorrhizal species or those with reduced mycorrhizal infection, cluster roots are thought to provide an alternative means to mycorrhiza in phosphate acquisition. Some species form cluster roots in response to Fe deficiency, both responses being mutually exclusive in most cases.^[5]

ROOT HAIRS

Root hairs are fast-growing extensions of epidermal cells which function in the uptake of water and nutrients and are important for microbe interactions. Similar to lateral roots, root hairs reach a predictable length and greatly increase the surface area of the root. The formation of root hairs does not occur in all species, indicating that root hairs are not essential for the functions listed above. The development of root hairs can be divided into three stages: specification, initiation, and elongation. A large number of genes that control the development of root hairs have been identified by molecular genetic studies, mainly in *Arabidopsis thaliana*.^[7] Determination of the cell fate in hair cells (trichoblasts) and nonhair cells (atrachoblasts) is controlled by a transcription factor cascade, which interacts in a complex manner to produce the epidermal patterning typical of *Arabidopsis*. Initiation of root

hair growth starts with cell expansion in a small, disc-shaped area and the induction of expansins that catalyze wall loosening. During tip growth, new cell wall material is secreted to the cell tip and cytoskeletal elements accumulate at the tip. The direction of tip growth is controlled by a calcium gradient, GTP-binding proteins from the Rop family and microtubules. Pharmacological and genetic studies indicate that the plant hormones ethylene and auxin are involved in epidermal cell specification and elongation, acting parallel to or downstream of the cell specification genes, although the role of the hormones in cell specification is not unambiguous.

In the aging primary root and in laterals, cellular patterning can be modulated by environmental factors, mainly by the availability of phosphate and iron. Phosphate deficiency increases both the length and the density of root hairs (Fig. 2), leading to a decrease in a

Fig. 2 Effects of P status on the development of epidermal cells of *Arabidopsis* roots. A. control. B. P-deficient roots. (View this art in color at www.dekker.com.)

P-depleted zone around the roots that develops rapidly during phosphate uptake because of the low solubility of phosphate in the soil solution. Under iron shortage, in dicots and nongrass monocots, root hair proliferation is associated with a suite of adaptive processes which helps to acquire iron from sparingly soluble sources.^[8] Suboptimal Fe availability increases the density, but not the length of root hairs. In *Arabidopsis*, hairs that are formed in response to nutrient shortage are both in the normal position and in positions that are normally occupied by nonhair cells, indicating postembryonic changes in epidermal patterning.^[9]

In addition to root hair formation, root epidermal cells can undergo ultrastructural changes that are presumably important for nutrient acquisition. In response to phosphate and iron shortage, some cells in the zone of metaxylem differentiation develop into transfer cells, characterized by polarized wall ingrowths which are primarily located on outer tangential walls. The enlargement of the plasma membrane surface, which is associated with the development of this cell wall labyrinth, is thought to increase the flux of solutes between the rhizosphere and the symplast. The presence of numerous mitochondria and other organelles, in particular Golgi and endoplasmic reticulum, is typical of transfer cells, suggesting a high energy requirement. The physiological function of transfer cells is not yet clear, but from their spatial and temporal pattern, there appears to be justification for a function in the acquisition of iron and phosphate.^[10]

SENSING AND SIGNALING

Little is known about how information from the environment is sensed and transduced to downstream targets, and how these pathways converge with developmental control. Sensing of nutrient levels appears to be complex, involving (at least) two distinct signaling mechanisms: a systemic circuit integrating information of the nutritional status from different plant parts, and a second, local system that perceives the level of nutrients in the vicinity of the roots. An example for the latter type is the development of root hairs and rhizodermal transfer cells, which are not, or only in part, affected by the overall nutrient status of the shoot, dissimilar to homeostatic compensation of the nutritional levels by physiological responses which is systemically regulated.^[9] In contrast, the formation of cluster roots is mainly linked to the whole plant nutrient level and probably regulated by a long-distance signal generated in the shoot.^[6]

Nutrient sensors involved in changes in root development have not yet been identified. The nitrate transporter *AtNRT1.1* (*CHL1*) may play a role in nitrate sensing

besides its function in nitrate uptake.^[11] At low nitrate levels and low pH, *chl1* mutants show reduced growth of lateral root primordia, suggesting that the CHL1 product is required for lateral root maturation. A further component in the signaling pathway leading to localized proliferation of lateral roots is the MADS box transcription factor ANR1. Transgenic plants with low levels of ANR1 message lack the ability to respond to localized nitrate.^[3] Whether the level of nutrients is monitored by external sensor(s) facing the apoplast or after absorption by the plant remains to be elucidated. Nitrate does not need to be assimilated to induce meristematic activity in lateral roots, suggesting that plants are able to sense external nitrate. This might also be true for other nutrients. Several genes with putative function in signal transduction have been found to respond within hours to phosphate, potassium, and iron deficiencies, which are unlikely to be associated with significant changes in nutrient concentrations, supporting the assumption that plants can sense changes in the availability of nutrients in close proximity to the roots.^[12]

Auxin appears to be a key regulator in lateral root development. Application of auxin results in increased initiation of lateral roots, and an auxin-overproducing mutant in *Arabidopsis* forms lateral roots in high density. The direct participation of auxin in phosphate- and nitrate-induced changes in root development has, however, not been proven unequivocally. Free auxin levels are higher in phosphate-starved plants, but auxin mutants were shown to respond like the wild type to changes in phosphate availability.^[4] Transfer cells are induced by auxin, but mutants with reduced auxin or ethylene sensitivity showed no significant reduction in transfer cell frequency, questioning a primary role of hormones in their induction.^[10] More unambiguous information is available for the development of root hairs. Whereas functional products of genes involved in ethylene and auxin signaling are required for the development of iron stress-induced hairs, both hormones appear to play no direct role in the formation of hairs induced by phosphate deficiency, indicating separate regulation.^[9]

Pollen-Stigma Interactions

Simon J. Hiscock

University of Bristol, Bristol, U.K.

INTRODUCTION

The pollen-stigma interaction, as defined by Heslop-Harrison, consists of: 1) pollen capture; 2) pollen adhesion; 3) pollen hydration; 4) pollen germination; and 5) pollen tube penetration of the stigma. Successful completion of these events normally results in pollen tube growth to the ovary, leading to fertilization unless incompatibility/incongruity factors preclude. The pollen-stigma interaction is thus a necessary prezygotic courtship between the male gametophyte and the maternal tissues of the sporophyte. Molecules regulating the interaction reside at the surfaces of pollen and stigma (self-incompatibility proteins excluded), but our knowledge of their identity remains largely fragmentary.

THE STIGMA SURFACE

Stigmas can be broadly classified as wet or dry, depending on whether or not they possess a surface secretion.^[1,2] Such a classification is useful in the context of this review because the nature of the pollen-stigma interaction depends largely on the microecology of the stigma.^[2] For wet stigma species, investigations have focused largely on species from the Solanaceae (notably *Nicotiana*), whereas for dry stigma species, *Brassica* and *Arabidopsis* define the model.

POLLEN-STIGMA INTERACTIONS IN SPECIES WITH WET STIGMAS

Secretions on wet stigmas are primarily lipid-rich (e.g., Solanaceae) or primarily carbohydrate-rich (e.g., Liliaceae) and are clearly important for pollen capture and adhesion. This is because, on making contact with a wet stigma, pollen is quickly trapped and immersed within it. In *Nicotiana*, the absence of a stigmatic secretion results in aberrant pollen development on the stigma, preventing fertilization. Lipids have been shown to be the essential component of the stigmatic secretion necessary for pollen tube penetration because ablated stigmas of female-sterile *Nicotiana* can be restored to full fertility by the applica-

tion of a range of lipids, particularly *cis*-unsaturated triacylglycerides.^[3,4] Lipids within the secretion also appear to direct pollen tube growth toward the stigma by providing an increasing gradient of water potential between the desiccated pollen grain and the turgid cells of the stigma. In vitro simulations of the stigmatic environment using oil-in-water emulsions confirmed that *Nicotiana* pollen tubes grow down gradients of water potential toward an aqueous phase.^[4] Whether the carbohydrates in lily-type secretions play a similar role in guidance and penetration of pollen tubes remains to be determined. Wet stigma species usually lack a stigmatic cuticle, so once the pollen tube has germinated and begun to grow toward the stigma, its entry and passage into the transmitting tissue are largely unimpeded. Within the transmitting tissue, chemical cues—notably TTS (a Transmitting Tissue-Specific arabinogalactan glycoprotein)—may guide pollen tubes toward the ovules; physical cues such as cell surfaces may also guide pollen tubes toward ovules.^[4,5] It is also within the transmitting tissues of the style that pollen tubes of the self-incompatible (SI) members of the Solanaceae are inhibited by the action of style-specific S-RNases.^[5]

POLLEN-STIGMA INTERACTIONS IN SPECIES WITH DRY STIGMAS

For nearly thirty years, *Brassica* has been the model for studies of pollen-stigma interactions on the dry stigma. In *Brassica*, studies of the default state of (compatible) pollen-stigma interactions have been combined with studies of sporophytic self-incompatibility (SSI) because incompatible pollen is recognized and rejected at the stigma surface. More recently, studies of compatibility have shifted to the *Arabidopsis* model.

The stigma of *Brassica* and *Arabidopsis* consists of a dome of epidermal papillae covered by a continuous cuticle that forms a major barrier to pollen tube penetration. Upon the cuticle sits a thin membrane-like layer of protein, the pellicle, which forms the first site of molecular contact between the stigma and alighting pollen grains (Fig. 1). The protein composition of the pellicle has yet to be determined, but cytochemical studies have revealed the presence of esterases and glycoproteins.^[1,2]

Fig. 1 The dry stigma surface of *Brassica*. A) Stigmatic papillae stained with α -naphthyl acetate and fast blue RR salt to visualize nonspecific esterase activity. Bar = 10 μ m. B) Transmission electron micrograph (TEM) of oblique section through cell wall of stigmatic papilla stained with α -naphthyl acetate and hexazotized pararosanilin to visualize esterase activity of the pellicle (P). Bar = 0.2 μ m.

In the absence of a sticky stigmatic secretion, adhesion of pollen to the stigma appears to be largely a function of the pollen wall. Structural studies in *Brassica* suggested that the lipidic pollen coating mediates adhesion because immediately after making contact with the stigma, pollen coating is extruded from the exine onto the surface of the stigma where it forms an appresoria-like “foot”^[6] (Fig. 2). Nevertheless, pollen adhesion assays using the *Arabidopsis* mutant *cer6-2*, which fails to produce a pollen coating, did not indicate loss of adhesion in the coatless pollen.^[7] This observation points to the sporopollenin exine as being responsible for pollen adhesion. Indeed, *Arabidopsis lap* (*less adherent pollen*) mutants, compromised in pollen adhesion, show aberrant patterns of exine development.^[7] The adhesive function of the exine could be attributable to the exinic outer layer (EOL)—a thin surface layer surrounding the exine, which, like the stigmatic pellicle, has yet to be characterized.^[6] Interestingly, structural studies in *Brassica* suggest that upon contact, the EOL and pellicle fuse (S. J. Hiscock unpublished observation).

Two stigmatic members of the *Brassica S* gene family have been implicated in pollen adhesion. Gene knockouts of *SLR1* (*S* Locus Related glycoprotein 1) resulted in reduced adhesion of pollen on transgenic stigmas, and pretreatment of stigmas with antisera to SLR1 or SLG (*S* Locus Glycoprotein) also resulted in reduced pollen adhesion.^[8] Importantly, SLR1 and SLG each bind specific members of a group of pollen coat proteins (PCPs)—an interaction that may contribute to the adhesive effects of SLR1 and SLG on pollen.

The main role of the pollen coating appears to be in pollen hydration, because all *Arabidopsis cer* mutants are defective in pollen hydration and consequently do not produce a pollen tube on the stigma. Mutant *cer6-2* pollen, which has virtually no pollen coating, cannot stimulate water release from the stigma but germinates readily in liquid medium in vitro, and under high humidity in vivo. All *cer* mutants (*cer1*, *cer3*, *cer6*, and *pop1*) are unable to synthesize long-chain lipids^[5,7] The fact that *cer* mutants can be rescued by application of triacylglycerides suggests that lipids in the pollen coating play a role in pollen development similar to the lipids in the stigmatic secretions of *Nicotiana*.^[3,7] Lipids within the pollen foot may set up a gradient of water potential between the pollen grain and the stigma that acts as a guide to the growing pollen tube, indicating the direction of the stigma. In support of this assertion, pollen tubes of *Brassica* always grow through the pollen foot prior to penetration of the stigma.^[6]

Regulated hydration of pollen is clearly essential for normal pollen development on stigmas of *Brassica* and *Arabidopsis*, but pollen coat proteins (in addition to lipids) appear to play a key role in this process. GRP17 is an oleosin-domain protein present in *Arabidopsis* pollen coating that is necessary for normal hydration of the pollen grain. GRP17 belongs to a family of oleosin-domain *Arabidopsis* pollen coat proteins, orthologues of which are also present in the pollen coating of *Brassica*. It has been suggested that this variable group of oleosin proteins and a group of similarly variable pollen coat lipases may form

Fig. 2 The *Brassica* pollen foot. TEM of oblique section through pollen-stigma interface 1 hour after compatible pollination. P = pollen grain, Ft = pollen foot, S = stigmatic papilla. Bar = 2 μ m.

Fig. 3 Pollen tube penetration on the *Brassica* stigma. Fluorescence micrographs of pollen stained with decolorized aniline blue to visualize callose. A) Control pollination showing pollen tubes freely penetrating stigmatic papillae. Bar = 20 μm . B) Stigma treated with serine esterase inhibitor ebelactone B prior to pollination to inhibit cutinase; the convoluted pollen tube is unable to penetrate the stigma. Bar = 20 μm .

species-specific or subspecies-specific pollen recognition cassettes.^[5] How these species-specific pollen tags are read by the stigma is a matter for speculation, but an interaction with proteins of the pellicle is appealing.

Unlike species with wet stigmas, pollen tubes of *Brassica* and *Arabidopsis* must breach a cuticle during penetration of the stigma. In *Brassica* an intine-held cutinase is released at the pollen tube tip during penetration. This pollen cutinase is very similar to fungal cutinases, particularly in its sensitivity to serine esterase inhibitors—treating stigmas with DIPF or ebelactone B prior to pollination reduces pollen tube penetration by up to 70%^[9] (Fig. 3). Once the cuticle has been breached, the pollen tube grows within the papilla cell wall toward the base, where it emerges and continues to grow intercellularly toward the ovary. Pollen-held enzymes again appear to be involved in these processes, most notably a pectin esterase.^[9] In *Arabidopsis*, pollen tubes penetrate directly into the papilla cells, growing through the cytosol and then forcing through the basal wall region and into the transmitting tissues. Similar pollen tube behavior can be seen in *Brassica* when immature stigmas are pollinated.^[6]

Self-incompatible *Brassica* pollen can be arrested at any point during the pollen-stigma interaction. Pollen is recognized as self by means of a haplotype-specific protein-protein interaction between SRK, a stigmatic (*S*) receptor kinase, and SCR (*S* cysteine-rich), a small pollen coat protein similar to PCPs.^[5] Downstream events following this recognition that directly inhibit pollen development have yet to be characterized. However, the inhibitory machinery of SSI is preserved in self-compatible *Arabidopsis*, even though it lacks an *S* locus, because plants transformed with SRK and SCR derived from an *S* haplotype of close SI relative *A. lyrata* become SI.^[10] This major discovery will now make it possible to dissect the SSI response in the more tractable model *Arabidopsis*.

CONCLUSION

As more is becoming known about the molecular mechanisms of SI, interest is focusing on molecules that mediate the default state of the pollen-stigma interaction—compatibility. The importance of lipids on the stigma in early pollen development is becoming clear, and insight into pollen adhesion and hydration is being gained through studies of *Arabidopsis* male-sterile mutants. Further insight will follow as more subtle screens are devised for *Arabidopsis* mutants compromised at various stages of the pollen-stigma interaction. Key mutants will be those that show penetration defects, possibly resulting from lesions in pollen genes that encode enzymes such as cutinase. Another key challenge will be to identify and functionally characterize the proteins that constitute the pellicle of dry stigmas.

Polyploidy

Jan Dvorak

University of California, Davis, California, U.S.A.

INTRODUCTION

Polyploid organisms contain more than two genomes. The gametophytic (haploid) chromosome number is n , and the sporophytic (somatic) chromosome number is $2n$. The basic chromosome number in a phylogenetic lineage is x . Both n and x should be presented to describe ploidy unequivocally. For example, $2n = 4x = 40$ indicates that chromosome number is being described in a sporophyte that is tetraploid and has 40 chromosomes.

TYPES OF POLYPLOIDY

Two basic types of polyploidy are recognized: autopolyploidy (autoploidy) and allopolyploidy (alloploidy). They are defined according to either the origin of a polyploid or its meiotic chromosome behavior. According to the former definition, autopolyploids are of an intraspecific origin, whereas allopolyploids are of a hybrid origin. According to the latter definition, autopolyploids show multivalents at MI of meiosis and polysomic inheritance, whereas allopolyploids show bivalents at MI and disomic inheritance. The term segmental alloploidy,^[1] proposed for intermediate states between autopolyploidy and alloploidy, is inappropriate in most cases and should not be used.^[2]

The genomic constitution of polyploids is expressed by formulas in which genomes are designated by capital letters according to their relatedness (Table 1). An autotetraploid may have a formula AAAA, reflecting the fact that its genomes originated from within a single species. Its chromosomes are homologous and it likely shows polysomic inheritance. In contrast, an allotetraploid may have a formula AABB, reflecting the fact that its genomes were contributed by two different species, one contributing the A genomes and the other contributing the B genomes. The corresponding chromosomes in the A and B genomes are very likely homoeologous and the species likely shows disomic inheritance.

The sources of genomes are identified by genome analysis of the polyploid.^[3] Description of various methods of genome analysis can be found in a compendium on this subject.^[4] In its classical form, it consists of analyses of chromosome pairing at MI in hybrids from crosses between a polyploid and its relatives.^[3] Sharing of iso-

zyme alleles—chloroplast genome restriction fragments and nucleotide sequences—and restriction fragments of nuclear repeated nucleotide sequences—in situ hybridization of labeled heterologous genomic DNA—can provide additional valuable information on the origin of polyploid species. Once a diploid species (or its closest extant relative) that was the source of a genome in a polyploid is identified, the same letter is assigned to that genome in the polyploid and the diploid (Table 1). Genome evolution that may have occurred since the origin of a polyploid, extinction of a diploid ancestor, or hybridization may result in failure to find a diploid whose genome fully fits a genome of a polyploid. An imperfect fit between genomes is indicated by assigning superscripts or subscripts to genome designations or by other notation in genome formulas.

GENETIC TRANSMISSION

Polyploidy greatly impacts gene segregation. In an autotetraploid, three heterozygous states—simplex (Aaaa), duplex (AAaa), and triplex (AAAA)—are possible in addition to the two homozygous states, nulliplex (aaaa) and quadruplex (AAAA). Additionally, there is an opportunity for double reduction if a crossover occurs between the locus and centromere. Double reduction creates an opportunity for sister alleles getting into a gamete instead of homologous alleles. The maximum equational segregations of a duplex heterozygote AAaa (A being completely dominant over a) is 19.5 dominant phenotypes:1 recessive phenotype, as compared to the 35 dominant phenotypes:1 recessive phenotype for strictly reductional segregation of the duplex.^[5]

In an allotetraploid, a chromosome can pair during meiosis either homogenetically, i.e., with its homologue (e.g., chromosome 1A pairs with 1A), or heterogenetically, i.e., with a homoeologue (e.g., chromosome 1A pairs with 1B). A vast majority of allopolyploids are meiotically diploidized, meaning that only homogenetic pairing occurs. In some polyploids, heterogenic chromosome pairing is genetically suppressed. An example of a heterogenic pairing suppressor is the wheat *Ph1* locus. If the gene is mutated or removed by aneuploidy, heterogenic

meiotic pairing occurs at MI. Diploidized allotetraploids show disomic inheritance, provided that the locus duplicated in the other genome pair is homozygous recessive. If both loci are heterozygous (*AaAa*) and A is completely dominant over *a*, an allotetraploid segregates 15 dominant:1 recessive phenotypes.

INCIDENCE

Polyploidy is widespread in plants but rare in animals.^[6] Its incidence may be as high as 70% in angiosperms. It is claimed that as much as 95% of all species of homosporous ferns are polyploid, although this figure is still being

debated. The highest chromosome number and highest ploidy among plants was recorded in fern *Ophioglossum pycnostichum* ($2n = 84x = 1260$). In angiosperms, polyploidy is more abundant in monocots than in dicots. For example, as many as 80% of all grass species were estimated to be polyploid. Polyploidy is more abundant in herbaceous angiosperms, particularly those that are perennial, than in woody species. Polyploidy is rare in gymnosperms. For example, only 1.5% of coniferous species are polyploid.

ORIGINS

The principal mechanism by which natural polyploids originate is the union of an unreduced gamete with a reduced gamete or two unreduced gametes.^[7] The union of an unreduced diploid gamete with a reduced monoploid gamete of the same species results in an autotriploid. Autotriploids are usually highly male-sterile but partially female-fertile, and may serve as bridges in the origin of autotetraploids.^[8] Autotetraploids were estimated to originate with a frequency of about 10^{-5} .^[8] The frequency of unreduced gametes is greatly elevated in interspecific hybrids. Therefore, the frequency of the emergence of allopolyploids is more dependent on the frequency of interspecific hybridization than on the production of unreduced gametes by the parental species. The cross-pollinating mating system enhances the incidence of allopolyploidy. Both auto- and allopolyploids originating from cross-pollinating species, including those that are self-incompatible, are usually self-pollinating, which assists nascent polyploids in their propagation and establishment.

EVOLUTIONARY SUCCESS

Polyploids have sometimes been portrayed as genetically depauperized taxa exploiting an available habitat at the expense of long-term evolutionary success. This view is incongruous with the tendency of allopolyploids to become geographically widespread. Moreover, molecular mapping has demonstrated that some apparently diploid plant lineages are actually paleopolyploid (Table 1), showing that polyploids can establish successful phylogenetic lineages. It has been demonstrated for more than 30 species that polyploids originate recurrently in natural populations.^[9] Recurrent origin and interploidy hybridization, followed by introgression, broadens the polyploid gene pools and enhances the potential of polyploids to adapt to changing environment. Nascent allopolyploids are notorious for their genetic and meiotic instability, caused by recombination and subsequent segregation, DNA rearrangement, and transposition, and epigenetic variation

caused by differential methylation. These mechanisms increase variation in nascent polyploid populations and contribute to their adaptation and evolutionary success.

INDUCED POLYPLOIDY

Polyploidy can be induced by temperature shocks and numerous other treatments interfering with mitosis. The most effective is treatment with the alkaloid colchicines, which blocks entry of a mitotic cell into the anaphase. Because colchicine is always applied on multicellular tissues, treated plants become polyploid chimeras. Nitrous oxide dissolved in cytosol under pressure also blocks polymerization of microtubules and results in polyploidization. The gas can be applied at the time of zygotic division, resulting in the entire plant being polyploid. Endopolyploid cells, which are frequent in somatic tissues of plants, can also be a source of polyploids regenerating from them. Endopolyploidy is the principal cause of polyploidy of adventitious shoots and plants regenerated from tissue culture. Autotriploids can be produced by crossing diploids with autotetraploids. In some cases, this cross is difficult (triploid block) or is possible in only one direction.

PHENOTYPIC EFFECTS

The primary effect of autopolyploidy is larger cell size. Therefore, autopolyploids are often more robust, have thicker and darker leaves and larger stomata and pollen size, and are slower developing and less tolerant of environmental stresses than their diploid counterparts. There is often a specific ploidy level for increase in plant size due to autopolyploidy. Allopolyploids tend to be intermediate between parents, although they may resemble one of the parents in specific traits or may show altogether new traits.

POLYPLOID CROPS

Polyploidy was about as frequent in crops as in their noncrop relatives.^[10] Polyploid field crops and fruit trees, their genome formulas, and synopses of their genome analysis are listed in Table 1. The majority of polyploid crops are allopolyploid. Low fertility of triploids has been exploited in the production of seedless triploid varieties of watermelon and bananas. In sugar beet, triploid varieties are more productive than their diploid and autotetraploid counterparts, and have been commercially used to produce monogerm varieties. Some varieties of apples and cherries are triploid.

CONCLUSION

Polyploidy is an important evolutionary strategy in the plant kingdom. Many important crops are polyploid, although the incidence of polyploidy in crops does not appear to be any higher than in their noncrop immediate relatives. Polyploidy greatly modifies inheritance. In autopolyploid populations, recessive phenotypes appear in much lower frequencies than in diploid populations with similar allele frequencies. A general tendency of natural allopolyploids is to genetically “diploidize,” (i.e., to evolve bivalent meiotic chromosome pairing and disomic inheritance). The molecular and genetic mechanisms of this process remain poorly understood. Also poorly understood are gene expression and genome evolution in allopolyploid species.

Population Genetics

Michael T. Clegg

University of California, Riverside, California, U.S.A.

INTRODUCTION

Genes are the fundamental hereditary units transmitted from parent to offspring in every generation. Population genetics is concerned with the statistical rules that govern the transmission of genes within collections of interbreeding individuals over time. Changes in the frequencies of genes within populations are the basis for evolutionary change, as well as the basis for the genetic improvement of plants and animals that provide human sustenance.

Population genetics employs mathematical models to describe trajectories of genetic change under various scenarios. These models are also used to design experiments to dissect the processes of evolution. The basic mathematical models of population genetics were developed long before it was established that DNA is the chemical basis of heredity. The challenge today is to analyze and learn from the rapidly accumulating body of genome sequence data. The basic models of population genetics are highly relevant to this enterprise because they are general, in the sense that change in gene frequency can be substituted with change in individual nucleotide frequency without any alteration in the underlying mathematics. This article provides a brief outline of the theory of population genetics as it applies to changes in the composition of DNA molecules over time. Several excellent books provide a comprehensive introduction to population genetics theory, including works by Hartl and Clark and Hedrick.

EVOLUTIONARY FORCES THAT DRIVE DNA SEQUENCE CHANGE

Five forces determine genetic change.^[1,2] These begin with mutation, defined as a permanent heritable change in a gene. A second force is recombination, which is a randomizing force that can also lead to permanent heritable changes in a gene. Genetic random drift, defined as the small fluctuations in gene frequencies caused by the sampling of individuals in reproduction, is third. The fourth force is migration, or the movement of genes among different populations. Fifth is natural selection, in which some individuals are more successful in transmitting their

genes owing to superior adaptation to their environment and hence improved survival and reproduction. Natural selection is the force that leads to adaptive genetic change; it essentially sorts among mutations to eliminate those that are deleterious and increase the frequency of those that are advantageous.

MUTATION: THE SOURCE OF GENETIC NOVELTY

Gene or nucleotide sequences are subject to constant change. To begin, mutation takes many forms, each of which has some likelihood of occurring at each DNA replication cycle. From this it is apparent that any DNA molecule is subject to mutational erosion over time; this erosion process is a form of evolutionary change. DNA sequences that code for functionally important molecules are expected to be conserved because natural selection rejects most deleterious mutational changes in functionally important genes. Current genome sequencing efforts suggest that much of the DNA of organisms does not code for proteins or regulatory signals—these regions may be evolving relatively rapidly.

GENETIC RANDOM DRIFT: THE ROLE OF CHANCE IN EVOLUTIONARY CHANGE

Once a new mutation has arisen in a single DNA molecule (to create a new allelic form of a gene or a new allele), it may be transmitted to the next generation or it may be lost. Assuming the new mutation has no effect on fitness, the probability of transmission to the next generation is $1 - [1 - 1/2N]^{2N}$ in diploid organisms, where N is the population size. This result follows from the fact that a new mutation will initially occur in a single individual (frequency = $1/2N$). The pool of gametes is assumed to be much larger than the N reproductive individuals in the population, so sampling with replacement is appropriate. (This expression is the probability of not being lost in the first generation, derived assuming binomial sampling.) In the vast majority of cases a new mutation will be lost through the vagaries of sampling within a generation or

two. A very small proportion will drift to high frequency and be fixed (i.e., become the sole allele in the population or species).

An important result of mathematical genetics indicates that the probability of ultimate fixation of a new neutral mutation is $1/2N$ (the concept of neutrality is discussed later). Because there is a constant flux of new mutations, there will also be a constant rate of fixation of new allelic variants over the long term. In fact, the rate of fixation of new alleles is simply μ , the mutation rate. This result provides a formal justification for the molecular clock hypothesis (see article on [molecular evolution](#)), because it indicates that the rate of mutational change should be constant over time if the mutation rate is constant.

A second important theoretical result from population genetics demonstrates that the average time until the fixation of a new mutation is $T \sim 4N_e$, so for large N_e , many mutant alleles are expected to be in transition to fixation at any point in time. (N_e is a population size adjusted to take account of variation in reproductive output among different members of a breeding population.) For example, many plant species must have population sizes in the order of 10^6 to 10^7 . The rate of mutation per nucleotide site per generation is approximately $\mu = 5 \times 10^{-9}$. If a typical gene is 10^3 nucleotide sites in length, the total probability of a new mutation in the gene in any single generation is 5×10^{-6} . For a species size ($2N$) of 10^6 , five new mutations in this particular gene are expected in the total species per generation. Moreover, the average new mutation that is destined to be fixed will drift in the species of size 10^6 for 4,000,000 generations. The probability of drawing two different alleles of the gene in a population or species can be shown to be approximately $1 - 4N_e\mu(1 + 4N_e\mu) = 19/21 = 0.90$ for this numerical example, so almost every pair of genes sampled is expected to be different. Thus, high levels of molecular polymorphism are expected in species. Current efforts to define all human single nucleotide polymorphisms (SNPs) verify these theoretical predictions.

THE NEUTRALITY HYPOTHESIS: AN INTERACTION BETWEEN MUTATION AND DRIFT

The theoretical results cited in the preceding discussion are based on the assumption that selection is absent. In the 1970s, Motoo Kimura^[3] and associates advanced a theory called the neutrality hypothesis that claims that a large proportion of molecular evolutionary change is neutral to natural selection. This hypothesis was in part motivated by an important calculation by J. B. S. Haldane,^[4] who showed that there is an upper bound to the rate of evolutionary change under natural selection.

Because selective change requires differential survival and reproduction, the reproductive excess of the species defines this upper bound. Stated differently, some or all of the reproductive excess of a species is consumed by the process of selection. Empirical evidence on rates of molecular change appear to be too high to be consistent with this upper bound, especially for long-lived low-fecundity organisms like the human. As a consequence, it was postulated that a large proportion of molecular change is not driven by selection, but by random drift and mutation.

The test of the neutral theory is to ask how well observed data fit the theoretical calculations outlined earlier. Because the neutral theory provides precise mathematical predictions, the theory is testable; moreover, these tests provide a very useful context for identifying particular genes that are selected. This is because it is known precisely how neutral genes should behave, and departures from neutrality are likely to arise from selection. To date, available data do suggest that many polymorphisms are neutral or only very weakly selected. However, the statistical power to detect departures from neutrality increases with database size, which are growing very rapidly at present.

NATURAL SELECTION: THE ENGINE OF ADAPTIVE CHANGE

Natural selection operates at the level of phenotypic differences, so an allelic change must alter some aspect of phenotype to be perceived by selection. The phenotypic dimensions of organisms, and the ways these may be perceived by various environmental factors, are very complex. These range from subtle changes in rates of flow through a metabolic pathway, to resistance to disease, to the ability to withstand extreme stress environments, to aspects of behavior, and so on. The list is virtually endless. Moreover, each aspect of phenotype may be determined by a number of different genes and by the way these genes interact in development and metabolism. It is similarly difficult to identify the precise facets of an environment that may act as a selective agent. As a consequence, selection is often identified retrospectively. That is, the analytical tools of population genetics may support the inference that selection has affected a genetic locus based on the pattern of change through time. Such an analysis rarely tells the reasons why a particular change is adaptive.

A number of mathematical results that provide useful predictions about the statics and dynamics of selective genetic change are available from population genetic theory. We will mention just one result from this large body of work. The probability of fixation of a new mutant

that is favored by selection (assuming the heterozygous genotype is intermediate in its fitness between the two homozygous genotypes) is $\sim 2s$, where s is the selective intensity favoring the new mutant allele. So if $s=0.02$ (implying a 2% selective advantage), the favored allele will still be lost 96% of the time. This result demonstrates that most new favored mutations will still be lost owing to drift.

The average time to fixation of a new favored mutant is approximately $T \sim (2/s)\text{Ln}(2N_e)$ generations (where Ln denotes the natural logarithmic function). Numerical iterations of this equation, compared to the neutral case, reveal that the time to fixation of selectively favored alleles is much shorter than for a neutral allele. Indeed, fixation of a selected allele can take place in orders of magnitude less time than a neutral allele. This calculation suggests that in contrast to the high levels of neutral polymorphism expected from the neutral theory outlined in the fore going, it may be relatively rare to find a selected gene in transition when one allele is favored over the other allele. The exception to this statement is the case where two or more alleles are favored, either because they lead to a higher fitness among heterozygotes or because their advantage is frequency-dependent (frequency dependent means that s is not constant, but instead depends on allele frequencies). Both of these situations are referred to as balanced polymorphism. Classic examples of a balanced polymorphism are often associated with disease resistance, where the resistance allele causes some other disadvantage or where there is a constant arms race between the disease agent and the target organism favoring new mutations at a resistance locus (a case of frequency dependence). An example of such a balanced polymorphism arises from the multiple major histocompatibility polymorphism (MHC) alleles in human populations.^[5] In this case, disease resistance is strongly implicated because the MHC locus is involved in the recognition of potential disease agents.

RECOMBINATION AS BOTH RANDOMIZING AND CREATIVE FORCE

Recombination refers to the rearrangement of genes with respect to one another on chromosomes. Recombination is a randomizing force, but it is also much more. It is a creative force that operates at many levels within plant genomes.^[6] Thus, molecular evidence has revealed that recombination is responsible for the generation of many gene novelties. For example, studies of different allelic sequences of a gene often show traces of past intragenic recombination events where new allelic forms have arisen,

owing to the exchange of stretches of sequence between two different alleles. This reciprocal exchange can yield a new allele that is different from both parental forms.

THE COALESCENT: LOOKING BACKWARD IN TIME

An important theoretical construct from population genetics is known as the coalescent. Consider a set of DNA sequences that are drawn from a single locus within a species. The sample of sequences must have all descended from a common ancestor. The point where all alleles trace back to the most recent common ancestor is known as the coalescent. It is straightforward to estimate the genealogical history of the sample by using phylogeny estimation tools (discussed in the bioinformatics article). If the nucleotide sequence diversity in the sample is the result of a drift/mutation process at equilibrium, then the arrival times of new mutation events are given by an exponential process.^[7] This result provides a useful framework for testing sequence samples to see if they conform to a neutral process.

A particularly important statistic calculated from a sample of sequences is θ , a measure of the nucleotide sequence diversity. A different statistic that also measures nucleotide sequence diversity is π . (Both of these quantities are related to the probability of drawing two different nucleotides at a single site averaged over all sites examined.) If we calculate π and θ as an average over many independent replications of the evolutionary process that led to the observed sample, and if the underlying evolutionary process is the result of a drift/mutation process at equilibrium, then both θ and π should be approximately equal to $4N_e\mu$. Thus, the difference between π and θ should be zero under the drift/mutation assumption. A test statistic introduced by Tajima^[8] based on a function of the difference between π and θ allows one to ask whether a data set conforms to the drift/mutation assumption by testing whether this difference is zero. If the difference is nonzero, then other forces such as selection or demographic change must be invoked. Many standard computer programs for sequence analysis implement these calculations (i.e., DnaSP).

Another statistic that features importantly in coalescence theory is T_{MARCA} (time to the most recent common ancestor of the sample). Mathematical calculations show that T_{MARCA} is also approximately equal to $4N_e$ when the drift/mutation assumption is satisfied. Finally, if μ is known it is possible to estimate N_e for the species or population from which the data came. Estimates of N_e from a few important crop plants vary over nearly an order of magnitude from 2×10^5 (wild barley) to 3×10^5 (pearl

millet) to 18×10^5 (maize).^[9] These data are derived from broad samples of the entire species so the estimates can be viewed as the best estimates of long-term effective population size for each species.

MIGRATION: THE SPATIAL DIMENSION OF GENETIC CHANGE

Every new mutation must have originated in a single individual at a specific location in space. This means that the spread of a mutation through a species is a spatial process, and it is possible to gain some insight into historical migration patterns through the analysis of geographic samples of gene sequences. Moreover, the coalescent framework has been refined to include spatial considerations, so migration rates can be quantified. Efforts to measure migration are still in very early stages, but contemporary data suggest that plants and their genes have been quite mobile over long periods of time.

There is great contemporary concern over the spread of so-called transgenes from agricultural plants into wild or weedy relatives through migration. This question has stimulated much work on the direct measurement of migration in plants. Current results suggest that gene migration rates may be higher than previously believed.^[10]

CONCLUSION

Although population genetics is a mature science with a history of nearly 100 years, it is more relevant today than ever. The theoretical models of population genetics provide the conceptual and statistical tools to address important questions ranging from concerns about transgene escape to detection of the influence of selection on specific genes. As the body of genome sequence data expands, these tools will become ever more important in interpreting and mining this new resource.

Population Genetics of Plant Pathogenic Fungi

Bruce A. McDonald

Swiss Federal Institute of Technology (ETH), Zürich, Switzerland

INTRODUCTION

Pathogens evolve. As a result of pathogen evolution, resistance genes and fungicides can rapidly lose their effectiveness in agroecosystems. To understand the processes that drive pathogen evolution, we must understand pathogen population genetics. The population genetics of all organisms is determined by interactions among five evolutionary factors: mutation, random drift, mating/reproduction system, gene flow, and natural selection. The end result of interactions among these factors is the population genetic structure of a species.

GENETIC DIVERSITY AND POPULATION GENETIC STRUCTURE

Genetic structure (often called population structure) refers to the amount and distribution of genetic diversity within and among populations. Because many pathogens have an asexual reproduction phase, pathogen genetic diversity has two components, gene diversity and genotype diversity. Gene diversity is determined by the number and frequencies of alleles at individual loci within a population. Genotype diversity is determined by the number and frequencies of genetically distinct individuals in a population. Measures of genetic diversity are especially important when considering the evolutionary potential of a pathogen population. According to Fisher's Fundamental Theorem of Natural Selection,^[1] the rate of increase in fitness of any organism is proportional to its genetic variance in fitness. In other words, pathogen populations with greater genetic diversity are expected to evolve more quickly than populations with less genetic diversity. Thus we begin to learn about pathogen population genetics and evolutionary potential by analyzing the genetic structure of pathogen populations.

THE FIVE EVOLUTIONARY FORCES

Mutation is the ultimate source of genetic variation, causing changes in the DNA sequence of a gene and

creating new alleles. Mutations are rare and would not cause pathogen evolution if they operated in isolation. But when mutation is coupled with selection, mutants can increase in frequency rapidly and cause significant changes in allele frequency. Mutations from avirulence to virulence and from fungicide sensitivity to fungicide resistance are especially important in agriculture.

Population size affects the probability that mutants will be present, and also influences the diversity of genes in populations through a process called random genetic drift. Large populations have more mutants than small populations because mutation rates are relatively constant and usually quite low. Thus, large populations are expected to have greater gene diversity (more alleles) than smaller populations. Genetic drift occurs when a small random subset of a population survives a catastrophic event that causes a severe reduction in population size (a bottleneck) or when a small random subset of a pathogen population colonizes a new host population (founder event). The frequency of mutant alleles in the surviving or founding population can differ significantly from the frequency of the mutant alleles in the original population. Founder events often occur in plant pathology when a disease is introduced into a new area by accident or as a result of a breach of quarantine. Bottlenecks often occur at the end of a growing season when the crop is harvested or during a crop rotation that reduces overseasoning pathogen inoculum.

Gene flow is a process in which particular alleles (genes) or individuals (genotypes) are exchanged among geographically separated populations. For strictly asexual organisms that do not recombine genes with the recipient population, entire genotypes are exchanged among populations (genotype flow). Gene flow substantially increases population size by increasing the size of the genetic neighborhood over which genes or genotypes are exchanged. Gene/genotype flow is the process that moves newly arisen virulent mutant alleles among different field populations. It is clear that the size of the genetic neighborhood is affected by the method of natural dispersal of pathogen propagules. Pathogens with air-dispersed spores are likely to have a larger genetic neighborhood than soilborne pathogens. But humans move many pathogens beyond their natural dispersal limits as a result of intercontinental travel and global commerce.

Reproduction and mating systems affect the way gene diversity is distributed within and among individuals in a population, leading to differences in genotype diversity. Pathogen reproduction can be sexual, asexual, or mixed (having both sexual and asexual components). Mating system is relevant only to the sexual component of reproduction, and can vary from strict inbreeding to obligate outcrossing. Some pathogens (e.g., all *Fusarium oxysporum* formae speciales and most bacteria) reproduce only asexually in agroecosystems. These pathogens exist as a series of discrete clones or clonal lineages with little evidence of recombination among clonal lineages. Populations of these pathogens usually exhibit a low level of genotype diversity. In strictly asexual pathogens, measures of genotype diversity are more meaningful than measures of gene diversity because most of the genetic diversity is distributed among clonal lineages. An advantage of sex is that, with each generation, new combinations of alleles come together through recombination, leading to an increase in genotype diversity that may enable some component of the pathogen population to survive in a variable and potentially hostile environment (e.g., on a resistant host). A disadvantageous result of sex is that fit combinations of alleles (coadapted gene complexes) are broken up through recombination, so it becomes difficult to maintain groups of alleles that offer an advantage in specific environments. Sexual pathogens usually exhibit a high degree of genotype diversity, so measures of gene diversity are needed to compare populations. Pathogens with mixed reproduction systems have significant advantages over strictly asexual or strictly sexual pathogens. During the sexual cycle, new combinations of alleles (genotypes) are produced that can be tested in different environments. During asexual reproduction, combinations of alleles (genotypes) that are most fit are held together through clonal reproduction and may increase to a high frequency. Thus these pathogens can exhibit high levels of both gene and genotype diversity. The spatial and temporal distribution of clonal lineages within and among populations will depend mainly on the dispersal of the asexual propagules. If asexual spores are capable of long-distance dispersal, then the clone with highest fitness can become distributed over a wide area through genotype flow relatively quickly.

Selection is the force that is most easily managed in agroecosystems. The strong directional selection that occurs when a major plant disease resistance gene becomes widely distributed drives the increase in frequency of the virulent pathogen mutant that has the corresponding virulence allele. The many examples of resistance genes that are overcome by new pathogen strains offer abundant evidence that selection is efficient in agricultural ecosystems that are based on monoculture and genetic uniformity. Resistance gene deployment strategies that

impose disruptive selection, such as cultivar mixtures, can slow the evolution of pathogen populations and extend the usefulness of resistance genes.^[2]

AN EXAMPLE OF GENETIC STRUCTURE

By using selectively neutral genetic markers and hierarchical sampling to determine the genetic structure of pathogen populations, we can begin to understand the evolutionary forces that shaped these populations, and infer the importance of the individual evolutionary factors for each pathogen.^[3] Commonly used DNA-based marker systems include RFLPs, microsatellites, AFLPs, and DNA sequences. DNA fingerprints are used to identify clones within pathogen populations. To determine whether a pathogen population has a sexual component of reproduction, it is common to clone-correct the dataset, using only one representative of each clone in the analysis of underlying allele frequencies. For diploid pathogens, the starting point is to test for departures from Hardy-Weinberg equilibrium. If a population is at Hardy-Weinberg equilibrium, then there is no deviation between expected and observed genotypic proportions within loci, and associations among loci are random, a state called gametic equilibrium. For haploid pathogens, it is common to test for departures from gametic equilibrium (a state called gametic disequilibrium) in a clone-corrected dataset to determine whether a pathogen population is undergoing sexual recombination. Comparisons between populations are made by comparing allele frequencies to obtain measures of genetic similarity. Population subdivision is measured using F-statistics (diploid pathogens) or Nei's G_{ST} (haploid pathogens).

From a population genetics perspective, the best characterized fungal pathogen at this time is *Mycosphaerella graminicola* (anamorph *Septoria tritici*), which causes the septoria leaf blotch disease on wheat.^[4] Over 5000 isolates of *M. graminicola* from field populations around the world have been characterized for diversity in mitochondrial and nuclear genomes using a combination of RFLPs, DNA fingerprints, and DNA sequence loci. Field experiments were conducted to differentiate among the five evolutionary forces and obtain empirical estimates for each factor in an agricultural setting. Through population genetic analysis, we now know that *M. graminicola* has a mixed reproduction system, with sexual recombination occurring mainly between growing seasons but also during the growing season. Asexual spores move between plants by splash-dispersal and sexual ascospores move by wind. As a result, the typical field population is composed of a mosaic of overlapping clones, with few clones distributed over a spatial scale of more than a few meters. On average, each leaf is colonized by a different

pathogen genotype, and it is common to find many different genotypes within the same lesion on a leaf. Regular sexual reproduction maintains the two mating types at a 1:1 ratio through frequency-dependent selection, and unlinked loci are at gametic equilibrium. The genetic neighborhood is large as a result of long-distance movement of windblown ascospores, so that populations separated by 1000s of kilometers on the same continent are genetically very similar. Populations on different continents also are very similar, suggesting that the pathogen has been spread globally through infected seed. Approximately 80% of the world's genetic diversity is found within an area 1 m² in any field sampled anywhere in the world. Populations are stable over time and a large number of alleles are found at individual RFLP loci, suggesting that effective population sizes are large (at least 70 individuals per square meter). Selection coefficients associated with specific clones competing in field experiments were large, illustrating the potential for rapid evolution in field populations. Taken together, these findings well explain the observed rate of evolution in populations of *M. graminicola*.

CONCLUSION

Knowledge of pathogen population genetics can be applied to the development of resistance breeding strategies and gene deployment that may lead to resistance that is durable over long periods in the field, and can guide disease management strategies.^[1] For example, a wilt

pathogen such as *Fusarium oxysporum* that has low evolutionary potential as a result of strict asexual reproduction, low gene flow potential, and small population size may best be controlled by using single major resistance genes. A powdery mildew pathogen such as *Blumeria graminis* that has high evolutionary potential as a result of a mixed reproduction system, high genotype flow, and large population size may require quantitative resistance and an intensive resistance gene management strategy (such as cultivar mixtures) to obtain durable resistance.

Post-Translational Modifications and Recombinant Therapeutic Proteins

Lokesh Joshi

Miti M. Shah

C. Robert Flynn

Alyssa Panitch

Arizona State University, Tempe, Arizona, U.S.A.

INTRODUCTION

Bioengineered plants are being developed to produce a variety of recombinant macromolecules for biomedical and tissue and cell engineering applications. However, many of these therapeutics and biomaterials require posttranslational modifications for proper structural and functional characteristics, which are understudied in plants, especially in relation to the production of foreign proteins. Therefore an understanding and evaluation of some of the key biochemical events such as glycosylation and hydroxylation are essential before commercial-scale production and manufacturing of recombinant therapeutics can become commonplace. Here we provide a brief review of the various PTMs, with emphasis on glycosylation and hydroxylation, which affect proteins in the context of plant-derived recombinant therapeutics.

POST-TRANSLATIONAL MODIFICATIONS

Several eukaryotic proteins, including many proteins of therapeutic value, are processed by a series of modifications that occur during and after translation. These chemical modifications, called co- and post-translational modifications, play important roles in folding, structure, intracellular targeting, stability, and functioning of the proteins.^[1] Among PTMs, proteolytic cleavage, phosphorylation, glycosylation, and hydroxylation are some of the most frequently occurring and important modifications. All eukaryotic organisms can proteolytically cleave the initiating methionine and remove the N-terminal signal peptides on proteins destined for secretion. Phosphorylation and dephosphorylation of proteins are transient events and occur in all eukaryotic organisms.

Most cell surface and secreted proteins are non-reversibly glycosylated in the endoplasmic reticulum (ER) and the Golgi apparatus by covalent attachment of sugar residues to asparagine (*N*-glycans) or to serine/threonine (*O*-glycans) side chains in proteins, as described

in the following sections. In some instances, glycans are subjected to further modifications such as acetylation, sulfation, or phosphorylation. Glycosylation is known to impart a wide variety of functions in the cells, and, in many instances, glycosylation affects protein structure, solubility, stability, and function.^[2]

N-Linked Glycosylation

N-linked glycosylation is a co- and post-translational modification event, and requires the consensus amino acid sequence, Asn-Xaa-Ser/Thr (Xaa=any amino acid except proline), for carbohydrate attachment in the ER. N-linked glycosylation is initiated by the transfer of a preformed 14-sugar oligosaccharide unit, GlcNAc₂Man₉Glc₃ (GlcNAc=*N*-acetylglucosamine, Man=mannose, and Glc=glucose), from dolichol-pyrophosphate oligosaccharide to the appropriate asparagines (Asn) of the nascent polypeptide chain in the ER. All the further steps of glycan processing in the ER are catalyzed by specific exoglycosidases. Glucosidase I and II remove the glucose molecules, and α 1-2 mannosidase removes mannose residues to generate the GlcNAc₂Man₈ structure.^[3] These structures are transported to the Golgi apparatus, where further trimming of mannose residues takes place followed by addition of monosaccharides, which is carried out by sugar and linkage-specific glycosyltransferases.^[4] Eukaryotic expression systems (e.g., yeast, insects, plants, and mammals) are able to perform both N-linked and O-linked glycosylation. The initial steps of N-linked oligosaccharide biosynthesis in the ER are similar in all eukaryotic organisms. However, there are significant differences in the glycosylation process in the Golgi complex, resulting in distinct final glycan motifs in all these organisms.

In mammalian cells, N-linked oligosaccharide chains often possess terminal sialic acid (SA) and penultimate galactose (Gal) residues at the nonreducing end. These reactions are carried out by linkage-specific and substrate-specific sialyltransferases and galactosyltransferases,

respectively. The presence of terminal SA residues is, in most cases, essential for the extended half-life of the glycoproteins in the animal serum. Glycoproteins lacking SAs on their glycan chains are recognized as “foreign” by asialoglycoprotein receptors and immune cells, quickly removed from the serum, and destroyed.^[5] This property renders many nonmammalian-derived glycoproteins unacceptable for human therapeutics. Fungi (*Saccharomyces cerevisiae*, *Pichia pastoris*, and *Aspergillus niger*) are unable to process the oligomannose chain to hybrid and complex glycans; instead, fungi perform hypermannosylation, resulting in up to 50 (or more) mannose residues per glycan chain.^[6] Insect cells have the ability to perform sialylation either by their intrinsic nature, as shown with recombinant tissue plasminogen activator (tPA), by manipulation of culture conditions, or by metabolic engineering.^[7–9]

To date, no reports have been published regarding whether or not plants are able to perform sialylation on glycoproteins. However, significant progress has been made in recent years toward humanizing the glycan chains on plant-derived glycoproteins. Palacpac et al.^[10] and Bakker et al.^[11] described the expression of mammalian β 1–4 galactosyltransferase in cultured tobacco BY2 cells and tobacco plants, respectively. Both groups of researchers were able to produce N-linked oligosaccharide structures terminating with Gal β 1–4 linked to GlcNAc. The *Arabidopsis* genome database contains evidence of putative genes homologous to mammalian sialyltransferases and CMP-SA transporter genes, indicating that the genomic machinery to perform sialylation may exist in plants (MIPS *Arabidopsis thaliana* database).

Plant-derived glycoproteins also carry an α 1–3-linked fucose (Fuc) on the proximal GlcNAc residue as well as a β 1–2-linked xylose (Xyl) on the core mannose residue. According to some researchers, these two “plant-specific” sugar residues are immunogenic in mammalian systems.^[12] However, there are reports suggesting that the presence of these residues does not alter the immunogenicity of the plant-derived glycoproteins.^[13] The issue of immunogenicity/antigenicity of plant-specific glycans needs further attention.

O-Linked Glycosylation

Addition of glycans to the hydroxyl group of serine or threonine amino acid residues is known as O-linked glycosylation. In some cases, glycans are added to hydroxylysine, such as in collagen, or hydroxyproline, such as in plant cell wall glycoproteins. Unlike N-linked glycosylation, O-glycosylation occurs (initiation and maturation) in the Golgi complex and does not require a

lipid-linked carrier such as dolichol-phosphate. Each monosaccharide is added in a sequential manner to generate a short (one to four sugar residues per glycosylation site), linear, or biantennary oligosaccharide structure bound to the protein. Moreover, the requirements of a consensus amino acid sequence is not clear. As O-glycosylation occurs on a fully folded protein, only serine or threonine on the surface of a protein can be O-glycosylated.^[14] Addition of N-acetylgalactosamine (GalNAc) to serine/threonine is the most common type of O-glycosylation in mammals, which is commonly known as mucin-type, core-1 (Gal β 1–3GalNAc α –O–Ser/Thr) glycosylation. Core-1 is generated by the action of UDP-GalNAc:polypeptide N-acetylgalactosaminyltransferase (GalNAc transferase) and core-1 β 1–3 galactosyltransferase. Core-1 structure can be extended by the action of linkage-specific sialyltransferases and GlcNAc transferases.^[15]

N-glycosylation on recombinant proteins, and its biosynthetic pathway, is relatively well studied in plants, but very little is known about mammalian-like O-linked glycosylation on plant-derived recombinant proteins. A quick search of the *Arabidopsis* genome reveals the presence of candidate glycosyltransferases involved in O-glycosylation that are waiting to be characterized and functionally assigned (MIPS *Arabidopsis thaliana* database). Recently, the Gal β 1–3GalNAc disaccharide conjugated to a rice seed protein, glutelin, was reported.^[16] This study demonstrated that plants have the ability to recognize Ser/Thr as potential O-glycosylation sites and perform core-1 O-glycosylation.

Hydroxylation

Hydroxylation is the addition of an –OH group to the side chain of specific amino acids and occurs in many eukaryotic proteins. Lysine and proline are the two most common amino acids targeted for this modification. In plants, 4-hydroxyproline is primarily found on cell wall proteins known as hydroxyproline-rich glycoproteins (HRGPs) such as extensins, 4-hydroxyproline-rich lectins, and arabinogalactan proteins. Extensins, a family of insoluble plant cell wall glycoproteins, are the best-characterized HRGPs that contain multiple repeats of the pentapeptide Ser–4Hyp–4Hyp–4Hyp–4Hyp– sequences interspersed with tripeptide TyrLysTyr units.^[17] Most of the 4-hydroxyproline residues are O-glycosylated with oligoarabinosides. There is no published report on lysine hydroxylation on plant proteins.

In animals, 4-hydroxyproline, 3-hydroxyproline, and hydroxylysine are found primarily on collagens and other collagen-like proteins such as C1q of complement,

acetylcholinesterase, and mannose-binding proteins. The stability of collagens and collagen-like triple-helical domains in other molecules at physiological temperature is determined, to a large extent, by the hydroxylation of proline residues.

Prolyl 4-hydroxylase (P4H) (EC 1.14.11.2; procollagen-proline, 2-oxoglutarate 4-dioxygenase) catalyzes the formation of 4-hydroxyproline in collagens and other proteins with collagen-like sequences by hydroxylating preferably proline residues in the Y-positions of the -X-Y-Gly- sequences. In vertebrates, the enzyme is an $\alpha_2\beta_2$ tetramer with a molecular mass of about 240,000 Da, consisting of two types of monomers with molecular masses of about 63,000 Da (α subunit) and 58,000 Da (β subunit). Subcellular fractionation studies have demonstrated that P4H is located in the rough ER, and both the active enzyme tetramer and the protein disulfide isomerase (PDI) subunit (β) are soluble ER luminal proteins. The polypeptide chains of the fibril-forming collagens vary in their hydroxyproline content, in the range 92–126 residues per 1000 amino acids. Approximately 50% of the proline residues are hydroxylated.^[18]

The genome of *Arabidopsis thaliana* encodes six P4H-like polypeptides, one of which, a 283-residue soluble monomer, was cloned and characterized. Catalytically critical residues identified in animal P4Hs are conserved in this P4H, and mutagenesis of these residues led to complete or almost complete inactivation. The recombinant *Arabidopsis* P4H effectively hydroxylated poly(L-proline) and many synthetic peptides corresponding to proline-rich repeats present in plant glycoproteins and other proteins. Surprisingly, collagen-like peptides were also good substrates, with the V_{\max} with (Pro-Pro-Gly)₁₀ similar to that with poly(L-proline). The other five *Arabidopsis* P4H polypeptides have yet to be characterized.^[19]

In previous reports, plant cells were cotransformed with chimeric nonplant P4H to achieve hydroxylation of proline residues.^[20] However, with the cloning, characterization, and structural improvements of *Arabidopsis* P4H, the use of plant P4Hs to efficiently hydroxylate prolines may be a possibility in the near future.

CONCLUSION

Most eukaryotic proteins undergo cotranslational modification and PTM. There are over 200 PTMs known to date that occur on the N-terminus or C-terminus of the polypeptides and side chains of amino acids. Many proteins of pharmaceutical importance require some of these PTMs for their physicochemical and physiological

states. Plants are able to perform most of the mammalian-like PTMs, but the structural and underlying molecular and biochemical details of these modifications are very limited. With the emerging importance of plants as suitable expression systems for biomedically important proteins, a better understanding of plant PTMs is required.

Potassium and Other Macronutrients

Patrick H. Brown

University of California, Davis, California, U.S.A.

INTRODUCTION

The mineral nutrients K, Mg, Ca, and S are unique and highly varied with respect to their acquisition from the soil, distribution within the plant, metabolic roles, and deficiency responses. An exhaustive analysis of these processes is beyond the scope of this article, thus only a brief overview is provided. For each element, however, a more detailed description of a single physiological process that is either unique or broadly illustrative of an important principle in plant nutrition is provided.

POTASSIUM

Potassium is the most abundant univalent cation in the cytoplasm of plants. It forms only weak complexes and does not compete strongly with other cations in metabolic reactions. As a consequence of these physical and chemical characteristics, K is uniquely suited to serve as the primary inorganic cellular osmoticum and, through thereversible formation of complexes with soluble and insoluble anions, as a cytoplasmic pH buffer. The critical functions of K in plants include osmoregulation, turgor-related processes (e.g., tropisms, stomatal opening, and cell expansion) and counterbalancing of ions in the movement of sugars into the phloem.

Uptake and Cellular Compartmentation

The importance of K as a cellular osmoticum and pH buffer requires that the uptake and cellular compartmentation of K be tightly regulated and highly responsive to changes in local K availability and cellular K demand. The mechanism of transport of K across membranes is the best studied of all mineral elements and is broadly illustrative of the process of nutrient acquisition and regulation in plants.

In the early 1950s Emmanuel Epstein and colleagues at the University of California, Davis, provided important early insights into nutrient uptake by plants.^[1] Two mechanisms were postulated. The first, or high-affinity,

system operated at low external concentrations of K, was saturable, and could be described by Michaelis-Menton kinetics. A second mechanism operating at higher concentrations of K was postulated to be present either in the same or in different membranes (i.e., plasma membrane and tonoplast, respectively). With the completion of the genomic sequence from *Arabidopsis* and the advent of powerful molecular and biophysical techniques, it is now clear that transport of K is even more complex than originally envisioned. At least three gene families with a total of 34 individual genes are known to contribute to K uptake and transport. The various K transporters differ in their affinity for K and the specific mechanisms by which they facilitate uptake of K. These can be divided into high-affinity carriers (such as HKT1) and low-affinity channels, of which there are many examples (e.g., the KAT and SAT families). The HKT1 gene functions as a Na-K cotransporter that at high concentrations of Na preferentially transports Na and as such may contribute to salinity stress. The exact mode of action of these transporters remains uncertain, although the large number of K transporters with apparent redundancy likely provides plants with the capacity for closely regulated uptake of K under a variety of environmental conditions.^[2]

Functions of Potassium

The majority of functions associated with K occur by virtue of its role as an osmoticum for turgor-driven processes, as a counterion for charge balance associated with H⁺ and solute transport, and as a stabilizer of enzymes and proteins. The processes of both cell expansion and stomatal opening involve the active transport of large amounts of K into the vacuole. The subsequent accumulation of water in the cell results in the increase in cell turgor required for stomatal opening and cell expansion. Potassium functions in photosynthesis as the dominant counterion to photosynthetic H⁺ flux across the thylakoid membranes of chloroplasts. Potassium facilitates the loading of sucrose into phloem by providing the required osmotic potential in source tissues and through its role as a counterion for sucrose and H⁺ transport into phloem sieve tubes.

Deficiencies of Potassium

Potassium is sometimes required in amounts that equal or even exceed the requirement for nitrogen in crop plants that produce large amounts of carbon-rich structures such as grains, fleshy fruits, tubers, and nuts. The characteristic symptoms of K deficiency include marginal and tip burn of mature leaves. This is a consequence of the high mobility of K in the plant that favors K movement from old to young plant parts and of the role of K in water relations of the leaf.

CALCIUM

Plants require substantial amounts of Ca. Among the mineral nutrients, only N and K are required at higher concen-

trations. The functions of calcium in the plant fall broadly into two categories—structural and signaling. The structural role involves the formation of stable but reversible complexes in the cell wall and membrane. The signaling role is critical in several signal transduction pathways.

Uptake and Cellular Compartmentation

The majority of Ca in the cell is found in the apoplasm where it is either strongly bound in structures or present in exchangeable pools in cell walls or at the external surface of the plasma membrane. Calcium is not freely mobile in the phloem and is delivered to growing cells largely through xylem flow. As a consequence, Ca concentrations increase with tissue age and the supply of Ca may be inadequate to satisfy demand in apical meristems, leaf

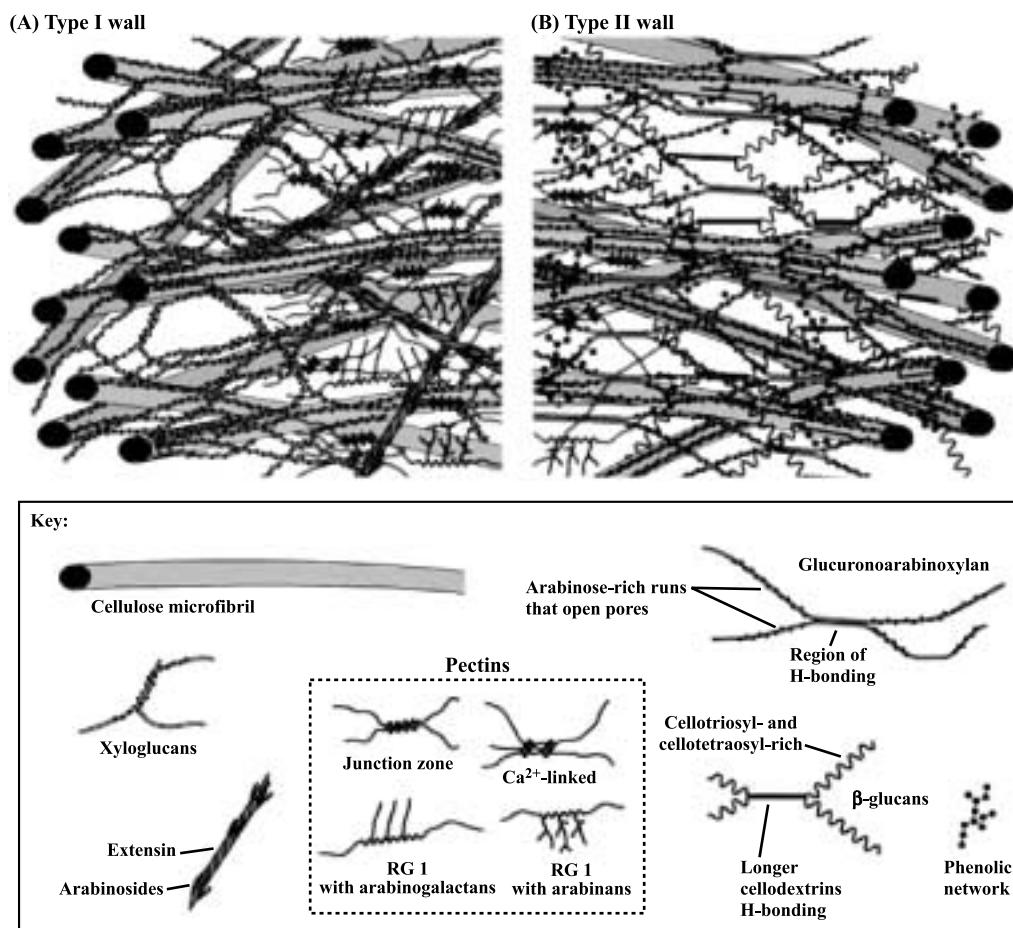

Fig. 1 A three dimensional molecular model of the Type I (non-grass) and Type II (grass) wall shows the molecular interactions between cellulose, xyloglucans, pectins and wall proteins. Pectin in the cell wall provides sites for Ca binding which then cross link with adjacent pectin HGA to form junction zones. The density of these junction zones and the degree of esterification as well as the distribution of borate di-esters (not shown) influences cell wall pore size, structure and function. (View this art in color at www.dekker.com.)

tips, and fruits with poor vascular connectivity and rapid growth. In contrast to the highly variable and unregulated accumulation of Ca in the apoplast, cytoplasmic Ca concentrations are extremely low and highly regulated. No fewer than four families of Ca channels, as well as a Ca^{2+} -ATPase, have been found in the plasma membrane, rough ER, tonoplast, and mitochondrial membranes. Two of these channels can be activated by ligands, whereas others are sensitive to voltage changes or activated by mechanical stretching.

Functions of Calcium

In plant cell walls the cellulose-xyloglucan framework is embedded in a pectin matrix. Pectin methyltransferase in the

cell wall cleaves some of the methyl groups from homogalacturonan (HGA) and provides sites for Ca binding, which then cross-link with adjacent HGA to form junction zones. The density of these junction zones and the degree of esterification as well as the distribution of borate diesters influences cell wall pore size^[31] (Fig. 1). In fruit ripening there is a solubilization of Ca that precedes the softening process. Spray application of Ca to fruits is widely practiced to increase the concentration of Ca in tissue and to delay fruit softening.

Calcium plays a critical role in the stabilization of the plasma membrane and is essential for the activity of membrane-bound enzymes and selectivity of ion uptake. In the absence of adequate Ca, membranes become leaky and ultimately disintegrate with a loss of cell

Fig. 2 Interactions of intracellular and extracellular Ca^{2+} in cell signaling. The relationships of Ca^{2+} stores in plant cells are known to be complex, concentrations of Ca^{2+} being high in organelles and in the cell wall and low in the cytoplasm. When the cell is signaled, channels are opened in various organelles or in the plasma membrane, allowing Ca^{2+} to enter the cytoplasm by diffusing down its electrochemical gradient. Ca^{2+} ATPases and perhaps $\text{Ca}^{2+}/\text{H}^{+}$ antiporters return the cytoplasmic concentration to resting value. Where known, subcellular concentrations of Ca^{2+} are indicated (quoted values in the ER vary from 0.1 to 1 mM). The concentration of cytoplasmic binding sites has been measured at about 0.15 to 1 mM. Free cytoplasmic Ca^{2+} is in equilibrium with these binding sites. Increases of cytosolic calcium, $[\text{Ca}^{2+}]_i$, activate calmodulin, thereby initiating subsequent downstream events. IP_3 , inositol 1,4,5-triphosphate. (View this art in color at www.dekker.com.)

compartmentation. A primary consequence of saline stress occurs when Na replaces Ca at membrane-binding sites, resulting in a loss of membrane functionality.

The internal concentration of Ca, $[Ca^{2+}]_i$, is a principle component in signal transduction pathways in plant cells. This role of Ca requires that cytosolic Ca concentrations (100–200 nM) be maintained many orders of magnitude lower than in the cell wall (1–10 mM). Changes in cytosolic Ca occur in response to a variety of environmental and developmental cues that initiate an opening of Ca channels and a rapid transient increase in $[Ca^{2+}]_i$. The increase in cytosolic $[Ca^{2+}]_i$ activates numerous Ca^{2+} -binding proteins (calmodulin and calmodulinlike protein kinases) that bind and activate a variety of target proteins. In this manner, changes in $[Ca^{2+}]_i$ initiate a wide range of responses, including stomatal closure, gravitropism, pollen tube orientation, and many others. The increase in $[Ca^{2+}]_i$ is dissipated by Ca-ATPases located in the tonoplast, ER, and plasma membrane (Fig. 2).

Deficiencies of Calcium

The critical role of Ca in cell wall formation and membrane stability requires that Ca always be present in adequate amounts in all meristematic tissues. Calcium transport within the plant, however, is largely passive, being driven by water movement and local diffusion. Only very limited Ca movement occurs in the phloem. Calcium deficiency often results in a rapid inhibition of growth and subsequent tissue necrosis. In fleshy organs (fruits, tubers), Ca deficiency results in membrane leakiness, reduced cellular cohesion, and enhanced tissue breakdown. This is particularly evident in fast-growing tissues where demand might exceed supply. Leaf tip burn in lettuce, bitter pit in apple, and blossom end rot in tomato are examples of disorders that are induced by Ca deficiency. Correction of these disorders requires that Ca supply be maintained throughout plant growth. Supplemental Ca applications postharvest can significantly increase storage life of fruits and vegetables.

MAGNESIUM

Magnesium is a divalent cation that functions primarily through the formation of ionic complexes with nucleophilic ligands and as a bridging molecule between phosphoryl groups and other molecules or enzymes. Magnesium uptake likely occurs through both channels and ATP-dependent pumps; however, the specific mechanisms of Mg transport are poorly understood. K^+ , NH_4^+ , Ca^{2+} , and Mn^{2+} each compete with Mg^{2+} for uptake and cause Mg^{2+} deficiency in plants from many environments.

Functions of Magnesium

Magnesium is essential for chlorophyll. Consequently, chlorosis and reduced photosynthesis are primary consequences of Mg deficiency. Depending upon Mg supply, Mg in chlorophyll varies from 6–60% of total cellular Mg. Magnesium also influences photosynthesis through its role as a regulator of Calvin cycle enzymes such as Rubisco and fructose 1,6 biphosphatase. Magnesium functions as a bridging moiety between enzymes and ATP. Hence, the substrate for ATP-ases, as well as inorganic polyphosphatases, is Mg-ATP rather than free ATP. In roots with sufficient Mg, as much as 90% of cytoplasmic ATP is complexed to Mg. Furthermore, ATP synthesis has an absolute requirement for Mg.

Deficiency of Magnesium

Interveinal chlorosis of the oldest leaves is a characteristic symptom of Mg deficiency. This is a consequence of the role of Mg in chlorophyll synthesis and the high mobility of Mg that results in export of Mg from old tissues to young when Mg becomes limiting. In many Mg-deficient crops, photosynthate accumulates in source leaves as transport to sinks is inhibited.

SULFUR

Sulfur is primarily acquired by plants as the sulfate anion (SO_4^{2-}). The majority of the SO_4^{2-} that enters the plant is then reduced to cysteine and is subsequently converted to methionine and a variety of secondary sulfur-containing molecules. Unlike nitrogen, which is always utilized in the reduced form, SO_4^{2-} may be directly incorporated into a variety of sulfated compounds, including sulfolipids in plant membranes. Animals and humans cannot reduce sulfur, and hence require dietary sources of cysteine and methionine to provide their sulfur needs.

Sulfur Uptake and Transport

Sulfate is relatively abundant in the environment, particularly in industrialized regions where gaseous SO_4^{2-} is present as a pollutant. Sulfate uptake is primarily mediated by a family of proton cotransporters located in various plant membranes. 13 SO_4^{2-} transporter genes have been identified in *Arabidopsis*. Many of these genes respond differently to SO_4^{2-} availability, and the full complex of transporters is likely essential for the normal regulation of sulfur metabolism.

Fig. 3 Overview of sulfur metabolism, reduction, and transport in plants. Like nitrate, sulfate uptake across the plasma membrane is energized by an electrochemical gradient that is maintained by a proton-pumping ATPase. Sulfate is stored in vacuoles. Reduction of sulfate and its assimilation into cysteine take place in plastids of root and leaf cells. APS, 5-adenylsulfate; PAPS, 3-phosphoadenosine-5'-phosphosulfate. (View this art in color at www.dekker.com.)

Functions of Sulfur

Sulfur-containing compounds function in a diverse array of metabolic processes, including as structural components of proteins and membranes; in redox and methyl-

ation reactions; and in the detoxification of herbicides, heavy metals, and oxidants. Sulfur-containing coenzymes and vitamins—including the ethylene and polyamine precursor S-adenosyl-L-methionine, coenzyme A, and S-methylmethionine—participate in group transfer and

methylation reactions in a variety of metabolic pathways (Fig. 3). The thiol group of cysteines present in proteins can be oxidized, allowing for the formation of disulfide bonds between adjacent cysteine residues. These cross-links are central in determining the tertiary and quaternary structure of proteins. The dithiol–disulfide interchange also occurs in a variety of sulfur-containing molecules (thioredoxin, glutaredoxin, and glutathione) and is critical for the maintenance of cellular redox potential. Glutathione, the major nonprotein thiol in plants, is central for cytoplasmic redox regulation, sulfur storage, heavy metal detoxification, environmental stress tolerance, and as a precursor to phytochelatins. Glutathione detoxifies many toxins and herbicides through the formation of glutathione conjugates that are transported to the vacuole by an ATP-binding cassette (ABC) transporter. Glutathione is also the precursor to phytochelatin ((γ -Glu-Cys)_n Gly), which plays a critical role in the detoxification of heavy metals such as Cd.

Sulfur Deficiency

Sulfur requirements (0.1 to 0.5%) vary between families (Gramineae < Leguminosae < Cruciferae) and reflect differences in sulfur content of proteins in these families. The most prominent feature of S deficiency is chlorosis, which occurs uniformly throughout the plant. The sulfur content and concentration of proteins declines in grains during storage and results in important changes in quality (in the case of baking flour) and value as animal feed. Deficiencies of S are most common in acid and leached

soils but are becoming more prominent worldwide as levels of pollutant S in the air decline.

Pre-agricultural Plant Gathering and Management

M. Kat Anderson

Natural Resources Conservation Service, University of California, Davis, California, U.S.A.

INTRODUCTION

During most of the 150,000 year history of humanity, people survived by the hunting and gathering lifestyle. Throughout this extensive period, many cultural groups developed a sophisticated understanding of the inner workings of nature. Hunter-gatherer groups around the world have relied upon hundreds of wild plant species for basketry, ceremonies, foods, furniture, poisons, traps, and weapons for millennia. Their hard-earned, detailed traditional ecological knowledge included information about how wild plants respond to gathering and cultivation. For certain plant species, indigenous people practiced judicious harvesting, adjusting the variables (season, frequency, pattern, scale, intensity, tool) of collecting to influence the growth and abundance of native plant populations. Prior to the invention of agriculture, many areas were also actively managed for increased densities and abundance of wild plants to meet an array of cultural needs. The land management practices that predate agriculture included burning, irrigating, pruning, transplanting, weeding, sowing, and tilling, applied to a multitude of habitat types. This article discusses examples of these practices, along with their potential ecological consequences, and puts forth a view of human-plant interactions as part of a continuum from gathering to domestication.

WILD PLANT MANAGEMENT FOR FOODS

Wild plant gathering for food was traditionally a female responsibility in most hunter-gatherer groups, whereas hunting and fishing were male activities. Many different kinds of plant parts were harvested for food. Small seeds and grains of wildflowers and grasses, and underground swollen stems from herbaceous plants are discussed here (Fig. 1, Tables 1 and 2).^[1,3]

Wildflower Seed and Grass Grain Management

Today, cereal grains such as wheat, oats, barley, rice, and corn are the most important of all food crops in the world. One of the oldest forms of sowing in the world is the

broadcasting of fruits of wild grasses and the seeds of wildflowers for food. This involves grain and seed selection, saving, and dispersing, often after some kind of ground preparation. It is from this repeated act of broadcasting, together with certain modes of harvesting, that cereal domestication arose.^[4] The harvesting strategy of seedbeating coupled with the horticultural techniques of saving and sowing seed, in conjunction with fire management, created ecological effects at the species, population, community, and landscape levels (see Fig. 2A). Seedbeating plants, burning vegetation, and sowing seed tended to select for specific genotypes that hold up well to and even thrive under human harvesting and management regimes.

The Bagundji traditionally repeatedly fired the grasslands in what is now New South Wales, Australia, to increase seed production of Mitchell grass (*Astrelba pectinata*). Patches of grass and brush were burned over to ensure a better crop of edible seeds by the Northern Tonto, Southern Tonto, and White Mountain Apache of the American Southwest. The Southern Paiute of the Great Basin sowed the seeds of Indian rice grass (*Achnatherum hymenoides*). California provides many case examples of tribes managing numerous landscapes to foster the growth and abundance of herbaceous plants for edible seed. The Central Sierra Miwok of the Sierra Nevada cultivated six kinds of seeds with burning, sowing, and harrowing in the Sierra Nevada foothills. Two of these are farewell-to-spring (*Clarkia purpurea* ssp. *viminea*) and mule ears (*Wyethia helenoides*). The Modoc, east Shasta, Achomawi, Northern Maidu, and Nisenan tribes of northern California sowed the seeds of many kinds of wild herbaceous plants.

Bulb, Corm, and Tuber Management

Perennial plants with underground storage organs offer rich sources of starch and other carbohydrates, as well as substantial protein and trace minerals. They were dug with a digging stick by hunter-gatherer groups (see Fig. 2B). Prior to domestication of the onion, potato, cassava, yam, and other underground swollen stems, indigenous people all over the world cultivated subterranean organs of wild plants for foods. This activity was perhaps the oldest form of tillage—one that became the precursory management

regime and provided the ecological foundation for the development of root crop agriculture in many areas. Specific strategies were employed to perpetuate populations of favored plants, such as 1) replanting of cormlets and bulblets; 2) deliberately breaking of the bulb above the root crown, leaving some stem and root tissue; 3) leaving an upper section of the tuber with a vine stem; 4) weeding around favored plants; 5) and burning of areas to decrease plant competition and recycle nutrients. Through human selection, protection, and replanting of offsets, certain geophyte species have probably undergone genetic changes. The excavation of plants with vegetative reproductive parts and the replanting or breaking off of such parts would likely select for specific genotypes that benefit under human disturbance regimes.^[5]

Gidjingali women in Arnhemland, Australia, still gather wild *ganguri*, a type of yam (*Dioscorea transversa*), with a digging stick, being careful to leave the vine stem and a small section of tuber behind, replanting it so that it will grow again. The San of South Africa traditionally burned the veldt at the end of the dry season to promote the growth and abundance of edible bulbs and tubers. The Nez Perce of the eastern Columbia Plateau in North America harvested camas (*Camassia quamash*), returning immature bulbs and half of the mature ones to the soil. The preferred digging season was after the seeds set to ensure a future supply. The Western Mono and Sierra Miwok of California harvested the corms of blue dicks (*Dichelostemma capitatum*), purposely breaking off the cormlets and replanting them.

WILD PLANT MANAGEMENT FOR BASKETRY

Making baskets is a worldwide phenomenon. Roots and branches of trees and shrubs, and the leaves and rhizomes of grasses, sedges, and ferns must be pliable, straight, long, and uniform, without insect or disease damage. Yet wild plants often exhibit crooked, brittle growth, with evidence of insects or diseases, making them unsuitable

Fig. 1 Native plants used by the pre-agricultural people of California. (A) Soaproot (*Chlorogalum pomeridianum*)—a very important plant to the majority of California tribes. The bulbs provided glue, fish poison, and food; the old leaf sheaths that clothe the bulb formed the bristles for brushes. The young edible leaves were roasted. The plant is still gathered today. (B) Flowerstalks of deergrass (*Muhlenbergia rigens*)—a perennial bunchgrass—are utilized in the foundation of coiled baskets by numerous California Indian tribes. (C) The now rare and endangered Hall's Wyethia (*Wyethia elata*) that grew prolifically in the montane forests kept open by Indian-set fires were significant for their edible seeds, gathered by the Western Mono of the western Sierra Nevada mountains.

Table 1 Cultural uses assigned to native plants by pre-agricultural peoples

Cultural use	Example
Adhesives	The Coast Salish of British Columbia used the pitch of western white pine trees (<i>Pinus monticola</i>) to fasten arrowheads onto shafts.
Basketry	The Makah and other tribes of Washington and British Columbia used (and still use) the pliable leaves of a sedge (<i>Carex obnupta</i>) in twined basketry.
Clothing	A leafy crown from the vines of <i>Mascagnia macroptera</i> was made by the Seri of the Gulf of California in Sonora, Mexico, for protection from the sun and to keep the hair in place.
Cordage	Bast fibers in stems of the perennial dogbane (<i>Apocynum cannabinum</i>) were twisted together to make a tough string used for fishing line, nets, tump lines, carrying bags, and bowstrings by tribes of the Pacific Northwest, California, and the Great Basin.
Foods	!Kung Bushmen of the northwest region of the Kalahari Desert relied traditionally on mongongo (mangetti) nuts (<i>Ricinodendron rautanenii</i>) for 50% of their vegetable diet. (Mongongo nuts have five times the calories and ten times the protein per cooked unit, compared to cereal crops.)
Games	Boomerangs are cut from bark of river red gum trees (<i>Eucalyptus camaldulensis</i>) and are used as toy weapons by aboriginal boys of central Australia.
Medicines	The Attikamek of Quebec used smashed roots of harlequin blueflag (<i>Iris versicolor</i>), a perennial wildflower, for a poultice to apply to burns.
Musical instruments	Hollow young branches of blue elderberry shrubs (<i>Sambucus mexicana</i>) are carved into clapper sticks and flutes by many California Indian tribes.
Structures	The Thompson of southern British Columbia used leaves and stems of broadleaf cattail (<i>Typha latifolia</i>) for mats, wall insulators, and in constructing temporary summer houses.
Tools	Paddles for guiding canoes were made of yellow cedar (<i>Chamaecyparis nootkatensis</i>) wood by the Tlingit of Alaska.
Utensils	Spoons were fashioned of bear grass (<i>Nolina microcarpa</i>) leaves by the Cibecue, White Mountain, and Tonto Apache of Arizona.
Weapons	The aborigines of Groote Eylandt in northern Australia made spear shafts of yellow hibiscus (<i>Hibiscus tiliaceus</i>) for use in hunting wallabies.

Table 2 Pre-agricultural peoples' management techniques

Operation	Description	Example
Burning	Application of fire to particular vegetation areas under specified conditions such as seasonality, fire return interval, and aerial extent to achieve select cultural purposes.	The Australian aborigines of Victoria dug up tubers of murnong (<i>Microseris scapigera</i>); gathering areas were historically burned over to increase production.
Irrigating	To supply select land areas with water by means of artificial channels.	The Owens Valley Paiute of the Great Basin artificially watered a host of plants such as wheat grass (<i>Agropyron</i> sp.), Great Basin wild rye (<i>Elymus</i> sp.), and blue dicks (<i>Dichelostemma capitatum</i>) to increase their productivity and abundance.
Pruning	To remove dead and living parts from native plants to enhance growth, form, fruit, or seed production.	The Timbisha Shoshone of the Great Basin pruned honey mesquite (<i>Prosopis glandulosa</i>), a very important food resource, keeping areas around the trees clear of undergrowth, dead limbs, and lower branches.
Sowing	The broadcasting of seed collected from native plants to an area (usually recently burned ground).	The Lummi Straits, Nooksack, and Nuuwahaha of the Pacific Northwest harvested the bulbs of camas (<i>Camassia</i> spp.) and placed broken stalks bearing ripe seed capsules into holes before they were recovered.
Tilling	The moving of soil to harvest underground perennial plant organs (e.g., roots, rhizomes, corms, bulbs), frequently followed by dividing of organs, leaving individual fragments or smaller clumps in soil.	The Dena'ina of Alaska purposely left fragments of underground swollen stems behind when digging to ensure the growth of new plants.
Weeding	Removing unwanted plants near favored plants.	Stands of sedge (<i>Carex barbarae</i>) along lowland creeks and rivers in central and coastal California were intensively weeded to encourage production of long, creeping rhizomes for use as weft or lacing in basketry by the Pomo, Ohlone, and other tribes.

for harvest. Many hunter-gatherer groups traditionally managed plant populations with burning, pruning, coppicing (severe pruning), and/or weeding to create useful growth. Clumps of beargrass (*Xerophyllum tenax*), a plant of widespread use for overlay designs in baskets of the

A

B

Pacific Northwest, were burned periodically by the Hupa, Karuk, Yurok, Chilula, and other tribes of northern California and Oregon to increase the production of stronger, more supple leaves. Over half the tribes in California relied on the harvesting of the flowering culms of deergrass (*Muhlenbergia rigens*) for the foundation (or stuffing) of their coiled baskets, and these culms are still gathered today. An ancient tradition among many tribes was to burn colonies of this perennial bunchgrass every two to five years to enhance flowering stalk production, clear out detritus, and keep shrubs and trees from encroaching. The Cibecue and White Mountain Apache in eastern Arizona burned willow (*Salix* sp.) and sumac (*Rhus trilobata*) to bring out the young shoots for basket weaving. Burning, pruning, or coppicing shrubs and trees such as maple (*Acer macrophyllum*), redbud (*Cercis occidentalis*), deerbrush (*Ceanothus integerrimus*), hazelnut (*Corylus cornuta* var. *californica*), and willow (*Salix exigua*) were standard practice among tribes throughout California. Willows and other species of shrub are subject to attack by a wide range of leaf-eating, stem-sucking, and wood-boring insects. Fire is also an effective agent to combat many kinds of diseases and insects.^[6]

VIEWING HUMAN-PLANT INTERACTIONS AS A CONTINUUM

In the repetitive gathering and cultivating of wild plant populations in specific areas over many years, nature was transformed at different scales of biological organization, from genetic to landscape scale. Thus, domestication of plant species grew out of a set of comprehensive land management systems and complex traditional ecological

Fig. 2 Plant gathering and management techniques used by the pre-agricultural people of California. (A) Cecilia Joaquin, a Central Pomo woman, collecting seeds with a seedbeater prior to 1924. Beating seeds of wildflowers and grasses with a shallow basket into a collection basket for food was the first in a series of management steps. Afterward, areas were burned to reduce plant competition and recycle nutrients; some of the seed was saved and broadcast in the burned area. These practices are recorded for tribes throughout western North America. (Photograph by Edward Curtis, courtesy of the National Anthropological Archives, Smithsonian Institution, #75-14715.) (B) A Wintu couple, Rosa Charles and Billy George, digging for yampah (*Perideridia* spp.) in 1931. The digging of many different kinds of bulbs and tubers with a hardwood digging stick, replanting propagules, and burning over areas to increase numbers, densities, and size of subterranean organs of wild plants for food was a common practice throughout the world. These had subtle yet significant effects in shaping the ecology of many ecosystems. (Photograph by J.P. Harrington, courtesy of the Santa Barbara Museum of Natural History.)

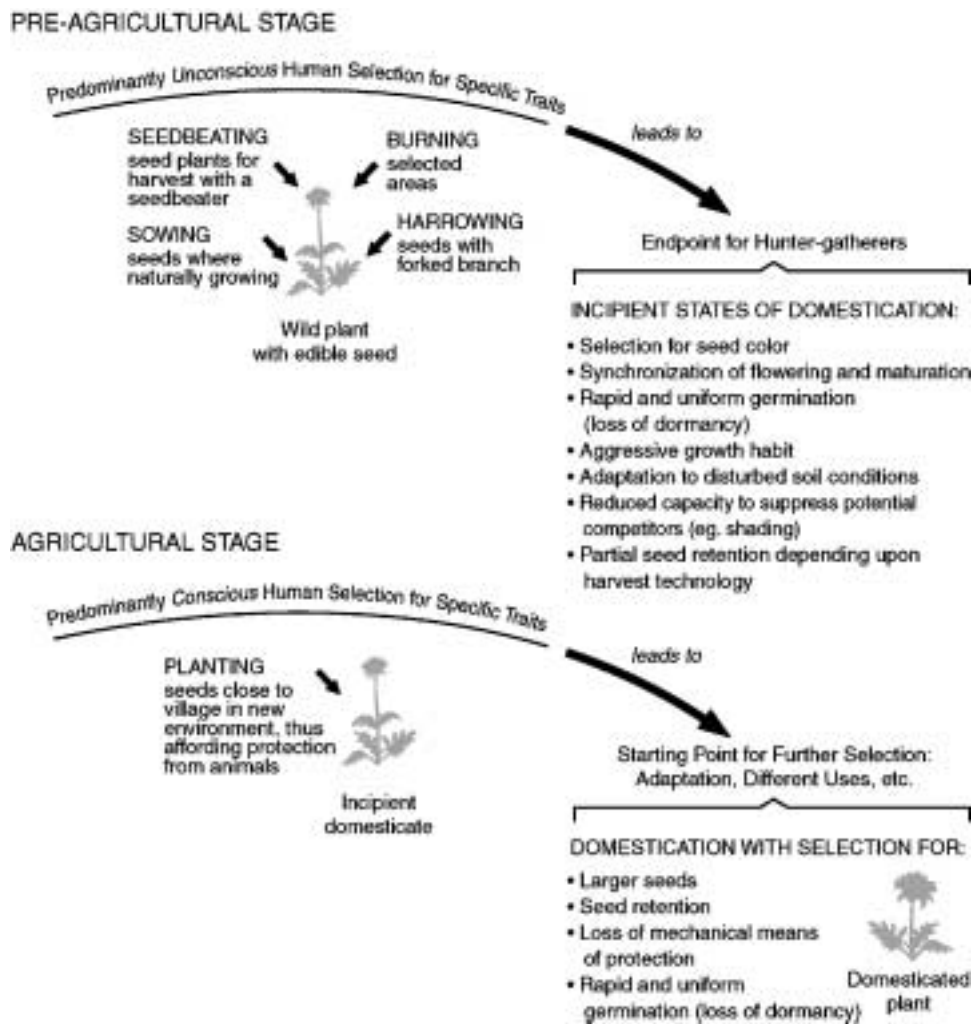

Fig. 3 The continuum of human-induced vegetation change from gathering to domestication can be conceptualized as two major stages on a gradient of ecological change induced by human modification. These stages are not clear-cut, but grade into each other. The diagram does not imply that given enough time, hunter-gatherers would advance from one level of interaction with plants to the next.

knowledge already in place in many different parts of the world for thousands of years prior to the origin of agriculture. Therefore, the distinction between domestic and wild in plant exploitation is not a sudden or marked change, but a gradual transition. Human-plant interactions can be appropriately viewed as a continuum from gathering to tending, to cultivation, to domestication.^[7,8]

In areas where plant domestication or the practice of agriculture never occurred, long-term cultivation practices with wild plants would still very likely lead to genetic changes that make plants better suited to the conditions of human-disturbed environments—such as burned over areas—and less adapted to the conditions of natural environments. The pathway of vegetation change that leads to seed domestication, for example, is probably a similar one in different areas. This pathway starts with selection pressures on plants in areas that are harvested repeatedly.

Nevertheless, certain types of harvest methods will not automatically lead to selection of the corresponding domestication trait (i.e., lack of seed dispersal). For example, beating wild plants to harvest seeds (Fig. 2A) will select against any mutant that has a stiff rachis. Thus, the selection pressure exerted in this case will not lead to domestication, at least from the standpoint of seed dispersal. Further along the pathway to vegetation change is the actual burning of areas, preparation of soil, sowing of seed, and harrowing of brush. These activities can, over time, favor specific features of the seed or plant, and produce faster or more robust growth, which favors survival and flourishing with reliable production to the point where full domestication is not necessary. The evolutionary modifications are significant enough to lead to incipient or intermediate states of domestication. It is proposed that these intermediate states are evident in certain kinds of

native plants labeled as wild. It can be postulated that systems of seed production of hunter-gatherer groups in many parts of the world evolved to a point on the continuum of human-plant interaction that stopped short of the endpoint of full domestication (see Fig. 3). Thus, domestication is but one kind of biologically defined symbiotic relationship, and the manipulation of wild plants for edible seeds is an example of the many other types.^[9]

Protein Quality in Transgenic Plants: Improvements

Jesse M. Jaynes

Kennesaw State University, Kennesaw, Georgia, U.S.A.

INTRODUCTION

Past expansions of the world's food supply have relied primarily on plant breeding directed toward improving yields, increases in available cultivable lands, and augmentation of irrigation techniques. Because we are now encountering further constraints in all of these areas, future emphasis must include enhancing the "nutritional content" of the world's basic food and feed crops, especially those that are indigenous to developing nations. Such nutritional enhancement can result in lowering per capita intake of plant-based food crops, ultimately making more food available for expanding populations. These developments are made possible through advances in the fields of biochemistry and molecular biology, which has caused the "biotechnology revolution."

The composition of plant storage proteins, a major food reservoir for developing seeds, roots, and tubers, determines the nutritional value of plants and grains when they are used as foods and feed for humans and domestic animals. The amount of protein varies with genotype or cultivar, but in general, cereals contain 10% of the dry weight of the seed as protein, while in legumes, the protein content varies between 20% and 30% of the dry weight. Roots and tubers retain far less, generally around 2–3%. In many seeds, storage proteins account for 50% or more of the total protein and thus determine the protein quality of seeds. Each year, the total world cereal harvest amounts to some 1700 million tons of grain. This yields about 85 million tons of cereal storage proteins harvested each year and contributes about 55% of the total protein intake of humans. It has been difficult to produce significant increases in the level of protein and essential amino acids of crop plants utilizing classical plant breeding approaches. This is primarily because of the fact that the genetics of plant breeding is complex and that an increase in either trait may be offset by a loss in other agronomically important characters. In addition, it is probable that the storage proteins are very conserved in their structure and their essential amino acid composition would be little modified by these conventional techniques.

With respect to human and animal nutrition, most seeds do not provide a balanced source of protein because of deficiencies in one or more of the essential amino acids in the storage proteins. Consumption of proteins of unbal-

anced composition of amino acids can lead to a malnourished state which is most often found in people inhabiting developing countries where plants are the major source of protein intake. Thus the development of a more nutritionally balanced protein for introduction into plants takes on extreme importance.

PAST WORK

Over the last two decades, much work has been performed in an attempt to improve the nutritional quality of plant storage proteins by transferring heterologous storage protein genes from other plants.^[1–3] The development of genetic engineering and the various gene transfer systems have made this approach possible. Genes encoding storage proteins containing a more favorable amino acid balance, by and large, do not exist in the genomes of major crop plants. Furthermore, modification of native storage proteins has met with difficulty because of their instability, low level of expression, and limited host range. However, there has been some success in recent years in improving the content of single amino acids using this approach. For example, 2S methionine-rich Brazil nut albumin (18% methionine) has been used to enhance levels of seed protein methionine in canola. A chimeric gene regulated by a phaseolin promoter was fused to the 17-kDa Brazil nut albumin and expressed in transgenic canola plant seeds. The methionine-rich protein exhibited temporal regulation with significant accumulation of the protein late in development, thereby correlating with that of wild-type 11S-canola seed protein. There was a 33% increase in the methionine level, as well as a 4% increase in the total protein level.^[4] In the case of Brazil nut 2S albumin, the highly allergenic nature of the protein, however, renders it unsuitable for use in food plants. A possible alternative to the chimeric gene approach would be to design *de novo* a more nutritionally balanced protein that retains certain characteristics of the natural storage proteins of plants, yet contains all of the essential amino acids at their proper ratio for the feeding of humans and animals.

The biosynthesis of amino acids from simpler precursors is a process vital to all forms of life as these amino acids are the building blocks of proteins. Organisms differ markedly with respect to their ability to synthesize amino

Table 1 Consumption necessary

Food stuff	Requirement in grams/day ^a
Cassava	4400
Corn	1800
Plantain	6100
Potato	2100
Rice	3100
Sweet potato	5760
Wheat	2300
Beef	170
Egg	180

^aThe values are what are necessary to consume in grams/day to achieve minimum daily requirement for all essential amino acids for a 10-year-old child. This assumes that the protein, in each foodstuff, is 100% bioavailable, and we know it is not, so these numbers should be increased to an even higher level.

acids. In fact, virtually all members of the animal kingdom are incapable of manufacturing some amino acids. There are 20 common amino acids that are utilized in the fabrication of proteins and essential amino acids are those protein building blocks that cannot be synthesized by the animal. It is generally agreed that humans require 8 of the 20 common amino acids in their diet: isoleucine, leucine, lysine, methionine, phenylalanine, threonine, tryptophan, and valine, to maintain good health.^[5] Protein malnutrition can usually be ascribed to a diet that is deficient in one or more of the essential amino acids. Therefore a nutritionally adequate diet must include a minimum daily consumption of these amino acids.

When diets are high in carbohydrates and low in protein, over a protracted period, essential amino acid deficiencies result. The name given to this undernourished condition is “kwashiorkor” which is an African word meaning “deposed child” (deposed from the mother’s breast by a newborn sibling). This debilitating and malnourished state, characterized by a bloated stomach and reddish-orange discolored hair, is more often found in children than in adults because of their greater need for essential amino acids during growth and development. In order for normal physical and mental maturation to occur, a daily source of essential amino acids is a requisite. Essential amino acid content, or protein quality, is as important a feature of the diet as total protein quantity or total calorie intake.

Some foods, such as milk, eggs, and meat, have very high nutritional values because they contain a disproportionately high level of essential amino acids. As mentioned previously, many plants are notoriously deficient in essential amino acids. The amino acid composition of

most plants is insufficient to sustain proper human growth and development. To rely solely on plants as a source of food (as so many people in developing countries must do) requires large intakes and mixtures of plant material to obtain all of the essential amino acids required to sustain life. To satisfy the minimum daily requirement of essential amino acids of a human child, a very unbalanced amount of plant foodstuffs are required as compared with the amounts necessary to consume from egg and beef (Table 1). As we know from experience, obtaining such essential amino acids from animal products creates an increasing demand on basic food crops such as corn, soybeans, and wheat. At this time, increases in animal production to meet future food needs are not viable options, at least through traditional methods.

PRODUCTION OF NOVEL PROTEIN

De novo artificial plant storage proteins have been designed to accomplish this nutritional goal.^[6,7] These proteins can be adjusted to accommodate any composition of essential amino acids desired for the consumption by animals and humans, based on any parent crop. Moreover, unlike many storage proteins found naturally in plants—that are only “partially” bioavailable to those consuming them—the proteins produced as a result of these designs are near 100% bioavailable. In collaboration with Dr. Marceline Egnin and Dr. C.S. Prakash, of Tuskegee University, we have introduced one of these artificial

**Fig. 1** Amount necessary to consume.

plant storage protein genes into sweet potatoes. Several years of field trials have been completed and small animal feeding studies have been conducted. The results of this work have been most promising. The roots of this transgenic plant T5 contain a more balanced amino acid composition provided by the new gene, as well as substantially higher levels of overall protein content^[8] (Fig. 1). Thus we have within our grasp the capability of producing indigenous, edible plant foodstuffs and feedstuffs for humans and domesticated animals that would be efficient, cost-effective, and provide complete protein and essential amino acid sources; no supplementation with animal protein sources would be necessary. It is estimated that the total food or feed intake necessary to meet these daily needs could be reduced by more than 75% after this technology is implemented.

CONCLUSION

Improving the essential amino acid composition of basic food and feed crops, as well as increasing their overall protein content, can make a major contribution toward helping to meet the world's future food needs. That advancement combined with conference of disease and stress resistance could result in a better-fed world in the future.

INTRODUCTION

Isolated plant protoplasts have several biotechnological applications, including their fusion to generate novel somatic hybrid and cybrid plants and the production of transgenic plants expressing specific characteristics. Normally, plant breeders rely upon sexual hybridization to combine useful genetic traits from different species or genera, but hybridization may be impeded by natural complex incompatibility barriers. The fusion of protoplasts isolated from somatic cells circumvents such barriers. Unique combinations of nuclear and organellar genomes generate novel germplasm; during protoplast fusion, there is no strict maternal inheritance of organelles, unlike in sexual hybridization.

FUSION OF ISOLATED PROTOPLASTS

Protoplast fusion can be induced chemically or electrically, or by a combination of these techniques, using small- or large-scale procedures.^[1] Plasma membranes of protoplasts destabilize during fusion, establishing cytoplasmic continuity between tightly adhering protoplasts. Polyethylene glycol (PEG) is a common fusogen, sometimes in combination with high pH and Ca^{+2} .

Electrical fusion of protoplasts is more reproducible than chemical fusion and often gives greater fusion frequency. Versatile electrofusion instruments can be constructed.^[2] Prior to electrofusion, isolated protoplasts are suspended in a medium of low conductivity [e.g., mannitol with CaCl_2] to stabilize plasma membranes. Exposure of protoplasts to an alternating current of 0.5–2.0 MHz at 100–400 V cm^{-1} induces protoplasts to align into “pearl chains” perpendicular to the electrodes; increasing the field strength induces close membrane-to-membrane contact. A subsequent direct current pulse of 10–200 micro-seconds and 500–2000 V cm^{-1} coalesces adhering plasma membranes at the poles of the proto-

plasts. Protoplast fusion normally occurs about 10 minutes after electrical treatment.

NOVEL HYBRIDS AND CYBRIDS GENERATED BY PROTOPLAST FUSION

Symmetric nuclear hybrid plants resulting from fusion are generally rare, with most being asymmetric hybrids. Plant breeders often require the introgression of a limited number of chromosomes, parts of chromosomes, or only organelles (chloroplasts and/or mitochondria) from one species into another. Consequently, effort has focused on generating asymmetric nuclear hybrids and cytoplasmic hybrids (cybrids). Cybrids are those with a nuclear genome of a given genus or species (recipient) with plastids from the other partner, or, more rarely, a mixed population of plastids from the recipient and donor. Cybrids harbor a mitochondrial genome partly or totally from the recipient or the donor, or novel mitochondria following recombination of recipient–donor mitochondrial DNA.

Asymmetric hybrid production is stimulated by treatment, before fusion, of protoplasts of one partner with X or gamma irradiation and exposure of the protoplasts of the other parent to a metabolic inhibitor (e.g., iodoacetamide). Irradiation stimulates partial genome transfer, the irradiated and nondividing but metabolically active protoplasts overcoming the inability of inhibitor-treated protoplasts to undergo mitosis. Frequently, somatic hybrid plants resemble the partner used as the source of the inhibitor-treated protoplasts.

GAMETOSOMATIC HYBRIDIZATION

Transfer of genetic information into cultivated plants can be achieved by generating addition or substitution lines via

the sexual production of generating triploids. Infrequently, triploids arise during the fusion of diploid protoplasts, as in *Citrus*. They can also be generated by fusing diploid with haploid protoplasts. The latter can be isolated from haploid plants.^[3]

PRODUCTS OF PROTOPLAST FUSION: SELECTION OF SOMATIC HYBRID TISSUES AND PLANTS

Fusion of protoplasts of the same genetic composition generates homokaryons, producing plants with increased ploidy. In contrast, heterokaryons from the fusion of protoplasts of different genetic composition have application in plant improvement, as they contain the nuclei of both parentals, initially in a mixed cytoplasm. The selection of heterokaryon-derived tissues and somatic hybrid plants remains a difficult aspect of somatic hybridization. In some combinations, heterosis (hybrid vigor) results in heterokaryon-derived tissues developing first in culture. Such tissues can be selected manually prior to plant regeneration.

Micromanipulation is useful when parental protoplasts are morphologically distinct. For example, fusion of suspension cell protoplasts with green leaf protoplasts generates heterokaryons initially with colorless plastids in one half of their cytoplasm and chloroplasts in the other half. Fluorochromes and flow cytometry can also be used in heterokaryon identification. Hormone autotrophism has also been exploited for hybrid selection.^[4] Complementation systems have been devised to select somatic hybrids. The most simple involves fusion of protoplasts of nonallelic albino mutants to generate hybrid cells that complement to chlorophyll proficiency in the light.

Auxotrophic mutants have been exploited in selection, the nitrate reductase deficiency of the *nia-63* mutant of *Nicotiana tabacum* being complemented by the chlorate-resistant line (*cnx-68*). Protoplasts of the mutants fail to grow on nitrate-supplemented medium. However, somatic hybrid cells undergo complementation and can be selected on nitrate-containing medium. Antibiotic resistant cells are also useful in selection. Dominant antibiotic resistant genetic markers can be introduced by transforming parental cells prior to protoplast isolation.

In addition to antimetabolites being used to promote cybridization, such compounds that inhibit cell development have been exploited in hybrid selection. In the somatic hybridization of *Lactuca sativa* with the wild species *Lactuca virosa*, hybrids were selected by inactivation of *L. sativa* protoplasts with iodoacetamide, combined with the inability of *L. virosa* protoplasts to divide in culture.^[5] Transformation to kanamycin resist-

ance has also been combined with metabolic inhibition to select hybrid cells and plants.

CHARACTERIZATION OF SOMATIC HYBRID PLANTS

Characterization of plants generated by protoplast fusion necessitates morphological, cytological, and molecular analyses. Traits characteristic of both parents may be readily apparent in somatic hybrid plants, with leaves, flowers, and pigmentation being intermediate between those of both parents. In other cases, characteristics from one parent may be dominant.

Theoretically, plants regenerated by fusing two diploid somatic cell protoplasts should be tetraploid, which is the case in some combinations. However, plants with complete chromosome complements of both parents are generally rare. Hybrids often possess an asymmetric combination of parental chromosomes, following elimination of parts of genomes during culture.^[6] The reasons for chromosome elimination are unclear. Some somatic hybrid plants are fertile; others may be sterile.^[7] Cytological analyses of backcross progeny provide evidence of parental chromosomal behavior during mitosis and meiosis following introduction of somatic hybrids into breeding programs. Flow cytometry can estimate the ploidy of plants and provide a baseline for cytological analyses. DNA fingerprinting^[8] permits detailed characterization of nuclear and organellar genomes of parental and somatic hybrid plants.

Organelle events are complex in somatic hybrids. Initially, heterokaryons contain a mixed population of organelles. Subsequently, plastids usually segregate, with those of one partner becoming dominant;^[7] in some cases, the plastids of both partners persist in hybrids. Recombination of plastid DNA is rare. Analysis of ribulose biphosphate carboxylase–oxygenase, linked to the chloroplast DNA restriction enzyme profile, confirms the parental origin of chloroplasts in somatic hybrids. Recombination of mitochondrial DNA commonly generates “new” organelles, as evidenced by the restriction enzyme digestion patterns.^[7] Importantly, DNA recombination in organelles increases genetic diversity arising from protoplast fusion.

Examples exist of the transfer of agronomical traits by protoplast fusion. Considerable effort has focused on the Solanaceae, such as potato and tobacco, together with the Brassicaceae. An excellent example is provided by studies in which protoplasts of *Solanum tuberosum* were fused with those of the wild potato, *Solanum bulbocastanum*,^[9] generating hybrids having improved resistance to late blight. Importantly, this resistance was transferred to other breeding lines by back-crossing.

TRANSFORMATION OF ISOLATED PROTOPLASTS BY DNA UPTAKE

Induction of DNA Uptake

The induction of transient pores in the plasma membrane permits uptake of DNA by chemical and/or physical procedures.^[10] Several agents induce DNA uptake into protoplasts, including salt solutions with Ca²⁺ at high pH and PEG. Electroporation, using short duration, high-voltage electrical pulses, often with PEG, is also used for DNA uptake into protoplasts. DNA has also been microinjected into protoplasts.^[11] PEG and electroporation remain the most successful procedures for protoplast transformation, even though the frequency is low and, at best, only about 1 in 10⁴ protoplasts develops into transformed tissues. Protoplasts can be transformed simultaneously with more than one gene, the genes being either on the same or on separate vectors.

Factors Influencing Protoplast Transformation

Parameters have been identified that influence protoplast transformation. The stage in the cell cycle is important, efficiency being higher when protoplasts are in the S or M phases. Consequently, it is beneficial to synchronize cells prior to or immediately following protoplast isolation. Heat shock or irradiation of protoplasts before DNA uptake also stimulates transformation, irradiation probably increasing recombination of genomic DNA with incoming DNA or initiating repair mechanisms that favor DNA integration. Complex integration patterns have been observed following DNA uptake into protoplasts.

MISCELLANEOUS STUDIES WITH PROTOPLASTS

Isolated protoplasts have also featured in physiological, ultrastructural, and genetic studies. Their development into colonies of single cell origin has been exploited to isolate clonal lines and plants, including those for increased secondary product synthesis. Exposure of isolated protoplasts to mutagenic agents or irradiation permits the induction and selection of mutants. Protoplasts take up macromolecules, which has been exploited in studies of endocytosis and virus infection and replication. The osmotic fragility of isolated protoplasts permits their controlled lysis for isolating cell components. In physiological studies, isolated vacuoles have been used to investigate sugar accumulation; protoplasts from barley aleurone cells contain protein storage vacuoles and a lysosome-like organelle, designated the secondary vacuole. Protoplasts

are ideal for studying ion transport and regulation of the osmotic balance of cells.

Light-induced proton pumping has been investigated in guard cell protoplasts. Other studies have focussed on cell fusion and metabolism in microgravity, elicitor binding sites, binding of fungal phytotoxins to plasma membranes, and auxin accumulation and metabolism. Protoplasts have also provided unique material for studying cell wall synthesis and the role of microtubules during cell development. Protoplasts from totipotent cells, are useful for assessing the effects of pharmaceuticals, food additives, cosmetics, and agrochemicals on plant cells, whole plants, and their progeny over seed generations.^[12]

INTRODUCTION

Plant protoplasts represent the living contents of cells, each bounded by a plasma membrane and enclosed by a cell wall. The plasma membrane is involved in wall synthesis. Consequently, there is usually intimate contact between these two structures. However, when cells are stressed osmotically, their plasma membranes contract away from their surrounding walls. Subsequent removal of the walls enclosing plasmolyzed protoplasts enables the latter to be isolated as spherical, osmotically fragile, “naked” cells. The isolation of large populations of protoplasts from a range of plants is now routine. Such isolated protoplasts are ideal for studies of cell development, physiology, and cytogenetics. When cultured in the laboratory, isolated protoplasts undergo wall resynthesis and mitotic division. Protoplast-derived cells may express their totipotency, regenerating into fertile plants under the correct physiological and physical stimuli. This feature, unique to plant cells, is exploited in genetic manipulation through somatic hybridization and cybridization, both involving protoplast fusion, and transformation by direct uptake of foreign DNA.

ISOLATION OF PLANT PROTOPLASTS

The physiological status and age of tissues is crucial for the isolation of viable protoplasts. While leaves of glasshouse-grown plants are a convenient source of protoplasts, seasonal variation in illumination, temperature, and humidity may necessitate the use of environmental cabinets to ensure uniformity of material. Generally, cultured shoots and *in vitro* grown seedlings are more uniform as source material than pot-grown plants. Haploid pollen tetrads and mature pollen will release protoplasts; cell suspensions are convenient and frequently exploited as a source of protoplasts.^[1]

Combinations of commercially available cellulase, hemicellulase and pectinase enzymes are used to release large populations of protoplasts. The cell wall composition of source tissues dictates the enzyme mixture required. Consequently, enzyme concentrations and conditions must be determined empirically for protoplast isolation from specific plant tissues.^[2] The time of enzyme digestion, usually at 25–28°C, may be of short duration (e.g., 4–6 hours) or overnight (12–20 hours). Removal of the lower epidermis or dissection of leaves into thin strips facilitates tissue digestion and protoplast release. Preconditioning of donor plants or explants by exposure to reduced illumination or preculture of donor explants on suitable media may increase protoplast yield and viability.

Passage of enzyme-protoplast mixtures through sieves of suitable pore sizes following enzyme incubation removes undigested cells. Gentle centrifugation (e.g., 100 × g; 10 min) through a suitable osmoticum [e.g., 13% (w/v) mannitol] generally pellets the protoplasts, leaving fine debris in suspension. Mixing protoplasts with 21% (w/v) sucrose in a salts solution,^[3] or with a solution of Percoll or Ficoll, followed by centrifugation, causes protoplasts of many species to float, facilitating their collection.

CULTURE OF ISOLATED PLANT PROTOPLASTS

Nutritional Requirements of Protoplasts: Culture Media

Protoplasts commence wall regeneration within hours of being introduced into culture. However, they require osmotic protection until they have regenerated a new primary wall of sufficient strength to counteract the turgor pressure exerted by the living cytoplasm/vacuoles.

Many media have been reported for protoplast culture. The nutrient-rich KM-type formulations^[4] are beneficial for culture of protoplasts at low densities; other media are often based on the well-tested MS^[5] and B5^[6] formulations. Ammonium ions are detrimental to some protoplasts, particularly those of woody species. Sucrose is the most common carbon source, although glucose may act as both a carbon source and osmotic stabilizer. Maltose stimulates shoot regeneration from protoplast-derived cells, especially in cereals.^[7] Most protoplasts require one or more auxins or cytokinins in the culture medium to sustain mitotic division.

Systems for Protoplast Culture

Incubation of isolated protoplasts in liquid medium in Petri dishes or in a shallow liquid layer overlaying semisolidified medium are simple methods of culture. The inclusion of a filter paper at the interface between the liquid and semisolid phases may stimulate cell colony formation. Isolated protoplasts can also be embedded in semisolidified media. Several gelling agents are available, with agarose often enhancing protoplast plating efficiencies (calculated as the percentage of the protoplasts originally plated that develop into cell colonies), compared with agar. Semisolid medium containing the protoplasts may be dispensed as layers or droplets (the latter about 100 μl in volume) in Petri dishes. Alginate is a useful gelling agent for heat-sensitive protoplasts. Following suspension of the protoplasts, the alginate-culture medium mixture is semisolidified by pouring the warm mixture in which the protoplasts are suspended over an agar layer containing Ca^{2+} or by gently dropping the molten medium into a solution of such ions.

Plating Density and Nurse Cells

The density at which protoplasts are plated in the culture medium is crucial for cell colony formation. Generally, the optimum plating density is 5×10^2 – $1.0 \times 10^6 \text{ ml}^{-1}$. At greater densities, protoplast-derived cells often fail to undergo sustained mitotic division because of rapid depletion of nutrients from the medium. Protoplasts also fail to grow when plated below a minimum density. Medium previously “conditioned” by supporting the culture of actively dividing cells for a limited period, will stimulate the growth of isolated protoplasts. “Nurse” cells are often employed to promote division of protoplasts in culture.^[7] When using nurse cultures, the isolated protoplasts can be embedded in a semisolid layer, suspended in a thin layer of liquid medium, or spread in

a liquid layer on a cellulose nitrate membrane, overlaying the semisolid medium containing the nurse cells.

INNOVATIVE APPROACHES TO PROTOPLAST CULTURE

Chemical Supplements for Culture Media: Surfactants and Antibiotics

Some antibiotics (e.g., cefotaxime) stimulate protoplast division, such compounds being thought to be metabolized to growth regulator-like molecule(s). Supplementation of medium with the nonionic, surfactant *Pluronic*[®] F-68, increases the plating efficiency of protoplasts in culture. Surfactants may increase the permeability of plasma membranes, stimulating uptake of nutrients from the culture medium into protoplasts and protoplast-derived cells.^[8]

Manipulation of Respiratory Gases

Gassing of vessels with oxygen after introducing protoplasts into the culture medium increases the plating efficiency of protoplasts of jute and rice. A further novel approach for regulating the supply of respiratory gases to cultured protoplasts involves the use of inert, chemically stable perfluorocarbon (PFC) liquids.^[9] Such compounds dissolve large volumes of respiratory gases and have been exploited in animal systems as oxygenation fluids.^[10] PFC liquids, being about twice as dense as water, form a distinct layer beneath aqueous culture media. Consequently, protoplasts and protoplast-derived cells can be cultured at the interface between the lower PFC layer and the overlaying aqueous medium. Experiments revealed that protoplasts in such systems exhibited increased superoxide dismutase activity associated with oxygen detoxification. Other regulators of respiratory gases, notably chemically modified haemoglobin solutions, may also stimulate the growth of protoplasts in culture. Supplementation of culture media with commercial bovine haemoglobin solution (*Erythrogen*TM) significantly increased the plating efficiency of rice protoplasts, compared to untreated controls.^[11]

Physical Methods to Stimulate Protoplast Growth

Physical parameters have been shown to stimulate protoplast growth, including the use of cellulose nitrate filter

membranes (0.2 μm pore size) at the liquid/semisolid medium interface, often in conjunction with nurse cells in the underlying semisolid medium. Insertion of glass rods vertically into semisolid agarose medium stimulated mitotic division of cassava leaf protoplasts in the overlying liquid medium, the protoplasts probably receiving increased aeration where they aggregate in the liquid menisci around the glass rods. Electrical currents, both low and high voltage, also stimulate mitotic division and cell colony formation from protoplasts of many species.

PLANT REGENERATION FROM PROTOPLAST-DERIVED TISSUES

The induction and sustaining of plant regeneration in protoplast-derived tissues by different pathways of morphogenesis (organogenesis; somatic embryogenesis) is dependent, in part, upon the culture conditions, in particular, the composition of the culture medium, and the inherent totipotency of the donor species. Plant regeneration, via organogenesis, has been reported to occur for more than 70% of those species capable of regenerating plants from protoplast-derived tissues, most notably members of the Compositae, Cruciferae, Leguminosae, and Solanaceae. In contrast, plant regeneration from protoplast-derived tissues via somatic embryogenesis is restricted predominantly to members of the Curcubitaceae, Gramineae, Leguminosae, Rutaceae, and Umbelliferae.^[12] In a limited number of genera, protoplasts may develop directly into somatic embryos through early polar growth of their derived cells, as in *Medicago*, *Asparagus*, and *Persea*.

CONCLUSION

During the last 40 years, considerable progress has been made in regenerating plants from protoplast-derived tissues of an increasing number of genera and species, driven by a need for regeneration as a platform for many aspects of biotechnology. It is interesting to note that it is only recently that protoplast-to-plant systems have been developed for specific genera, an example being provided by *Sorghum*, in which the establishment of such a protoplast-to-plant system required nearly 20 years of on-going research.^[13] An extensive literature is directed to plant regeneration from isolated protoplasts.^[12] The expression of totipotency from protoplast-derived tissues remains an absolute requirement for the multifaceted applications of somatic cell technologies involving pro-

toplasts, such as somatic hybridization, cybridization, and direct DNA uptake, in plant genetic improvement programs. The relevance of these applications are discussed elsewhere in this volume.

INTRODUCTION

Domestication of many of today's main food crops occurred approximately 10,000 years ago with the beginning of agriculture. It has led to the selection by farmers of a wide range of morphological and physiological traits that distinguish domesticated crops from their wild ancestors. These characteristics are collectively referred to as the domestication syndrome and include changes in plant architecture (e.g., apical dominance in maize), gigantism in the consumed portion of the plant (e.g., fruit size in tomato and eggplant), and reduced seed dispersal (i.e., nonshattering or nondehiscence, as in the common bean, sunflower, and cereals). Many investigations based on multidisciplinary approaches—such as genetic, archaeological, and phytogeographical analyses—have succeeded in identifying progenitor species and centers of domestication. However, the genetic and molecular bases of morphological evolution in plants under domestication are largely unknown.

Advances in genome mapping, which have resulted in high-density molecular-marker linkage maps in most crops, have provided tools for dissecting the genetic basis underlying complex traits into their individual components, i.e., their quantitative trait locus (QTL). This method relies on the frequent ability to cross the crop and its wild progenitor. It enables the characterization of genetic differences in terms of the number and chromosomal location of the genes as well as quantitative estimates of the kind and amount of genetic effects associated with individual loci. Recent studies have analyzed the genetics of the domestication syndrome of crops belonging to diverse families.

GENETIC BASIS AND ORGANIZATION OF THE DOMESTICATION SYNDROME

Many quantitative genetic analyses have focused on individual traits that are related to domestication but comprehensive analyses of the inheritance of the domestication syndrome^[1] as a whole are scarce.

Major vs. Minor Genes

Research has revealed that numerous traits that distinguish crop plants from their wild relatives are often controlled by a relatively small number of loci with effects of unequal magnitude.

Many qualitative traits are controlled by one Mendelian locus such as seed shattering in sorghum^[2] and pearl millet.^[3] But even the traits that are usually considered as exhibiting quantitative inheritance involve few QTLs of large effect plus others of more modest effect. The genetic study of an F₂ population derived from a cross of maize (*Zea mays* ssp. *mays*) and its wild progenitor, teosinte (*Z. mays* ssp. *parviglumis*),^[4] revealed that the domestication traits are controlled primarily by five chromosomal segments (Table 1). One of the major QTLs, *tb1* (*teosinte branched 1*), conditions the dramatic alteration in plant architecture from a multistemmed, branched plant to the single-stemmed plant most people are familiar with. Similarly, in common bean, seed dispersal (pod dehiscence), seed dormancy, and photoperiod sensitivity are all determined by a few loci with effects of large magnitude.^[5] In eggplant, most of the dramatic phenotypic differences in fruit weight, shape, color, and plant prickliness that distinguish domesticated eggplant,

Table 1 Genomic regions showing QTL clustering for domestication traits

Crop	Biology	Mapping cross (domesticated × wild forms)	Cluster	Attribute of the corresponding traits
Maize ^[4]	Outcrossing, $2n = 4x = 20$	F ₂ : <i>Zea mays</i> ssp. <i>mays</i> × <i>Z. mays</i> ssp. <i>parviglumis</i>	Chr 1	Shattering (ear disarticulation), growth habit, branching pattern (<i>tb1</i>), ear and spikelet architecture
			Chr 2S	Number of rows of cupules
			Chr 3L	Growth habit, ear architecture
			Chr 4S	Glume hardness (<i>tga1</i>)
			Chr 5	Ear architecture
Common bean ^[5]	Self-pollinated, $2n = 2x = 22$	F ₂ : <i>Phaseolus vulgaris</i> cultivated form × <i>P. v.</i> wild form	LG D1	Growth habit and phenology
			LG D2	Seed dispersal (pod dehiscence) and dormancy
			LG D7	Pod length and size
Rice ^[7]	Self-pollinated, $2n = 2x = 24$	F ₂ : <i>Oryza sativa</i> × <i>O. rufipogon</i>	Chr 1	Growth habit (tillering & height), shattering, panicle architecture
			Chr 3	Shattering, panicle architecture, earliness
			Chr 6	Shattering, panicle architecture, earliness
			Chr 7	Panicle architecture
			Chr 8	Growth habit (height), earliness, shattering
Pearl millet ^[3]	Outcrossing, $2n = 2x = 14$	F ₂ : <i>Pennisetum glaucum</i> ssp. <i>glaucum</i> × <i>P. glaucum</i> ssp. <i>monodii</i>	LG 6	Shattering, spikelet architecture, spike weight, growth habit
			LG 7	Spikelet architecture, spike size, growth habit and phenology
Sunflower ^[8]	Outcrossing, $2n = 2x = 34$	F ₃ : <i>Helianthus annuus</i> var <i>macrocarpus</i> × <i>H. a.</i> var <i>annuus</i>	LG 17	Shattering, apical dominance, achene weight, earliness
			LG 09	Achene size and weight, growth habit, head size
			LG 06	Growth habit, achene size and weight, earliness, head size
Eggplant ^[6]	Self-compatible, $2n = 2x = 24$	F ₂ : <i>Solanum melongena</i> × <i>S. linnaeanum</i>		No obvious colocalization

Solanum melongena, from its wild relative, *S. linnaeanum*, could be attributed to six loci with major effects.^[6] On this basis, early domestication is most likely to have been a process involving major genes, while subsequent changes may have occurred by the accumulation of minor mutations. Some domestication traits result from the loss of wild-type function and are associated with recessive mutations. However, mutations altering gene regulation are also reported (discussed later).

Clustered Distribution of QTLs

Another interesting feature of the inheritance of domestication traits in crop plants is that the loci for such traits are frequently clustered in a few chromosomal regions

(Table 1). This pattern of genetic correlations across traits due to linkage has been documented in some cases of domestications (Table 1). For example, in common bean^[5] and maize,^[4] QTLs underlying domestication traits are largely restricted to three and five genomic regions, respectively. In pearl millet, two regions of the genome control most of the key morphological differences of the spike and spikelet, including seed shattering.^[3] Each of the segments identified has an effect on related but also unrelated traits, suggesting that they could carry either a single mutation with pleiotropic effects or several mutations in linked genes. Linkage among domestication QTL is predicted to evolve under strong selection, especially in allogamous species. Eggplant is a predominantly self-pollinated crop and does not provide strong evidence for the colocalization of domestication syndrome traits.^[6]

Table 2 Domestication-related loci with putative conservation across the fabaceae,^[9,10] poaceae,^[2] and solanaceae^[6] families^a

INDEPENDENT SELECTION OF ORTHOLOGOUS REGIONS UNDER DOMESTICATION?

Comparative genetic mapping provides insights into the evolution of genome organization within the species investigated. A framework of common markers provides a basis for evaluating the correspondence between the locations of genes that confer common phenotypes. Many investigations have highlighted the preservation of the basic gene order, especially across grass species. Because similar traits have been selected during the domestication of crops belonging to the same family (e.g., Poaceae or Solanaceae), a common set of loci may also have been selected under domestication. The initial report of orthologous QTL noted that a genomic region that had the greatest effect on seed weight in mung bean and cowpea spanned the same restricted fragment length polymorphism (RFLP) markers in the same linkage order in both species. Later works showed that pea and soybean also contained this conserved genomic region (Table 2). Another study^[2] described the comparative molecular analysis of QTLs associated with domestication of three crops, *Sorghum*, *Oryza*, and *Zea*, each on a different continent. Correspondence was evaluated among QTLs involved in sensitivity to photoperiod, shattering, and increased seed size. Genes/QTLs were found to correspond far more often than would be expected to occur by chance, suggesting that orthologous genes (i.e., homologous genes that trace back to a common ancestral gene as a result of speciation, so that the history of the genes reflects the history of the species) may be involved in the evolution of these phenotypes. In similar manner, comparison of the genomic locations of the eggplant fruit weight, fruit shape, and color QTL with the positions of similar loci in tomato, potato, and pepper revealed that 40% of the different loci have putative orthologous counterparts in at least one of these other crop species.^[6]

Overall, the results suggest that domestication within each family has been driven by mutations in a very limited number of homologous loci that have been conserved throughout the evolution of the different species. Correspondence in location of QTLs in different taxa does not prove identity between the underlying genes, but it does suggest the identity of some of them.

FROM MORPHOLOGY EVOLUTION TO MOLECULAR EVOLUTION

Plant domestication offers a powerful system for studying the genetic and developmental basis of morphological evolution. Cloning the genes that largely control the

differences between wild and domesticated plants provides the opportunity to examine the effects of selection on domestication genes at molecular and physiological levels, identify characters that are relevant for future crop improvement, and infer the history of domestication. The discovery of loci such as *tb1*^[11] in maize or *fw2.2*^[12] in tomato represented cases in which the evolution of better adapted phenotype was largely governed by a single locus, and the genes underlying each locus were subsequently identified and analyzed.

In tomato, a QTL, *fw2.2* changes fruit weight by up to 30% and appears to have been responsible for a key transition during tomato domestication. By applying a map-based approach, the gene responsible for the QTL was identified: *ORFX*.^[12] This gene has a sequence suggesting structural similarity to the human oncogene *c-H-ras* p21. Alterations in fruit size, imparted by *fw2.2* alleles, are most likely due to changes in upstream regulatory sequences rather than in the sequence and structure of the encoded protein. The large- and small-fruited alleles differ in the timing of *fw2.2* transcription (heterochronic allelic variation) by approximately 1 week and in total transcript level.^[13] Moreover, these differences are associated with concomitant changes in mitotic activity and are sufficient to cause a major change in final fruit mass. The large-fruit allele of *fw2.2* arose in wild populations long before being fixed in most domesticated tomatoes.^[14] However, despite the fact that this allele was likely a target of selection during domestication, it has not evolved at distinguishably different rates in domesticated and wild tomatoes.

The most thoroughly analyzed domestication gene is *teosinte branched 1* (*tb1*) in maize. It was shown to correspond to a QTL involved in apical dominance. During

Fig. 1 Predicted structure of *teosinte branched1* (*tb1*) and analysis of polymorphism (π) in maize and teosinte. (From Ref. 11.)

development, *tb1* acts as a repressor of axillary branch growth in those organs in which its RNA messenger accumulates. The difference in mRNA accumulation in between maize and teosinte alleles suggests that the evolutionary switch involved changes in the regulatory regions of *tb1*. Indeed, population-genetic analysis of nucleotide polymorphism in *tb1* from a diverse sample of maize and teosinte indicates that a strong selective sweep has occurred during domestication in the 5' NTR region of the gene but not in its coding region (Fig. 1).^[11] It was also inferred that the process of domestication could have taken at least several hundred years to bring the maize allele of *tb1* to fixation.

CONCLUSION

The archaeological record indicates that the domestication process of a crop, once initiated, may have been rapid, possibly encompassing only the few hundred years needed to fix relevant alleles of key genes and of their modifiers. A better understanding of the genetic differences between wild plants and domesticated crops adds important facets to the continuing debate on the origin of agriculture and the societies to which it gave rise.^[15] The study of crop domestication is also an opportunity for scientists who seek to understand the genetic basis of plant growth and development. The molecular dissection of complex traits through breeding approaches, coupled with the parallel analysis of gene expression, promises to add much to our understanding of the relationships between molecular polymorphism and phenotypic diversity and the genetic basis and evolutionary dynamics of adaptation.

Quantitative Trait Locus Mapping of Agronomic Traits

Mark E. Sorrells

Department of Plant Breeding and Genetics, Cornell University, Ithaca, New York, U.S.A.

INTRODUCTION

A quantitative trait locus (QTL), also used for the plural, loci, is the location of a gene(s) that affects a trait that is measured on a quantitative scale. QTL mapping has its basis in quantitative genetics theory but uses molecular genetics to “Mendelize” quantitative traits. The realization in the early 1900s that discrete Mendelian inheritance could not explain the inheritance of a large number of traits, resulted in numerous debates and theories that spawned a large subdiscipline devoted to understanding the genetic control of traits that exhibit a continuous distribution of phenotypes. The breakdown of discrete classes of phenotypes is caused by both multigenic inheritance and influence of non-genetic factors (environment). Examples of quantitative traits include plant height, grain yield, seed size, lodging resistance, and many other agronomic traits. Thus, mapping a QTL is not as simple as mapping a single gene that affects a qualitative trait (such as flower color). Linkage between a genetic marker and a QTL was first demonstrated by Sax^[1] in a study that reported an association between bean seed coat color and seed weight. The major limitations to earlier studies using visible markers were the number of useful, discrete markers and their poor distribution in the genome. Those limitations were alleviated in the early 1980s by the advent of isozyme and molecular markers such as restriction fragment length polymorphisms. The feasibility of constructing saturated genome linkage maps paved the way for the molecular dissection of complex, quantitative traits. The purposes of QTL mapping are to elucidate the genetic control of a trait of interest, identify molecular markers for marker-assisted selection, and characterize the genes controlling traits of agronomic importance, most of which are quantitative.

GENERAL QTL ANALYSIS REQUIREMENTS AND STRATEGY

The essential requirements for QTL mapping are a complete (saturated) molecular marker linkage map, a population segregating for markers and traits of interest, linkage disequilibrium (LD), and phenotypic data for traits of interest. The general strategy used

in QTL mapping is to first classify progeny by marker genotype, followed by a comparison of phenotypic means between marker classes to determine if the difference is statistically significant, and then to calculate the difference between the means for an estimate of the QTL effect. A QTL experiment is usually designed to maximize the amount of genetic variation in the mapping population to increase the statistical power for mapping QTL, and to provide genetic information such as linkage phases and recombination of markers. A number of different kinds of QTL analyses have been developed, some of which take advantage of the data structure to improve the accuracy of the analyses.

Single-marker or single-point analysis is based on analysis of variance (ANOVA), *t*-test, or regression of an individual marker locus and the phenotypic data for the population. Association of a marker and trait can also be resolved using the likelihood approach by finding the joint distribution of marker genotypes and possible QTL genotypes.^[2] Because the exact location of a QTL may not coincide with a marker, single-marker tests are limited by the confounding of QTL genotypic means and QTL locations resulting in inaccurate estimates of QTL effects and low statistical power at low marker densities.

Simple interval mapping (SIM) can more accurately estimate the QTL location using either maximum likelihood,^[2] or regression analyses (less computationally intensive).^[3] SIM analysis uses information from markers flanking an interval to estimate the peak of the QTL (Fig. 1). Additive and dominance effects can be estimated using a three-genotype system for F₂ populations by using multiple linear regression.^[4]

CIM^[5,6] is a combination of SIM and multiple linear regression where background markers are used to reduce the residual genetic effects. When multiple QTL segregate, sampling error about the target QTL may be inflated by other QTL. CIM fits parameters for a target QTL in one interval while simultaneously fitting partial regression coefficients for “background markers” to account for variance caused by non-target QTL (QTL not being analyzed). Genetic variance caused by QTL other than the target is absorbed by the regression coefficients of the background markers. Compared to SIM, CIM produces more precise estimates of the location of the QTL and can often resolve closely linked QTL (Fig. 1). The choice of background

Fig. 1 A comparison of likelihood ratio (LR) plots from SIM and Composite interval mapping (CIM) illustrating the improved resolution possible by using background markers to minimize residual effects. (View this art in color at www.informaworld.com.)

markers is somewhat arbitrary, although stepwise regression is often used.

Association mapping (AM) differs substantially from the standard QTL analysis methods described above in terms of the populations used and the statistical analysis methods. In contrast to methods employing a biparental cross population, AM uses a collection of diverse genotypes that exhibit varying degrees of genetic relationship.^[7] The association between a trait and a marker depends on the degree of LD in the collection of genotypes used and the distance from the marker to the functional polymorphism. Consequently, in germplasm sets where LD is low, many closely spaced markers are required for whole genome coverage, and AM is typically restricted to regions of putative QTL based on *a priori* knowledge. AM is complementary to standard QTL analysis because information on the locations of QTL can be used with AM to fine map the QTL and assess the effects of multiple alleles in a collection of germplasm accessions.

Types of Populations

There have been QTL analysis procedures developed for a wide range of segregating populations including inbred-derived populations and outcrossing populations. F₃ families derived from individual F₂s are frequently used for species that tolerate some degree of inbreeding. They are quick and easy to generate and very efficient for estimating additive and dominant gene action. The primary limitation is often the amount of seed available for replicating genotypes for evaluation in multiple replicates and environments. There is also limited genetic recombination resulting in high LD and large QTL intervals. A backcross population is especially useful when one of the parents is unadapted or has traits such as seed shattering that interfere with evaluation of traits of interest. One advantage is that the products can be integrated into a breeding program. Backcross populations are limited in seed supply, difficult to

generate in some species, and cannot be used to estimate gene action (no recessive QTL alleles). Doubled haploid lines are moderately easy and quick to generate for some species but are not available for others. The main advantage is that the lines are true breeding and therefore can be used for evaluation in many environments. Dominant gene action cannot be estimated and with only one meiosis, genetic recombination is very limited. Recombinant inbred lines (RILs) are true breeding, relatively inexpensive, and easy to generate for many species. Also there is generally about twice as much genetic recombination as for doubled haploids. Highly outcrossing species that cannot be easily inbred include species such as potato, alfalfa, and sugarcane. Specific genotypes of these species are usually propagated by cloning. To generate a segregating population, two clones are crossed to generate a progeny that is already segregating and does not require additional inbreeding to construct a map. In fact, because we are sampling gametes from two different individuals (instead of one F₁ as described above for inbreeding) two separate marker maps are constructed, one for each parent that are later merged. For polyploids, markers that are polymorphic for loci on more than one chromosome can often be used to identify homologous groups. This type of population is quick and easy to generate and is very efficient for estimating additive and dominant gene action. For polyploids, allele detection for all homologous chromosomes is difficult and replication requires clonal propagation. Full and half sib families can be easy and quick to generate in some species. Such family structures can be efficient for estimating gene action provided there is adequate genetic variation and map resolution; however, seed supply may be limiting for some species.

QTL Mapping Using Distributional Extremes

When one is interested in only one quantitative trait in a cross, substantial time and expense can be saved by determining marker genotypes only for those progeny, which have extreme values, both high and low, for the trait. Most of the useful mapping information can be obtained from the 10–20% of progeny that have the highest trait values and the 10–20%, which have the lowest trait values.^[2] This practice may be called “selective genotyping” and is based on the idea that once a QTL has been mapped to a particular interval, only recombinant individuals are informative and contribute to greater mapping accuracy. Unfortunately, this concept is less likely to apply to pooling DNA from the extreme genotypes. While DNA pooling has been successfully applied to mapping genes that control nearly all the variance in a trait,^[8] there has been less success in applying this technique to QTL.

Statistical Considerations

Test statistics are an attempt to quantify Type I (probability that a QTL declared to be significant does not exist) and Type II (probability that a real QTL is not declared significant) error rates. The t -test or F -value is often used for single-marker analyses and the R^2 value reflects the portion of the phenotypic variance explained by that marker. For the maximum likelihood analysis, a likelihood ratio statistic (LOD) of the null vs. the alternative hypothesis is used (Lander and Botstein) (Fig. 1). The LOD threshold for significance is a function of marker density and genome size. Power refers to the probability of detecting a QTL of known magnitude, given experimental parameters that affect the frequency of false positive associations such as population size and map characteristics (Fig. 2). Depending on genome size and statistical test used, for many maps, LOD 3.3 corresponds to an experiment-wise Type I error of 5%, $\alpha = 0.001$. Because random error can inflate the test statistic, permutation was proposed to empirically establish significance without assumptions.^[10] Permutation analysis randomizes the relationship between genotype and phenotype thousands of times, each time reanalyzing the data, to establish an error rate for each variable in each

experiment. Simulations may produce conclusions that are specific only to the experiments analyzed owing in part to the distribution of markers in the genome.

Because most QTL are affected by the environment, QTL effects will vary by environment, resulting in QTL x environment interactions. Estimating this interaction is important to breeders and geneticists because it determines the predictability of the QTL effect from one environment to the next. Currently, multiple interval mapping is widely used. This analysis is based on a multiple QTL model that improves the precision and power of QTL mapping and allows for the identification of epistatic interactions, genotypic values, and heritabilities.^[11]

Trait dissection or QTL analysis of components of complex traits is often used because of the complexity of many quantitative traits. For example, grain yield may be broken down into seed size, seed number per spike, number of spikes per unit area, disease resistance, duration of seed filling, etc. Such traits may have higher heritability or be easier to measure.

Software

A large number of commercial and freely available computer programs are available, which implement

Fig. 2 Relationship between linkage map marker density, r^2 for a QTL, and population size. The population size necessary was calculated by $n_{B_1} = \left(\frac{1-r^2 B_1}{r^2 B_1} \right) \left(\frac{z_{(1-\alpha/2)}}{\sqrt{1-r^2 B_1}} + z_{(1-\beta)} \right)^2$ where $\alpha = 0.05$ and $\beta = 0.10$. (Adapted from Ref.^[9].) (View this art in color at www.informaworld.com.)

one or more of the analyses mentioned above. Those include MapMakerQTL, MAPQTL, QTL Cartographer, MapManger QTX, and Qgene, just to mention a few. A computer program called TASSEL is freely available for AM.

CONCLUSIONS

Molecular markers and QTL analysis have revolutionized our understanding of the genetics of agronomic traits. These tools are critical for elucidating the genetic control of a trait of interest, marker-assisted selection, and gene cloning. A wide variety of populations and analysis methods have been developed to identify the number and location of QTL in agronomic species.

Radiation Hybrid Mapping

Ron J. Okagaki
Ralf G. Kynast
Howard W. Rines
Ronald L. Phillips

University of Minnesota, St. Paul, Minnesota, U.S.A.

INTRODUCTION

Radiation hybrid maps are physical maps of genomes that provide an alternative to traditional genetic maps. These radiation hybrid maps have two important advantages over genetic maps. First, distances on a radiation hybrid map are determined by the frequency of radiation-induced breaks between markers. The distribution of breaks is believed to be random; therefore, distances calculated along a radiation hybrid map are proportional to physical distances. Genetic crossovers (used to determine genetic distances) are not randomly distributed, making it impossible to predict physical distances between markers from genetic maps in maize and many other plant species. Second, any sequence of interest is readily placed on a radiation hybrid map. In contrast, only polymorphic markers can be mapped on a genetic map. Individual markers for genetic mapping must have detectable differences between the parents of the mapping population. A monomorphic marker—one for which there is no apparent difference in the population—cannot be mapped. High-quality maps produced by radiation hybrid mapping have proven their worth in the human genome project, with over 30,000 sequences mapped. It is anticipated that radiation hybrid maps will be similarly useful in plants.

RADIATION HYBRID MAPPING

Radiation hybrid (RH) mapping was developed in the 1970s as a tool for mapping genes in humans. Improved analytical and molecular methods allowed Cox and co-workers to develop RH mapping into an effective tool.^[1] This work spurred further developments, and RH maps are now under construction or completed for the human genome and a number of other species.^[2,3] Current information about projects may be obtained from the Radiation Hybrid Mapping Page at <http://compgen.rutgers.edu/rhmap/>. One reason for the popularity of radiation hybrid maps is that these are physical maps. This property makes

RH maps particularly useful in assisting the construction of bacterial artificial chromosome (BAC) or yeast artificial chromosome (YAC) contigs. In this role RH maps are contributing to genome sequencing projects. Map information has other uses; with the degree of gene, chromosome, and genome duplication in plants, positional information is vital for identifying candidate sequences.

In the widely used whole genome approach (WG-RH), a donor cell line from the species being mapped is irradiated to kill the cells and fragment the chromosomes. Then donor cells are fused with recipient cells. Some of the chromosome fragments become integrated into the host chromosomes or are retained as a new chromosome consisting of numerous fragments joined together. Each radiation hybrid cell line retains between 10% and 50% of the donor genome, and a group of approximately 100 cell lines forms a mapping population or panel.^[3,4]

The likelihood that a break will occur between markers is directly proportional to the physical distance between them at a given radiation dose. This property of radiation hybrid lines underlies the methodologies used to analyze RH mapping data. Plus-minus PCR assays are used to detect the presence of markers in RH lines; polymorphic markers are not required for mapping. These data are analyzed by one of several approaches to produce an RH map. Distances between markers are expressed in centirays (cR). One cR represents a 1% frequency of breakage between two markers at a specific radiation dose. Breaks are assumed to be distributed randomly, and this makes it possible to relate centirays to kilobases of DNA. Examples of methods used to analyze RH mapping data may be found in Barrett^[4] and in references contained in Walter and Goodfellow.^[2] Computer programs for analysis of RH data may be accessed through the Radiation Hybrid Mapping Page.

Whole plants instead of cell lines may be used to create RH lines.^[5] The starting materials here were oat-maize addition lines containing a single maize chromosome in an oat background. RH lines were selected from among the progeny of irradiated oat-maize addition lines (Fig. 1). RH lines produced by this method have different characteristics from WG-RH lines. First, most RH lines

1. Oat x maize crosses
 – Selection of haploid oat plants with one retained maize chromosome
 – Production of doubled haploid F2 offspring with disomic maize chromosome addition

2. Production of fertile oat plants with one single maize chromosome (monosomic additions for each of the 10 maize chromosomes) by backcrossing the disomic oat-maize addition plants to oat

2/3 of F1 hybrids eliminate all maize chromosomes and retain all oat chromosomes
 1/3 of F1 hybrids retain one or more of their maize and all oat chromosomes
 Maize chromosome transmission can vary from 0% to 90% depending on the oat background

3. Gamma-irradiation of seeds with monosomic maize chromosome additions

4. Offspring production and selection of radiation hybrid (RH) lines with maize deletions and maize-oat translocations for each of the ten maize chromosome

5. Allocation of large numbers of molecular markers to the identified segments of the RH lines and construction of RH maps for each of the ten maize chromosomes based on the sizes and overlaps of the chromosome segments

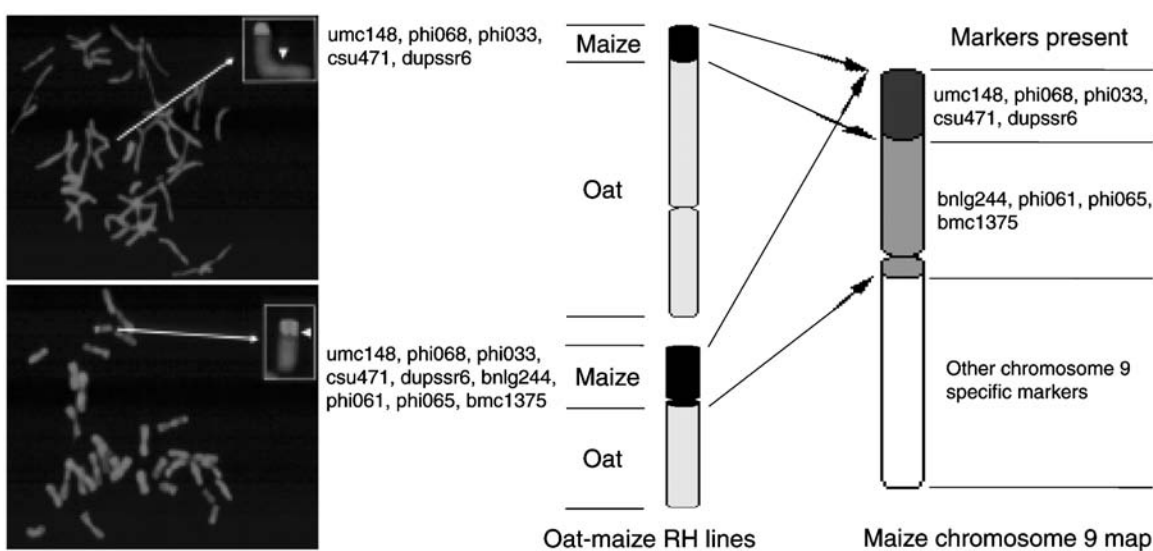

Fig. 1 Principal steps for development and use of oat-maize RH lines. A set of oat plants with a monosomic addition of one maize chromosome is produced from an oat x maize interspecies hybrid. Monosomic seed are irradiated to induce breaks in the maize chromosome. The maize chromosome fragments are transmitted either through their association with the maize centromere or through translocation to a centric oat chromosome fragment. In the segregating offspring, plant genotypes are screened for breaks by molecular and cytological means. The example shows two different oat-maize translocation plants that define three maize chromosome segments. (View this art in color at www.dekker.com.)

produced from addition lines appear to be stable (personal communication), whereas cell culture lines produced by the WG-RH approach are unstable. Second, lines produced from oat-maize addition lines have fewer chromosome breaks than do WG-RH lines. The need to maintain seed viability places limits on the level of chromosome breakage in oat-maize RH lines. A single contiguous fragment may be retained in these RH lines. With a few of these lines, markers may be quickly localized to a

chromosome segment. WG-RH lines retain many small fragments. Many WG-RH lines are required to map a marker, but the mapping can be very precise. The pattern of chromosome breaks in RH lines produced from addition lines may limit the practical resolution of these RH maps.

No WG-RH map from a plant has yet been reported. A variation of the WG-RH protocol is being developed in barley, where barley donor protoplasts are irradiated and

fused with tobacco recipient protoplasts.^[6] Results suggest that RH mapping can become a useful tool in plants.

OTHER PHYSICAL MAPPING APPROACHES

RH mapping represents only one approach to developing physical maps. Alien addition lines, such as the oat-maize addition lines, have been used for locating markers to chromosomes in several species. Aneuploid lines, nullisomic lines, and B–A translocation lines are also used to locate genes to chromosomes or chromosome arms. Examples of these systems are discussed elsewhere in this encyclopedia. Second, systems that fractionate chromosomes have been exploited to place sequences in sub-chromosome regions. Notable among this work are the wheat deletion stocks where hundreds of lines have been produced with cytologically characterized deletions.^[7] Work is ongoing to place molecular markers on these materials. A third approach is molecular cytogenetic maps. These are described in another article. Interest in plant genomics has fostered a desire for better physical maps of plant genomes. There are now several methods to make physical maps. Each approach has its own strengths and weaknesses for resolution, ease of development, and utility in particular species and applications.

STABLE RADIATION HYBRID LINES HAVE MANY USES

The primary reason for producing the oat-maize radiation hybrid lines was to develop a physical mapping system for maize. But mapping is not the only use for these materials. The stability of these materials allows other uses, three descriptions of which follow. First, chromosome pairing has been studied.^[8] Using the addition lines, the single pair of maize chromosomes can be specifically labeled and followed through meiosis in the addition lines. This greatly simplifies the task of observing chromosome behavior because only the maize chromosome is visible. With the RH lines it will be possible to study at the effect of removing specific chromosome regions. Specific chromosome landmarks (such as centromeres) can be isolated from other chromosome constituents in RH lines and observed. Second, flow cytometry can physically separate the maize chromosome from the oat chromosomes.^[9] It will be possible to make chromosome-specific libraries or libraries enriched for specific chromosome regions. Third, expression of maize genes in a foreign environment can be investigated. Ectopic expression of the *liguleless3* gene in chromosome 3 oat-

maize chromosome addition lines produces a characteristic hooked panicle phenotype reminiscent of the *liguleless3* mutant phenotype in maize.^[10] Other phenotypes have been associated with particular chromosome addition lines.^[11] Expression studies may determine the gene(s) responsible, and radiation hybrid lines may be an effective means to transfer traits from one species to another.

CONCLUSION

The set of oat-maize chromosome addition lines and RH lines is making important contributions to our knowledge of the physical organization of the maize genome. However, it is likely that BAC contig maps and genome sequencing will supplant RH maps and other physical maps of the maize genome for the purpose of mapping. RH mapping and other physical mapping techniques may remain useful in specific situations—for example, creating maps in species with very large genomes or where there is not the economic incentive to invest in contig maps and genome sequencing. The long-term value of RH mapping may therefore derive from other uses envisioned for the oat-maize radiation hybrid lines.

Recombination and Genetic Variation

Clifford F. Weil

Purdue University, West Lafayette, Indiana, U.S.A.

INTRODUCTION

Homologous recombination contributes to genetic diversity by breaking associations between alleles of genes on the same chromosome. Recombination can also produce translocated or inverted chromosomes, alter gene number in repetitive families, and, in some cases, create entirely new genes by mixing parts of existing genes and creating short regions of heteroduplex that result in mutations. The majority of recombination in plants occur during meiosis, although mitotic crossovers and recombinations among extranuclear genomes are also observed. Because plants form gametophytes late in development, all three contribute to genetic diversity. This review touches briefly on reciprocal and nonreciprocal genetic exchanges in plants, both meiotic and mitotic. The reader is referred to a rich and growing literature in this field (hardly done justice here), with apologies to those whose work is not cited because of space constraints.

Recombination and its role in genetic diversity can be studied at the population level where, for example, recombination contributes to increasing variation in fitness of individuals and may be favored under selective pressure. However, increasingly, diversity is assessed at the molecular level, and patterns of nucleotide diversity are correlated with patterns of crossover events along chromosomes. Overall, regions with lower recombination tend to show less sequence divergence, although this is not always the case.

The mechanics of recombination also influences genetic diversity in plants. For example, recombination does not occur uniformly throughout the genome and, in some species, shows different frequencies in male and female meiosis; the reasons for these differences remain unknown. Cytological studies of recombination and meiosis in plants over more than a century laid extensive groundwork for more recent genetic and molecular studies in maize, tomatoes, rice, *Arabidopsis*, and wheat, to name only a few. Additional levels of both complexity and control are being recognized in the recombination mechanism as a result of these studies.

MEIOTIC RECOMBINATION

Physical exchange between homologous chromosomes is an important step early in the alignment of chromosomes prior to full synapsis and is important for efficiently dispersing chromosomes during meiosis I. Proteins such as plant homologues of Rad51 and Dmc1 are implicated in homology searching between sequences,^[2] although the precise mechanism in plants remains unclear. Detecting homology becomes even more exacting in plants, where allopolyploidy can be relatively common. There, recombination generally occurs between homologous pairs, rather than between homologs.

Chromosome structure also plays an important part in dictating where recombination events between homologues initiate and the diversity of particular regions of a genome.^[1] For example, chromosomal inversions suppress diversity because recombinant products are typically lost as acentrics or dicentrics. It is also likely that interphase chromatin structure plays a key role in dictating where recombination events initiate. Individual genes that may suppress meiotic recombination would be of tremendous value because loss-of-function mutations in them would likely increase recombination, which is of great potential use to breeders.

At the other end of the process, points where sequence homology between chromosomes begins to break down (e.g., ends of genes, or, in some cases, ends of exons) are often frequent positions at which branch migration is stopped and Holliday structure resolution takes place.^[3] These positions are where recombinant sequence joints are located. Therefore proteins that control where exchanges are resolved help determine the limits of where sequence diversity will occur because of recombination. The Mus81 protein has been implicated as the resolvase enzyme in fission yeast and animals, although not in budding yeast, and a plant homologue has not yet been characterized. Interestingly, overexpressing a bacterial Holliday junction resolvase (RuvC) in plants stimulates somatic recombination,^[4] however, there is no evidence yet to support an increase in meiotic recombination.

Although the position of recombination events is one side of the coin, recombination frequency is the other. The rate of meiotic recombination is very likely under multiple levels of genetic control in many plant species. Variations in rate have been reported among accessions of *Arabidopsis* and between inbred lines in maize. In addition, candidate genes for these modifiers are beginning to be identified (e.g., the maize *desynaptic* gene and the *Arabidopsis SWI1* gene).

An important complex that may control both position and rate of meiotic recombination in plants can be seen in the electron microscope. Elliptical, proteinaceous “recombination nodules” associate with crossover events in the synaptonemal complexes of maize, tomatoes, and lilies.^[5] Similar nodules are observed in yeast and animal systems. The so-called “early nodules” convert into morphologically distinct “late nodules” that remain associated with chiasmata, and these late nodules cause the release of any other nearby early nodules. This relationship between nodules may explain “crossover interference”—the inhibition of one crossover event on formation of others nearby. The content of recombination nodules remains unknown, but may include the MLH1 mismatch repair protein. It will be interesting to see whether *Arabidopsis* has recombination nodules and how they interact; *Arabidopsis* may have two different meiotic recombination pathways, only one of which is subject to crossover interference.^[6]

UNEQUAL CROSSING OVER AND ILLEGITIMATE RECOMBINATION

Families of repetitive genes can serve as reservoirs of diversity by providing functional redundancy in the genome. In cases of tandemly repeated genes (e.g., rDNA repeats), recombination using sequence homology between misaligned members of a gene family can alter the number of family members present on each of the two homologues.

An additional outcome can be switching or alteration of coding sequences among members of a gene family. Examples of this include the maize *R1* locus^[7] and the *Xa21* disease resistance genes of rice.^[8] Rearrangements at the *R1* locus also result in novel, developmental patterns of gene expression as coding sequences and promoter of elements exchange.

On a larger scale, plants show an enormous diversity in overall genome size. Much of the variation is attributed to accumulation or removal of transposable elements. Illegitimate recombination is likely to be a means of limiting or even reducing the size of plant genomes.^[9]

NONRECIPROCAL EXCHANGE (GENE CONVERSION)

Exchange of information without the exchange of flanking markers occurs in plants. The alternative explanations for these exchanges are gene conversion or reciprocal, double crossover events. In organisms such as fungi, where all the products of a single meiosis can be accounted for, gene conversions are scored readily and conclusively as deviations from the typical Mendelian segregation of alleles. In plants, this has been more complicated, although the evidence, while indirect, is extremely compelling. For instance, double crossover events in some cases (e.g., maize) are deemed unlikely because crossover interference (see above) is extremely high. Taking a more theoretical approach, Haubold et al.^[10] used the relationship between physical distance and linkage disequilibrium along a 170-kb piece of the *Arabidopsis* genome to estimate as much as 90% of the observed recombination, which is, in fact, gene conversion. Whether this is the case for the rest of the genome or for other plants remains to be seen. The most promising development has been the *quartet* mutation in *Arabidopsis*,^[11] which causes all four pollen grains formed from a single meiosis to remain joined, effectively allowing fungal-style tetrad analysis and the possibility of formally demonstrating gene conversion. Data from yeast have shown that crossover and noncrossover products of recombination arise at different times during meiosis,^[12] and it will be interesting to see whether the same holds true in plants.

MITOTIC RECOMBINATION

Plants show low rates of somatic, homologous recombination, possibly because the highly repetitive nature of many plant genomes would make frequent illegitimate recombination a problem. An important consequence of this low rate has been a frustratingly low level of homologous gene targeting (with the curious exception of the moss *Physcomitrella*^[13]). Numerous, cleverly designed constructs have been used to enhance recovery of somatic homologous crossovers (e.g., Ref. [14]). These constructs have also helped identify *cis*-acting and *trans*-acting factors involved in mitotic recombination.^[15] Complementation of yeast mutations such as *rad1*, *rad25*, *sgs1*, and others using plant genes has been used to identify specific functions that might relate to mitotic recombination (e.g., helicase, exonuclease, or endonuclease activities), but whether the complementing plant genes are directly homologous is less clear. A curious result of these studies has been that mutations in DNA repair genes

such as *Rad50* seem to cause mitotic hyperrecombination phenotypes, suggesting that the normal roles of these genes may include suppressing somatic recombination.^[16]

CONCLUSION

Understanding the contributions of recombination to genetic diversity and how they occur remains an important research area for the future. Of the three primary engines of diversity (mutation and rearrangement being the other two), recombination serves as the most frequent, probably the most regulated, and arguably the most important.

Reconciling Agriculture with the Conservation of Tropical Forests

Wil de Jong

Center for International Forestry Research, Bogor, Indonesia

INTRODUCTION

The expansion of agriculture is widely held to be one of the causes of tropical deforestation. Simply stated, the progressive expansion of agriculture into areas of tropical forest can only occur when forests are slashed. There is little doubt that in many places an increased need for agricultural land goes hand in hand with expansion into forestland. However, the relationship between agricultural expansion and tropical deforestation is more complex than a simple addition and subtraction formula suggests. Many forms of tropical agriculture are integrated with forestry activities. Forests play an important role in the complex of resource management among many farmers in the tropics. Although such tropical agroforestry is no alternative for strict forest conservation in protected areas, it is a viable alternative—especially from a conservation point of view—to other agricultural development schemes that are often proposed or blindly copied in many tropical countries.

SWIDDEN AGRICULTURE AND FOREST MANAGEMENT

One of the most common types of agriculture in areas of tropical rainforest remains swidden agriculture. Swidden agriculture implies using a single field for intensive cultivation for one or a few years, after which the field is fallowed. During the intensive production cycle farmers grow crops like rice, manioc, and bananas, usually in combination with a few or many other crops. The reason farmers practice swidden—rather than permanent—agriculture is that soils' natural nutrient reserves do not permit permanent annual cropping. In most cases, the main purpose of the fallow period is to allow the restoration of the nutrient stock in the vegetation. This nutrient stock is released again into the soil when, at the end of the fallow period, the vegetation is slashed and burned. This new nutrient boost allows a subsequent round of intensive crop production. An additional benefit of the fallow vegetation is the reduction of obnoxious weeds that put

high pressure on farmers' labor reserves and may also reduce crop yields.

Forests do constitute an important role in many swidden fallow agricultural systems. They are where swidden fields are originally developed. The vegetation that grows on swidden fields that are being fallowed will eventually develop into secondary forests. Besides the nutrient restoration, these swidden fallow secondary forests are also important for forestry production. Forestry production is an important component of many swidden agricultural systems. This forestry production may occur in forest remnants that have been spared from conversion to agricultural lands. It may also occur in so-called secondary forest gardens—fields that were once used for agriculture, but that have changed to tree vegetation resulting from the partly spontaneous/partly actively pursued regrowth of trees.^[1]

Forest Remnants and Primary Forest Gardens

In the remote corners of the world, where most swidden agriculturists reside, forests supply an important number of products for daily needs. They supply food, like edible leaves, mushrooms, berries, and game. In addition, they also supply construction material to build houses, medicinal plants, and sites where spirits are believed to reside and where graveyards are made. Considering this importance of forests, many swidden farmers may spare important areas of forests when advancing their agricultural fields into the forest. Examples of these forest remnants can be found in many locations. They are reported mostly in countries in Southeast Asia.^[2,3] They are also common in many rural areas in Africa, where they are kept as sacred groves. These groves hold important spiritual meanings for the people who protect them.

Most primary forest gardens are safeguarded from conversion to agricultural land for the sake of assuring the supply of a wide range of forest products. Some forest gardens, however, are known for their production of economically important species. For instance, small producers cultivate *Psychotria ipecacuanha*, a medicinal

herb, in tropical forests in several countries in South and Central America.^[4] Originally from Brazil, this species is now being produced in small areas in fully grown primary forests in Costa Rica and Nicaragua. In similar fashion, indigenous Dayak farmers in areas of West Kalimantan, who partly rely on rubber production for their monetary income, may plant rubber in their primary forest gardens.^[3]

Swidden Fallow Secondary Forests

The most common type of forests cooccurring with swidden agriculture is the swidden fallow secondary forest.^a These forests regenerate largely through natural processes in woody fallows of swidden agriculture for the purpose of restoring the land for cultivation again. In a typical swidden fallow land use system, swidden fallow secondary forests often constitute the largest part of the area under some kind of vegetation cover. Besides their role in restoration of nutrient stocks, this type of forest is habitat for an important number of species that have some use value for their owners. Because these forests are usually located closer to settlements than are primary forests, they often may be the first place where farmers will turn to collect forest products.

Although swidden fallow secondary forests have often been classified as degraded forests, there is increasing evidence of their importance in fulfilling the functions that primary forests used to fulfill: conservation of biodiversity, regulation of the water flow that affects downstream areas, and carbon sequestration. It can indeed be expected that in many places of the world these functions will increasingly be fulfilled by some kind of secondary forest.^[5]

Secondary Forest Gardens

Secondary forest gardens are managed forests that appear on land once used for cropping that has subsequently been designated for forestry production. In addition to spontaneous vegetation, these forest gardens hold a number of species that may be planted or tended after they occur spontaneously. They play an important role in the livelihood of many farmers, precisely because they provide a larger suite of products than natural forests or primary forest gardens. They may occupy significant areas in swidden agricultural villages all over the world.^[3,6]

^aChokkalingam and de Jong^[1] distinguish six types of secondary forests, two of which are related to swidden agriculture: swidden fallow secondary forests and secondary forest gardens.

TRANSITION, INTENSIFICATION, AND THE FOREST LANDSCAPE

It has been a widely held belief that farmers who practice swidden agriculture will progressively expand their activities into natural forests, or that increased population pressure will lead to the progressive decline of forests in regions where swidden farmers have still managed to preserve areas of forest. None of these general belief is correct. The myth of progressive encroachment into natural forests is largely wrong. In most cases, swidden farmers will limit themselves to occupying an adequate area of agricultural land on which to rotate their swidden fields. When populations increase, there follows in many instances a period during which the relative length of the fallow period will decline, leading to wider presence of vegetation that has trees of lower height and less biomass. Many examples can be found, however, in which a land use intensification process eventually occurs.

Van Noordwijk^[7] described three possible options for intensification of swidden agriculture. These three options include tree-cash crop production, food crop production, and fother-pasture production. In cases where tree crop intensification takes place, the outcome is often beneficial for the general presence of forests in the landscape and related biodiversity and environmental functions. A recent study on secondary forests in tropical Asia^[8] provides several examples in which tree crop intensification may actually contribute to the presence of forests in a landscape that had been gradually losing its forest cover. For instance, swidden agriculturists in some villages in West Kalimantan, Indonesia, have gradually been changing their traditional production of subsistence agriculture complemented with commercial forest product extraction to production of rubber in mixed secondary forest gardens. Data from one village in West Kalimantan show that the reforestation of land with these mixed rubber–secondary forest gardens outweighed the conversion of primary forests for agricultural purposes.^[3,8] The same study describes examples of how farmers in the Himalayas of northern India gradually are changing their traditional swidden agriculture to mixed agriculture–forestry production, centered around the production of *Alnus nepalensis*.^[9] Additional examples have been reported from several countries in Africa where, as a result of farmers' activities, forests have expanded into savannas.^[6]

CONCLUSION

Although a diverse swidden agriculture landscape with its mixture of anthropogenic forests may not be a better alternative to true conservation in protected areas, such

a landscape suggests an important potential in other instances. The kind of agriculture–forestry interaction described here has many conservation and environmental advantages over other large-scale estate plantations and other kinds of intensified agricultural production such as oil palm production, pulp-wood plantations, and the like. Where it is necessary to make alternative choices, it is useful to consider the benefits that intensified swidden agriculture production may offer, including intensified forestry production as described here. Second, where efforts at development of swidden agriculture are pursued, it matters to an important degree to what extent traditionally managed forests are being taken into consideration. This will have different impacts on the forest, the biodiversity in the landscape, and the watershed protection that this landscape provides.

Regeneration from Guard Cells of Crop and Other Plant Species

Jim M. Dunwell

University of Reading, Reading, U.K.

INTRODUCTION

Guard cells, the components of the stomata within the leaf epidermis, are usually considered to be terminally differentiated and only of interest to plant physiologists concerned with gas exchange within the leaf. However, as will be described, these cells are of much greater general interest for their capability of being induced into division and even regeneration into complete plants.

HISTORY

Examination of the botanical literature from the last hundred years reveals several reports of abnormal development of guard cells from a variety of species. These references have been largely overlooked and only relatively recently^[1] has there been any real discussion of their significance. Among the early studies was the first attempt to induce division in mature guard cells *in vitro*.^[2] It was more than sixty years before this specific ambition was achieved, although during that period, evidence of guard cell division was reported in wounded leaves of various magnoliaceous species^[3] and in cucumber (*Cucumis sativus*) hypocotyls exposed to particular red light conditions.^[4]

DIVISION AND REGENERATION IN VITRO

There are three examples in which complete plants have been produced from guard cells *in vitro*; these will be considered in sequence below.

Tree Tobacco (*Nicotiana glauca*)

The first report of successful cell division *in vitro* involved an accidental discovery with cultured guard cell protoplasts of *N. glauca*. These were being grown in culture in an attempt to mimic normal development, but surprisingly some were found to develop into undifferentiated callus. Subsequently, experiments were performed to optimize conditions for culturing such protoplasts and

to determine whether they were indeed totipotent.^[5] Protoplasts were isolated from adaxial epidermal tissue of leaves of plants grown under fluorescent light (800–900 $\mu\text{mol m}^{-2} \text{s}^{-1}$ of photons of photosynthetically active radiation [PAR]). To increase the probability that the guard cells were of uniform osmotic potential at the time of harvest, leaves were collected in darkness, just before the beginning of each light period. Protoplasts were cultured in liquid media similar to those used for culturing mesophyll cell protoplasts of *Nicotiana tabacum* but with modified pH and KCl, CaCl₂, sucrose, and glycine concentrations; concentrations of growth regulators were 0.3 mg l⁻¹ α -naphthaleneacetic acid (NAA) and 0.075 mg l⁻¹ of 6-benzylaminopurine (BAP). Protoplasts were incubated in darkness at 25°C in 8-well microchamber slides at a density of 1.25 $\times 10^5$ cells ml⁻¹. Cell divisions began within 72–96 hours (h) of initiation of cultures, with an average cell survival of 57% at this time. After 8–10 weeks of culture, cell colonies were transferred to a callus initiation medium containing agar and incubated under continuous white fluorescent light (25 $\mu\text{mol m}^{-2} \text{s}^{-1}$ of photons of PAR) for another 8–10 weeks. Green callus tissue was then transferred to a callus growth medium and incubated under the same conditions. After a further 8–10 weeks, the callus was transferred to a shoot differentiation medium and incubated similarly. Two weeks later multiple shoots appeared and were transferred to a root differentiation medium. When roots were sufficiently developed (6–8 weeks), plants were transplanted to soil and grown in a growth chamber. It was concluded that guard cell protoplasts could survive and divide in culture and are totipotent.

In a later study,^[6] additional modifications in protocol were reported that allowed directed development either to callus production or to maintain normal guard cell behavior. In particular, it was shown that temperature is an important determinant of survival, growth, and differentiation. As the temperature was increased from 24 to 32°C, the survival of cells cultured for 7 days (d) was increased from approximately 20% to approximately 80%. At all these temperatures, approximately 90% of surviving cells divided to form callus tissue. Cells cultured for 7 d at 34 to 40°C also survived in high percentages (approximately 80%), but in contrast, they retained a morphology similar

to that of guard cells and they did not divide. These observations were explored further in a later study using differential display technology to define the various cell types.^[7]

Sugar Beet (*Beta vulgaris*)

The most valuable practical application of guard cell culture is that developed for sugar beet. This procedure was founded initially on the application of advanced microscopical techniques to address a difficult culture problem.^[8] Using a computer-controlled microscope system to assist in the positioning and rapid relocation of large numbers of cultured cells, it was found to be possible to identify those specific leaf protoplasts with the capacity to divide within a highly recalcitrant culture in which only a tiny fraction (0.5%) of the total population was able to produce viable microcalli. It was discovered that such regenerable microcalli come only from guard cell protoplasts (60% capacity for cell division), and not from protoplasts derived from mesophyll or other leaf tissue. This important discovery led to the development of an optimized protocol for the efficient and rapid genetic modification of this species.^[9,10] This involved a polyethylene glycol-mediated DNA transformation technique applied to protoplast populations enriched specifically for this single totipotent cell type in order to achieve high transformation frequencies. Bialaphos resistance, conferred by the *pat* gene, produced a highly efficient selection system. The majority of plants were obtained within 8 to 9 weeks of selection and were appropriate for plant breeding purposes; all were resistant to glufosinate-ammonium-based herbicides. Detailed genomic characterization revealed verified transgene integration, and progeny analysis showed Mendelian inheritance. This system has since been applied to the large-scale production of a range of transgenic sugar beet.

Cotton (*Gossypium hirsutum*)

The most recent extension of this technology is its application to cotton,^[11] a species generally considered recalcitrant to many regeneration methods. Rather than relying on protoplast isolation, this method comprised development of a regeneration system from stomatal guard cells directly on epidermal strips, especially from bracts. The most important factors affecting embryogenic callus initiation in both of the varieties tested (Coker 312 and 315) were the source of the epidermal tissue, including plant age (4–5 months old), the developmental stage of the flower (opening flower stage) from which bracts were obtained, the composition of the culture

medium, and light irradiance. The flower developmental stage was critical for callus formation, which was observed only from bracts obtained from opening flowers. In addition, epidermal strips excised from the bract basal region were more responsive in culture than those obtained from the upper region. Improved callus initiation was obtained on epidermal strips, which had their cuticle in contact with the culture medium. Light irradiance was a limiting factor for embryogenic callus formation, which was observed only in calli cultured under the lower light irradiance ($15.8 \mu\text{mol m}^{-2} \text{s}^{-1}$). Somatic embryogenesis was observed on callus cultures subcultured consecutively in a culture medium containing NAA (10.7 μM) and isopentenyladenine (4.9 μM). Histodifferentiation of somatic embryos was improved in a medium containing NAA (8.1 μM), isopentenyladenine (2.5 μM), and abscisic acid (0.19–0.38 μM). Somatic embryo germination and plantlet development were obtained using established protocols with few modifications, and on average, one fully developed plant was obtained from the culture of about 100 epidermal strips in both cultivars.

CONCLUSION

It is likely that future investigations will extend the number of species from which totipotent guard cells can be isolated, either in intact epidermis or as protoplasts.^[1,12] In many ways the development of this procedure has mirrored the development of regeneration methods for another unusual and isolated cell type—namely microspores—that were also once considered to be a developmental dead end but were then shown to have a high level of totipotency.

It can also be assumed that methods for the isolation of RNA from guard cells^[13] will be applied to this particular culture process in order to investigate the details of this profound switch from the normal differentiated state to one capable of division.

Apart from the value of guard cells as a source of totipotent material for use in transformation experiments (e.g., sugar beet) and perhaps the regeneration of other transgenic plants in the future,^[1,12] stomatal formation in *Arabidopsis thaliana* is also emerging as an elegant and powerful model system to study the genetic and molecular control of cell-fate specification and pattern formation in multicellular organisms.^[14] Eventually it is hoped that the combination of these emerging analytical methods will help to not only uncover the nature of the molecular signals that restrict the developmental potential of guard cells in situ, but also allow more predictable methods for the induction of division in such cells when they are separated from the plant.

Retrotransposons and Their Contributions to Plant Genome and Gene Evolution

Amar Kumar

Scottish Crop Research Institute, Invergowrie, Dundee, U.K.

INTRODUCTION

Transposons are mobile genetic elements that have capacity to move from one to another location within host chromosomes. Retrotransposons are class I transposable elements, transposing via an RNA intermediate that is reverse-transcribed into extrachromosomal DNA and inserted into the genome by the encoded reverse transcriptase, RNaseH, and integrase enzymes.^[1] This replicative mode of transposition is similar to animal retroviruses. However, unlike the retroviruses, which are found only in animals, retrotransposons are found in all eukaryotes, where they are the most abundant class of mobile DNA. Moreover, retrotransposons constitute a major portion of all eukaryotic nuclear genomes and are commonly found as repetitive sequences interspersed on the entire length of host chromosomes.^[1,2] Many properties of transposable elements suggest that they are parasitic or selfish DNAs. However, as in any other component of a heritable genome, transposon DNA can serve as a genomic resource for mutation and natural selection. Indeed, a more recent paradigm suggests that transposable elements may play a central role in the evolution of gene function and genome structure in eukaryotic organisms.^[2,3] For example, transposons can contribute regulatory *cis*-factors, alter transcript splicing, promote exon shuffling, and facilitate chromosomal rearrangements or restructuring leading to changes in spatial and temporal expression patterns of host genes or even generation of novel genes.^[2-4] Furthermore, retrotransposons are involved in altering the genome size of eukaryotic organisms either by increasing or by decreasing their copy numbers within the host genome.^[2]

STRUCTURE, ABUNDANCE, AND DISTRIBUTION OF RETROTRANSPOSONS

Retrotransposons are classified into two types: those with long terminal repeats (LTRs) and those without LTR (non-LTR retrotransposons).^[1-3] Long-terminal-

repeat retrotransposons are further subclassified into the Ty1-*copia* and the Ty3-*gypsy* groups that differ from each other in both their degree of sequence similarity and the order of encoded gene products (Fig. 1). Ty1-*copia* retrotransposons are present throughout the plant kingdom, in species ranging from single-cell algae to bryophytes, gymnosperms, and angiosperms. Ty3-*gypsy* retrotransposons are also found widely distributed in the plant kingdom, including both gymnosperms and angiosperms. Furthermore, both these groups of retrotransposons are commonly found in high copy number (up to a few million copies per haploid nucleus) in plants with large genomes (Table 1). Nonautonomous LTR retrotransposons (i.e., lacking mobility-related proteins) are also abundant in plant genomes, and recently, a new group of such elements has been identified that are ubiquitous in plants.^[5] The non-LTR retrotransposons, long interspersed repetitive elements (LINEs) and short interspersed repetitive elements (SINEs), have also been found in high copy numbers (up to 250,000) in plant species studied to date. Like the LTR retrotransposons, both LINEs and SINEs are present throughout the plant kingdom. All in all, plant genomes, such as higher eukaryotic genomes, contain an exceptionally abundant and diverse set of retrotransposons: by contrast, functional retroviruses are either absent or present in very small numbers in the plant genomes. Table 1 shows a list of some well-characterized retrotransposons in plants.

REGULATION OF EXPRESSION AND TRANSDUCTION

The expression of retrotransposons in plants and in other eukaryotic organisms is regulated, thereby regulating their transposition frequency in the host genome.^[6] The evolution of control mechanisms for the transcription and transposition of retrotransposons in the host genome may be crucial to minimize their possible deleterious effects on the host. A correlation between transcription and transposition of retrotransposons has

LTR retrotransposons

Non-autonomous LTR retrotransposons

Retroviruses

Non-LTR retrotransposons

Fig. 1 General structures of the Ty1-copia, Ty3-gypsy, LINE, and SINE retrotransposons (Ref. [1–3]). The LTR retrotransposons have long terminal repeats in direct orientation at each end. Within the LTRs are U3, R, and U5 regions that contain signals for initiation and termination of transcription. The transcript initiates at the 5' end of R within the 5' LTR and terminates at the 3' end of R within the 3' LTR. The genes within the retrotransposons encode mobility-related proteins, including capsid-like proteins (CP), endonuclease (EN), integrase (INT), protease (PR), reverse transcriptase (RT), and RNase-H. Other sequences featured are primer binding sites (PBS), polypurine tracts (PPT), nucleic acid binding moiety (NA), inverted terminal repeats (IR), target site duplication (TSD), 5' untranslated region (5' UTR), 3' untranslated region (3' UTR), and Pol III A- and B-promoter recognition sites for RNA polymerase III. These figures are not drawn to scale, as the LTR retrotransposons range from a few kilobases up to 15 kb in size. LINES usually range in size from less than 1 kb to maybe 8 kb, while SINEs are normally 100–300 bp in size. Animal retroviruses are similar to the Ty3-gypsy elements but contain an additional ORF 3 encoding the envelope protein, which allows them to be infectious. The envelope (env) gene-like sequence in the position of ORF 3, where a functional env gene is present in the animal retroviruses, has been found in both Ty1-copia and Ty3-gypsy groups (not shown). The function of the env gene-like sequence in plant retrotransposons is unknown. Nonautonomous LTR retrotransposons such as TRIM elements.^[5] lack mobility-related proteins (e.g., INT, RT, RNase-H, etc.)

been demonstrated for the tobacco *Tto1* and rice *Tos17* retrotransposons. For example, transposition of *Tto1* and *Tos17* was concomitant with an increase in the levels of their RNAs, suggesting that transposition of these retrotransposons is regulated mainly at the transcriptional level. Many of the plant retrotransposons (e.g., *Tnt1* and *Tto1*) studied to date are transcriptionally activated by various biotic (e.g., inoculation with various viral, bacterial, or fungal pathogens) and abiotic (e.g., cell culture, wounding, methyl jasmonate, CuCl_2 , and salicylic acid) stress factors.

CONTRIBUTIONS OF RETROTRANSPOSONS TO THE EVOLUTION OF PLANT GENES AND GENOMES

Gene Mutation

Retrotransposons are involved in generating mutations through insertions near or within genes.^[2–4] Both LTR and non-LTR retrotransposons have generated mutations in plants. For example, a retrotransposon-induced mutation was responsible for the generation of white color skin in

Table 1 Properties of some plant retrotransposons

Retrotransposon	Size		Copy no.	Plant and genome size (1C)	Location	RNA transcript	Comments
	Total (kb)	LTR (bp)					
LTR retrotransposons							
<u>Ty1-copia group</u>							
<i>Tnt1</i>	5.3	610	>100	Tobacco (~2290 Mbp)	Dispersed euchromatin	Protoplasts, roots, wounding pathogen attacks	Actively transposing; isolated as an insertion in the <i>nia</i> gene in tissue-culture cells; transposes in transgenic tomato and <i>Arabidopsis</i>
<i>Tos17</i>	4.1	138	1–5	Rice (~420 Mbp)	Dispersed	Protoplasts, tissue culture	Transposes in tissue culture; mostly inserts in or near coding regions
<u>Ty3-gypsy group</u>							
<i>Cereba</i>	~10.0	—	1500	Barley (4873 Mbp)	Centromeric	—	Exclusively clustered in centromeric region
<i>Cyclops-2</i>	~12.5	1504	1000	Pea (~4400 Mbp)	Dispersed	—	Contains envelope-like sequences
Nonautonomous LTR retrotransposons							
TRIM-1	0.280	125	250	Rice (~240 Mbp)	Dispersed	Leaves	Involved in the rice genome organization
Non-LTR retrotransposons							
<u>LINEs</u>							
<i>Del2</i>	4.5	—	250,000	<i>Lilium</i> (29,000 Mbp)	Dispersed	—	Accounts for 4% of the <i>Lilium</i> genome
<i>Ta11</i>	6.1	—	1–6	<i>Arabidopsis thaliana</i>	Dispersed	—	A family of non-LTR elements; 17 additional reverse transcriptase sequences (Ta 12–28) were identified; <i>Ta17</i> is located in the mitochondrial genome
<u>SINEs</u>							
<i>S1_{Bn}</i>	0.170	—	500	<i>Brassica napus</i> (~630 Mbp)	Dispersed	Shoots, roots, callus	Elements are twofold more methylated than the average methylation level of <i>Brassica napus</i> nuclear DNA
<i>Ts</i>	0.206	—	>1000	Bell pepper (~3420 Mbp)	Dispersed	—	Transposed within the <i>PAP2</i> gene

grape cultivars.^[7] Many retrotransposon insertions within or close to genes affect their expression in a negative fashion by decreasing or abolishing transcription of the gene or by detrimental alterations in transcript processing and/or stability. In other cases, however, insertion of retrotransposon sequences within or near a gene has more complex effects on gene expression, including alterations of temporal and spatial patterns of transcription or the structure of the resultant protein. Interestingly, many plant genes currently considered wild type contain legacies of previous retrotransposon insertion.

Genome Size

Retrotransposons play a major role in determining the size of plant genomes.^[2] For example, small genomes in plants such as *Arabidopsis* (1C equal to about 130 Mbp), which only contains about 10% of the total genome as retrotransposons, might be the consequence of a lack of retrotransposon proliferation or/and a gradual elimination of retrotransposons. On the other hand, large genomes in plants such as maize (1C equal to about 3200 Mbp) might be the result of successful colonization and amplification of retrotransposons. An estimated divergence time between maize and sorghum is about 15–20 million years ago, and both have 10 chromosome pairs, but the maize nuclear genome is 3–4 times longer than the sorghum genome. Molecular hybridization and sequence analysis data have revealed that the increase in maize genome size was largely caused by an extensive proliferation of retrotransposons that has occurred within the last 2–6 million years.^[8] Nonetheless, retrotransposons are also responsible for the reduction of plant genome sizes following gradual elimination of their sequences, by various mechanisms, such as unequal recombination between the LTRs of an LTR retrotransposon (to generate solo LTRs) or other types of deletion. Interestingly, a correlation was shown between the *BARE-1* retrotransposon copy number and genome size in wild barley and the sharply differing microclimates in Evolution Canyon near Mount Carmel, Israel.^[9] This suggests the dynamic nature of the barley genome with respect to retrotransposon activation by environmental stimuli.

MOLECULAR TOOLS FOR PLANT GENOME ANALYSIS

Molecular Markers for Phylogenetic, Biodiversity, and Genetic Linkage Analyses

There are several advantages in using retrotransposon sequences as molecular markers.^[10] They are ubiquitous,

present in high copy numbers as highly heterogeneous populations, are widely dispersed on chromosomes, and show insertional polymorphism both within and between species in plants. Furthermore, active retrotransposons will produce new insertions in the genome, leading to polymorphism. The new insertions may then be detected and used to temporally order insertion events in a lineage, helping to establish phylogenies. These genetic properties have recently allowed retrotransposons to be exploited as DNA markers to study biodiversity in maize, pea, and barley^[10] and to generate genetic linkage maps in barley and pea.

Gene Tagging and Functional Analysis of Genes

Some retrotransposons have features that make them ideal genetic tools for gene tagging in plants.^[11] These include 1) retrotransposon-mediated insertion mutations that are stable because they transpose by a replicative mode, 2) transposition target sites that are unlinked to the site of the original copy, making it relatively easy to generate a large collection of random insertions for saturation mutagenesis, 3) transposition that can be regulated by abiotic and biotic stress conditions, 4) high mutagenicity as a result of preferential transposition into genes. In rice, the endogenous *Tos17* retrotransposon meets all the conditions mentioned above for its use in tagging genes. *Tos17* is highly active under tissue culture conditions and preferentially inserts into or near genes. It has been used to generate a large collection of random insertions for saturation mutagenesis and has been used to clone a number of genes in rice.^[11]

CONCLUSION

We now know that plant retrotransposons are responsible not only for generating mutations in plant genomes, but also for significantly increasing the size of many plant genomes. Their replicative modes of transposition have equipped them with the ability to proliferate rapidly within their hosts, allowing them to become a major component of higher plant genomes. Retrotransposons are also one of the most fluid of genomic components, varying greatly in copy number, genomic localization, and sequence structure over relatively short evolutionary times. These properties make retrotransposons one of the major forces influencing the structure of plant genomes. Although their initial and major continuing motivation appears to be selfish and/or parasitic, retrotransposons will continue to be used whenever possible by their hosts. Finally, it is clear from the above and other published reports that retrotransposons are central players

in the structure, evolution, and function of plant genomes. Hence retrotransposons may be selfish but are certainly not junk. In fact, they are not even very selfish because both host genome and scientists can use them for their own benefit.

INTRODUCTION

Carbohydrate partitioning from shoot to roots can comprise a substantial proportion of plant-photosynthetic CO₂ fixation (20–70%), and out of this fraction 4–70% can be released into the soil as organic rhizodeposition.^[1,2] This is not only a significant loss of reduced carbon but can also contribute by 30–40% to the total input of soil-organic matter^[2] with considerable impact as a source of carbon and nitrogen for soil microorganisms. Rhizodeposition is associated with dramatic changes in the activity and composition of soil-microbial communities, solubility of nutrients and toxic elements in the root environment, determining the rhizosphere as a compartment with major influence on pools, and fluxes of carbon and mineral nutrients in soils.

According to the mechanisms of release, organic rhizodepositions may be grouped into two major fractions: lysates, leachates from sloughed-off cells, and dead tissues as a consequence of root turnover. In contrast, root exudates (2–10% of translocated carbon) are released from intact root cells either passively as diffusates or actively as excretions or secretions with specific functions.^[2,3] Rhizodeposition can be enhanced in response to high light intensities, temperature extremes, the mechanical impedance of the substrate, toxic elements, low soil pH, nutrient limitation, and presence of microorganisms. It is affected by the plant-developmental stage and by expression of retrieval mechanisms in plant roots, which are able to recover up to 90% of amino acids and sugars released into the rhizosphere.^[3]

SLOUGHED-OFF CELLS AND TISSUES

Organic compounds released from sloughed-off root cells and tissues are a major carbon source for rhizosphere microorganisms but may indirectly have an impact as microbial metabolites on nutrient availability and on exclusion of toxic elements in the rhizosphere.^[4] However, even the liberation of sloughed-off root cells (root border cells) is a controlled process, which exhibits genotypic differences between plant species and can be modified by various environmental

factors. Border cells are able to produce antibiotics and attract root pathogens, thereby counteracting infection of the apical meristem. In response to infection with pathogens and to toxic aluminum levels, root border cells exhibit enhanced mucilage secretion, which seems to repel bacteria and alleviates aluminum toxicity.^[5] Limited longevity is also characteristic for root hairs and fine roots. Continuous root turnover is a general feature of plant development and insoluble root debris may comprise 50–90% of total rhizodeposition.^[6]

HIGH MOLECULAR WEIGHT COMPOUNDS

High molecular weight compounds, such as mucilage and ectoenzymes, are actively released via exocytosis. Mucilage is released from hypersecretory cells at the root cap as a gelatinous polyuronic acid polysaccharide. Subsequently, the secretory cells degenerate or are sloughed-off as root border cells. Mucilage has protective functions for the root meristem and improves root–soil contact by inclusion and aggregation of soil particles. A function as lubricant seems to be unlikely, since no water retention or swelling capacity can be demonstrated at water potentials <0. Mucilage secretion can facilitate Zn²⁺ transport from embedded soil particles to the root surface. It may also contribute to P desorption and to exclusion of toxic elements (Al, Cd, Pb) by complexation with galacturonates mainly in exchange with Ca²⁺.^[7]

Under P deficiency, enhanced root-secretion of phosphohydrolases (e.g., acid phosphatases, nucleases, phytases) can increase P availability by hydrolysis of organic P esters, comprising 20–80% of the total soil phosphorus (Fig. 2). Considerable genotypic variation exists in the ability of plant species for secretion of phosphohydrolases. In many soils, however, enzymatic hydrolysis is limited by low solubility of organic P forms (Ca/Mg and Fe/Al phytates). Another limiting factor is also the low solubility of secretory phosphohydrolases, restricted by immobilization at the cell wall or by adsorption and inactivation on clay minerals. Root-secretory phosphohydrolases may also contribute to P retrieval by hydrolysis of organic P, permanently lost into the rhizosphere from damaged root cells.^[7,8]

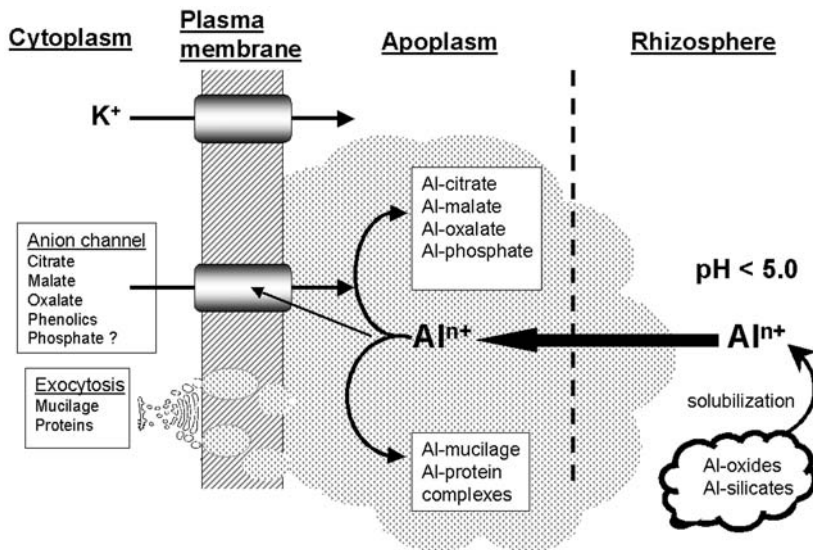

Fig. 1 Model for aluminum detoxification in apical root zones by release of Al-complexing root exudates. (Adapted from Ref.^{[3].})

LOW MOLECULAR WEIGHT COMPOUNDS

A wide range of low molecular weight compounds (e.g., sugars, amino acids, carboxylates, phytosiderophores, phenolics, vitamins, hormones) are released from plant roots. Particularly, certain phenolics, carboxylates, and phytosiderophores, which exhibit reducing properties and the ability for metal complexation, can directly affect the availability of nutrients and of toxic elements in the rhizosphere. A significant utilization of chelated metals by plant roots usually requires complex splitting by root-induced pH changes or metal reduction (Fe, Mn, Cu) at the root surface or in the apoplast.

Metal complexation by carboxylates is, on the other hand, an important mechanism to exclude uptake of

toxic elements, such as Al^{3+} in plant species and cultivars adapted to acid mineral soils (Fig. 1). Exudation of Al-chelating carboxylates (malate, citrate, oxalate) is triggered within minutes to several hours after exposure to Al^{3+} . The release is restricted to the apical root zones, which are most susceptible to toxic effects of aluminum.^[3,9]

Phosphorus deficiency-induced root exudation of carboxylates and H^+ can mediate the mobilization of sparingly soluble Ca phosphates in calcareous soils and of Fe/Al phosphates in acidic soils by mechanisms of ligand exchange, dissolution, and occupation of P sorption sites (Fig. 2). Among the various carboxylates in plant root exudates, citrate and oxalate are most efficient in P mobilization but significant P desorption

Fig. 2 Model for root-induced mobilization of sparingly soluble P sources in the rhizosphere by release of H^+ , carboxylate anions, and root-secretory phosphohydrolases. (Adapted from Ref.^{[7].})

usually requires high carboxylate concentrations (>1 mM) in the equilibrium solution. Comparable rhizosphere concentrations have so far been reported only for a limited number of plant species such as *Lupinus albus*, *Trifolium pratense*, and members of the Proteaceae. Under P deficiency, root exudation of carboxylates is frequently preceded by organic acid accumulation in the root tissue, which has been related not only to increased biosynthesis but also to reduced turnover of organic acids.^[3]

In graminaceous plants, release of nonproteinaceous amino acids (mugineic acids)—so-called phytosiderophores (PS)—with a high capacity to form stable chelates with Fe^{3+} even at high soil pH > 7, is a strategy to cope with low Fe availability in alkaline soils. Subsequent root uptake of Fe^{III} -PS complexes is mediated by a specific transport system (Fig. 3). Phytosiderophores can also mediate the extraction of considerable amounts of Zn, Mn, Cu, and even Cd and Ni in calcareous soils. Tolerance of graminaceous plants to Fe and Zn deficiency is roughly related to the amount of PS released in response to Fe and Zn starvation. However, considerable genotypical variation exists within each single plant species. Biosynthesis of PS increases in the root tissue under limited Fe supply even before Fe chlorosis appears, and rapidly declines after resupply of iron. Phytosiderophores are derived from nicotianamine as a trimerization product of S-adenosyl methionine with subsequent transamination and hydroxylation.^[3]

Localized release of root exudates in apical root zones with a low density of microbial colonization and secretion peaks over a limited period of time may counteract rapid microbial degradation and thereby increase the rhizosphere concentrations of exudate compounds for mobilization of nutrients. In principle, root exudation of carboxylates and other low molecular weight compounds can be mediated by diffusion along the steep concentration gradient of

organic solutes between the cytosol (millimolar range) and the rhizosphere soil solution (micromolar range). However, the selective secretion of chelating compounds involved in nutrient mobilization or exclusion of toxic elements may be mediated by specific transport mechanisms such as anion channels with a concomitant release of protons or K^+ to maintain charge balance.^[3,9]

In contrast to carboxylates, direct interactions of sugars and amino acids with soil minerals are weakly expressed due to the lack of charges or slow reaction kinetics with metal ions but may indirectly influence nutrient availability as products of microbial metabolism.^[4,10]

Root-secretory phenolics have important functions as chemoattractants, as nod-gene inducers for rhizobia, as signaling compounds for establishment of mycorrhizal associations, and are also involved in pathogen and allelopathic interactions.^[2,11,12]

FUTURE PROSPECTS

There is an obvious lack of noninvasive techniques for measurements of root exudation with a high spatial resolution and tracing origin and fate of organic compounds in the rhizosphere. Further miniaturization of sampling and analytical techniques (e.g., microprobes, reporter bacteria, isotopic tracer techniques, micro-suction cups, capillary electrophoresis, image analysis) should facilitate nondestructive measurements of rhizosphere processes at a high scale of resolution.

Much more experience is required concerning effects of root exudates and rhizosphere products on mobility and plant availability of nutrients and toxic compounds in soils under different environmental conditions and at realistic rhizosphere concentration levels, considering also synergistic effects of simultaneous chemical reactions. Fertilization management,

Fig. 3 Model for root-induced mobilization of iron and other micronutrients in the rhizosphere of graminaceous plants, mediated by release of phytosiderophores (PS). (Adapted from Ref.^[3].)

breeding, or biotechnological approaches may be employed for manipulation of the rhizosphere toward improved plant efficiency for nutrient acquisition, resistance to adverse soil-chemical conditions, or plant design for phytoremediation and phytomining strategies. However, first approaches to manipulate root exudation by simple overexpression strategies in transgenic plants revealed contradictory results,^[13] emphasizing the need for a detailed understanding of the physiological mechanisms involved in the regulation of root activity and of the related rhizosphere processes as well.

Rhizosphere Management: Microbial Manipulation for Biocontrol

Ben J. J. Lugtenberg

Faina D. Kamilova

Leiden University, Institute of Biology, Leiden, The Netherlands

INTRODUCTION

Several microorganisms—such as viruses, bacteria, and fungi—cause diseases on various plants, including economically important ones. Strategies to bring the disease level to economically acceptable levels include the use of chemical pesticides, plant cultivars resistant to a certain pathogen, and natural enemies. In the United States alone, over \$600 million is spent annually on agricultural fungicides. The use of chemicals is increasingly discouraged because some are a threat to the environment and human beings. Nongenetically engineered disease-resistant plants are widely used. Drawbacks are that resistance is usually accompanied by a yield decrease (of approximately 3%) and that after a few years, forms of the pathogen take over to which the resistant plant is sensitive. A modern approach—the use of genetically engineered resistant plants—is not accepted in some economically important regions in the world, especially in Europe.

Biological control of plant diseases is becoming increasingly popular, wherein cultivated natural enemies of the pathogenic microbes are applied to seeds, seedlings, or plants in a concentration sufficiently high to compete successfully with the pathogen for several months.

BIOCONTROL AGENTS (BCAs)

Biocontrol agents represent all organisms, (including microbes, nematodes, and insects) that are able to decrease disease levels of crop plants. These diseases can be caused by pathogenic microbes, weed plants, or animals such as nematodes and insects. This article focuses on the biocontrol of plant diseases caused by soilborne pathogens. This control takes place in the rhizosphere (i.e., the root and its immediate surrounding area). The rhizosphere is relatively rich in nutrients and therefore attracts many microbes—pathogens as well as beneficials. Certain insects feed on plants to the extent that plants become seriously diseased or even die. *Bacillus thuringiensis* is a gram-positive soil bacterium able to produce crystalline inclusions during sporulation. These consist of proteins

with highly specific insecticidal activity. They can be active against larvae of *Lepidoptera*, dipteran and coleopteran species. The crystals dissolve in the larval midgut where they are processed into smaller toxic proteins that generate pores in the midgut cell membrane. The larva stops feeding and consequently dies.^[1] Economically this is the most important application of biocontrol.

Many other plant diseases are caused by fungi, such as *Alternaria*, *Botrytis*, *Fusarium*, *Gaeumannomyces graminis* var. *tritici*, *Pythium*, *Rhizoctonia*, and *Verticillium*. Some pathogens of bacteria such as *Agrobacterium*, *Erwinia*, and *Pseudomonas* can cause crop damage also.

The BCAs used most frequently to control root diseases caused by fungi include the bacteria *Bacillus*, *Pseudomonas*, and *Streptomyces*, and the fungi *Gliocladium* and *Trichoderma* (Table 1). For more information, consult www.nal.usda.gov; www.epa.gov; www.bisolbi.com and www.biconet.com.

PROS AND CONS OF BIOLOGICAL CONTROL

In contrast to various chemical fungicides, BCAs are environmentally friendly. In cases, when they act through the production of an antifungal metabolite (AFM), this molecule is produced locally on the plant surface in small amounts. The molecule is biodegradable, does not reach drinking water, and is not harmful for workers.

In comparison with resistant plants, the use of BCAs has the advantages that: 1) they are inexpensive; 2) the decision to use them can be made relatively late; and 3) they do not cause a yield decrease, but have resulted in unexpected yield increases. Finally: 4) plants resistant to all pathogens do not exist; and 5) public perception of biologicals is positive.

Disadvantages also exist: 1) performance is not always consistent; 2) in comparison with chemicals, the shelf life of biologicals is short; 3) adoption of legislation governing the use of biologicals is an extremely slow process; and 4) the cost of registration is high, taking into account the small market share that biologicals currently represent.

Table 1 Commercially available biocontrol agents

Biocontrol agent	Formulation	Target pathogen	Crop
<i>Bacillus subtilis</i>	Dry powder; water-dispersible granules	<i>Pythium</i> ; <i>Phytophthora</i> ; <i>Fusarium</i> ; <i>Streptomyces scabies</i>	Cotton, peanuts, soybeans, vegetables, potato, ornamentals
<i>Burkholderia cepacia</i>	Peat-based dried biomass from solid fermentation	<i>Rhizoctonia</i> ; <i>Pythium</i> ; <i>Fusarium</i>	Alfalfa, barley, beans, clover, cotton, peas, grain sorghum, vegetable crops, wheat
<i>Pseudomonas fluorescens</i>	Powder	<i>Erwinia amylovora</i>	Tomato
<i>Pseudomonas chlororaphis</i>	Powder	<i>Pythium</i> ; <i>Rhizoctonia</i> ; <i>Cylindrocladium</i> ; <i>Fusarium</i>	Pea, ornamentals, cucumber
<i>Streptomyces griseoviridis</i>	Powder	<i>Fusarium</i> ; <i>Pythium</i>	Field, ornamental and food crops
<i>Gliocladium virens</i>	Granules; granular fluid	<i>Pythium</i> ; <i>Rhizoctonia</i>	Ornamental and food plants in greenhouses and nurseries
<i>Trichoderma harzianum</i>	Granules or dry powder	<i>Pythium</i> ; <i>Rhizoctonia</i> ; <i>Fusarium</i>	Tomato, cucumber, cabbage

ISOLATION OF BCAs

To test microbes for their action as BCAs, a system must be developed in which the plant is grown in the presence of the target pathogen. The disease pressure initially used is unnaturally high (60–80% diseased plants) in order to limit the number of plants required to produce a statistically significant result. Later, when the number of candidate BCAs is limited, larger experiments are carried out with lower disease pressure (20–40%).

Because biocontrol experiments are labor-intensive and time-consuming, scientists often make a prescreening or preselection, taking advantage of knowledge of mechanisms. For example, one can prescreen for organisms that inhibit growth of the pathogen (the antagonists) *in vitro*^[2] or one can preselect enhanced colonizers.^[3] This approach is biased by limited knowledge of BCAs' mechanisms of action.

APPLICATION OF BCAs

After growth, biocontrol microbes usually are not applied immediately on the plant but are stored. To avoid major losses of viable organisms, they are treated by special methods (often protected by patents) that increase their survival during storage (their shelf life). This process is referred to as formulation. Survival is relatively easy when dealing with dormant forms called spores. When non-sporeformers are to be formulated, successful formulation is much more difficult, although major progress has recently been made. BCAs can be formulated in solid or liquid state and in materials such as alginate, bentonite, carrageenans, peat, or vermiculate. Alternatively, liquid

seed-applied inoculants can be used. Ideally formulated, microbes can be used for more than one growth season so that leftovers from one season can be used at the beginning of the next. Formulated BCAs usually contain at least 10^9 viable microbes per gram or ml.^[4] One of the most successfully applied microbes is *Bradyrhizobium japonicum*, a biofertilizer of soybean.^[5]

Microbes can be applied on the seed or in the furrow before planting. Alternatively, they can be added to the plant during growth. BCAs are also used postharvest; for example, to protect oranges or potatoes from rotting during storage.

To monitor the success of BCAs' application, it is important to monitor plant performance as well. In case of poor performance, data on the viability and activity of the BCA are crucial for understanding whether poor performance is due to the BCA or to other circumstances. Early discovery of the cause of poor performance should allow additional control measures. Because any individual form of disease control can fail, it is advisable to have a combination of methods available.

MECHANISMS USED BY BCAs

Important techniques to study mechanisms of biocontrol are visualization of differentially labeled pathogens (Fig. 1A) and BCAs (Fig. 1B), genetics, and biochemistry. The best studied form of biocontrol is the use of antagonistic microbes. These organisms produce one or more molecules (e.g., AFMs) that inhibit growth of the target pathogen.^[6] To protect the whole root system against soilborne pathogens it is important that the BCA deliver the AMF along the whole root system.^[7] This can

Fig. 1 Visualization of *Pseudomonas fluorescens* biocontrol strain WCS365 and the pathogenic fungus *Fusarium oxysporum* f.sp. *radicis lycopersici* on tomato roots. The microbes were marked with an autofluorescent protein. The root shows red autofluorescence. (A) Initial stage of the contact: Fungal hyphae attach to root hairs. (From Lagopodi et al. *Mol. Plant-Microbe Interact.* 2002. 15, 172–179.) (B) Formation of a bacterial biofilm on the root. (From Bloemberg et al. *Appl. Environm. Microbiol.* 1997. 63, 4543–4551.) (C) Colonization of fungal hyphae (blue) by biocontrol bacteria (green). (From Lagopodi, A. and Bloemberg, G.V., unpublished). (View this art in color at www.dekker.com.)

be done by applying a successful root-colonizing BCA on the seed, which subsequently colonizes the whole growing root. The production of AFMs often requires high cell densities of the BCA.^[7] Indeed, bacterial BCAs are often present as microcolonies (Fig. 1B). AFMs are diverse in structure. AFMs produced by several BCAs are 2,4

diacetyl phloroglucinol, phenazine, HCN, and biosurfactants.^[6] The latter molecules are thought to be particularly active against zoospores (e.g., from the pathogen *Pythium*).^[8]

Some BCAs act through parasitism or predation. For example, because many fungi contain chitin in their cell

walls, the secretion of chitinase is considered a trait of some BCAs (e.g., of *Trichoderma*).

Other BCAs colonize the root system very well but fail to produce AFMs or exoenzymes *in vitro*. Although one cannot exclude that some of these BCAs do produce AFM in the rhizosphere, it is often thought that this class of BCAs acts through competition with the pathogen for niches on the root or for nutrients secreted by the root. These so-called exudates often contain amino acids, sugars, and organic acids, albeit in low concentrations.^[7]

BCAs of another class do not produce extracellular toxins, but induce a systemic reaction in the plant (e.g., the presence of certain *Pseudomonas* strains on the root triggers in the plant a faster, more severe response to pathogens present on the leaf). A variety of products of the BCA, including lipopolysaccharide, siderophores, and flagella, have been claimed to be involved in the induction of this form of resistance. It is assumed that bacteria that act through this mechanism, designated Induced Systemic Resistance,^[9,10] consist of subclasses that act by different mechanisms.

Using microbes labeled with autofluorescent proteins, confocal laser scanning microscopy studies showed that during biocontrol, hyphae of *Fusarium* become colonized by *Pseudomonas* BCAs (Fig. 1C). The resulting disabling of the pathogen may represent a novel biocontrol mechanism.

CONCLUSION

Mechanisms that allow for the isolation and construction of more robust strains are being developed. Clearly, the reduction of plant diseases by microbial control agents has a bright future.

Rhizosphere: An Overview

Roberto Pinton

Università di Udine, Udine, Italy

INTRODUCTION

Plant survival and adaptation to adverse soil conditions are strictly dependent on the capability of roots to interact with biotic and abiotic components of soil. Processes at the basis of the root-soil interaction concern a very limited area surrounding the root tissue. In this particular environment, exchanges of energy, nutrients, and molecular signals take place, rendering the chemistry and biology of this environment different from the bulk soil. In this chapter, an overview of the key processes occurring at the rhizosphere, which can account for the complexity of this environment, will be presented.

COMPLEXITY, DEFINITIONS, AND BOUNDARIES

The rhizosphere is a complex environment where almost every process involves multiple interactions between the soil-root-microbe triumvirate.^[1] It is well known that movement of water, nutrients, and microbial dynamics are more convoluted around the roots than in the bulk soil. Changes in pH and redox potential often occur. Furthermore, the rhizosphere generally experiences higher mineral weathering rates than bulk soil and is characterized by variable rates of mineralization of the native organic matter.

The term rhizosphere is generally used to define the field of action or influence of a root. Roots vary enormously in their morphology, longevity, activity, and influence on soil as a result of physiological, environmental, and genetic differences. It can be assumed that the rhizosphere forms around each root as it grows because each root changes the chemical, physical, and biological properties of the soil in its immediate vicinity.

The rhizosphere lacks physically precise delimitation; rather it can be described in terms of the longitudinal and radial gradients that develop along the axis of each root as a result of root growth and metabolism, nutrient and water uptake, rhizodeposition, and subsequent microbial growth.^[2] These will be gradients with depletion profiles (i.e., the solute concentrations will be lowest at the root surface), as in the case of most essential plant nutrients, and accumulation gradients (i.e., solute concentrations are

highest at the root surface), as in the case of the soluble organic solutes released by the roots.^[3]

The volume of the rhizosphere also depends on the rate of exudation and impact utilization of the rhizodeposits by microorganisms.^[4] Rhizodeposition includes lysates liberated by autolysis of sloughed cells and tissues, as well as biochemically defined root exudates released passively (diffusates) or actively (secretions) from intact cells. Exudation is not uniformly distributed along the whole root system. Usually apical root zones are characterized by a higher capacity for release of low-molecular-weight exudates, whereas basal parts of the root system generally show a higher microbial activity. This might affect rhizosphere microbial population. The longitudinal gradient of exudation may reflect the gradient in microbial catabolism of root exudates as well as differences in root cell activity. The gradients of microbial population and exudates along the root axis can have important implications for the uptake of nutrients by plants.^[5]

SOURCE OF NUTRIENTS (AND TOXIC ELEMENTS)

The rhizosphere also defines the soil volume from which plants take up mineral nutrients. In order to provide adequate supply of each essential nutrient, the plant can adjust the root architectural form and/or increase the uptake capacity.^[6,7] These modifications in soil-grown plants may occur at the local rhizosphere scale.

Roots can also modify the pH and redox state of the rhizosphere, thus altering the solubility of some nutrients.^[8]

Limitation in nutrient availability, as well as excessive availability of toxic elements, can be overcome by release from the roots of low-molecular-weight compounds, which include carboxylates, amino acids, and phenolic compounds.^[9] These processes can be greatly enhanced by adverse soil conditions.^[6]

Although genotypical differences have been observed in the capacity to acquire limiting nutrients and release of exudates from the roots, it has to be taken into account that these solutes can undergo microbial degradation, enzymatic breakdown, or sorption by soil colloids. Thus, the effectiveness of root exudates appears to be dependent on

the spatial and temporal characteristics of exudation^[5] and possibly on the presence of some protection provided by the spatial arrangement of root and soil surfaces.

ROOT-MICROBES: INTERACTIONS AND MOLECULAR SIGNALS

During their growth in natural conditions, plants continuously interact with soil microorganisms.

Microbial population in the rhizosphere may be one or two orders of magnitude higher than that of the bulk soil. Some of these microbes are deleterious, while others are beneficial to plants.^[10]

Root colonization is dependent on the release of root exudates. On the other hand, it has been demonstrated that root exudation can be stimulated by microbial colonization of plant roots and by the presence of microbial metabolites, the effects of microbes being species-specific.

Due to differences in rhizodeposition, not only different plant species but also different parts of the root system of the same plant may have distinctive rhizosphere microfloras,^[11] possibly reflecting the utilization profile of root exudates.

Among the beneficial microorganisms, bacteria belonging to *Rhizobium* or *Frankia* genera, as well as mycorrhizal fungi, are able to establish a symbiotic relation with their host plant.

It is well known that *Rhizobia*-legume symbiosis involves a molecular cross talk between the plant and the microbe; recently it has been shown that a similar signaling process might be involved in establishing a symbiosis with endomycorrhizal fungi.

Other rhizobacteria, generally designated as ‘‘plant growth-promoting rhizobacteria’’ (PGPR), stimulate plant growth by producing phytohormones or act indirectly as biocontrol agents through the production of antibiotics and siderophores and even by inducing plant resistance mechanisms.^[12]

Saprophytic microorganisms in the rhizosphere are responsible for the decomposition of organic residues and nutrient mineralization/turnover processes.

Many plant-associated bacteria use N-acetylated-homoserine-lactones (AHL) as quorum-sensing signals to control processes that are linked both to host interactions and to survival. Interestingly, exudates from some plants were found to contain AHL signal-mimic molecules. This suggests that molecular signals could also be exchanged between plants and non-pathogenic and non-symbiotic rhizobacteria.

Deciphering the molecular basis of root-microbes interactions is a major challenge for understanding the rhizosphere ecology. This would in turn allow the

management of the rhizosphere and possibly offer agronomic applications.

The complexity of the rhizosphere and its unique features are emphasized also by the biochemical events and molecular cross talk between host and parasitic plants: It has been shown that compounds released by host roots may act as molecular signals for parasitic plants.^[13]

It is worthwhile to say that caution should be used when transferring data obtained using artificial microcosms to the situation occurring in the soil. In fact, any bacterial species living in a mixed microbial population, such as that of the rhizosphere soil, may encounter not only the molecular signal produced by a cell of the same species but also molecular signals produced by cells of different species. The situation is made more complex by the presence of plant molecular signals and by the fact that the same AHL molecule can be used to regulate the expression of different biological processes in different bacterial species. On the contrary, some bacterial species can produce multiple AHLs, each having different effects on the phenotype. In soil, the situation is even more complex because the molecular signals can interact with surface active soil particles through electrostatic interactions, hydrogen bonds, and van der Waals bonds. In addition, molecular signals with anionic groups can be adsorbed by inorganic soil colloids by a ligand exchange mechanism.

ROOT SENSING OF THE ENVIRONMENT

To cope with the uneven distribution of ions in the surrounding root, plants have evolved mechanisms which include expression of transporter genes in specific root zones or cells and synthesis of enzymes involved in the uptake and assimilation of nutrients. Root development can also be significantly modified in response to variations in the supply of inorganic nutrients in the soil. These plant responses are largely controlled by the internal status of the plant. On the other hand, it has been recently shown that this behavior is also dependent on the capacity to locally sense the changes in the external concentration of the nutrient.^[14] These evidences support the existence in plants of sensing mechanisms for environmental signal(s) coming from the rhizosphere, including variations in the availability and distribution of nutrients.

Rhizosphere: Biochemical Reactions

Paolo Nannipieri

Università degli Studi di Firenze, Florence, Italy

INTRODUCTION

The rhizosphere soil is a site of complex interactions among plant roots, microflora, and microfauna. Therefore, all known biochemical reactions of living cells also occur in the rhizosphere soil. Pathways of primary and secondary metabolisms of microbial, animal, and plant cells also occur in the rhizosphere soil, including microbial degradation of natural and man-made recalcitrant compounds (pesticides, synthetic polymers, etc.), nitrification by autotrophic bacteria, or dissimilatory reactions of nitrate and sulfate. However, the biochemistry of rhizosphere soil shows some distinctive properties such as the presence of: 1) a variety of compounds released from roots (exudates, secreted lysates, chelators, and signal molecules) and from rhizospheric microorganisms (signal molecules, antibiotics, antifungal metabolites, toxins, antibiotics, phyto-stimulators, chelators, etc.), and 2) active enzymes in living root, microbial and animal cells, free extracellular enzymes, and enzymes adsorbed by clays or entrapped by humic molecules. Another peculiar aspect of rhizosphere biochemistry is its metabolism, which is the result of complex microflora-microfauna interactions.

RHIZODEPOSITION AND OTHER PARTICULAR ORGANIC COMPOUNDS IN THE RHIZOSPHERE

Rhizodeposition is the term used to indicate the overall compounds released by plant roots into soil. In addition to compounds of primary and secondary metabolism and polymers (mucilage), plant roots, in response to nutrient stresses, can also release chelators. Thus, grasses produce phytosiderophores under iron deficiency whereas dicotyledonous plants respond by increasing the release of organic acids, acidifying the rhizosphere and secreting reductants to increase iron availability to plants.^[1] Under iron deficiency, microorganisms of rhizosphere soil also produce chelators, called siderophores, which have a high affinity for iron; the complex interactions between plants and microorganisms under iron stress have been discussed by Crowley.^[1]

Microbes interacting with plants can be classified based on their effects on plants, as pathogenic, sapro-

phytic, and beneficial; the latter are also denominated plant growth-promoting rhizobacteria (PGPR). When microorganisms interact with plants, no matter if this interaction is beneficial or pathogenic, they use the same mechanism.^[2] The key event in the response of plants to microorganisms is recognition, which can occur through physical interaction or in response to specific compounds (signal molecules) released by the roots of the specific plant species to be infected. Thus, flavonoids and isoflavonoids are specific signal molecules in the legume-rhizobia symbiosis.^[3] Different plant species release different organic compounds that vary in their ability to induce or inhibit effective signalling by different soil bacteria.^[3,4]

Other compounds of the rhizosphere soil include antibiotics and hydrogen cyanide produced by plant growth-promoting rhizobacteria for the biological control of plant pathogen; antifungal metabolites are very important for the interactions of bacteria in the rhizosphere.^[2] Rhizobacteria can also produce phyto-stimulators, such as auxin derivatives.^[5] *Azospirillum*, a N₂-fixing bacteria, may promote plant growth by releasing phyto-stimulators rather than by its N₂-fixing capacity.^[2] Indeed, cytokinins, auxins, and gibberellines have been found in the supernatants of these bacteria.

In addition, as any microbial environment, the rhizosphere is characterized by the presence of signal molecules, which permit bacteria to communicate with cells of the same species and sometimes with other bacterial species.^[2] Intercellular signal compounds include N-acyl homoserine lactones, cyclic dipeptides and quinolones, and also volatile fatty acyl methyl esters.^[2,4] Microbial interactions have been studied in laboratory conditions without the presence of plants and soil colloids such as clay minerals and humic molecules. According to Pinton et al.,^[4] future research is needed to understand how the presence of plants and adsorbing surface-active colloids affects molecular cross talk among microbial cells.

ENZYMES IN THE RHIZOSPHERE

The enzyme activity is higher in the rhizosphere than in the bulk soil due to the higher number and activity of microorganisms, in response to the greater substrate

availability, and to the release of root-derived enzymes.^[6] Thus, acid and alkaline phosphatase activities were higher in the rhizosphere soil than in the bulk soil; these enzyme activities increased by approaching to the rhizoplane, whereas organic P concentration was negatively correlated with the increase in the enzyme activities. The inorganic P was depleted as the result of the root P uptake.^[7] The increases in enzyme activities were very high reaching, as the highest values among the different tested crop plants, 911% and 262% for acid and alkaline phosphatase, respectively.

The main problem in measuring an enzyme activity of rhizosphere soil is to distinguish the site of the various enzymes contributing to the measured enzyme activity. Indeed, enzymes can be active inside a plant, microbial, or animal cell or even in cell debris.^[8,9] In addition, enzymes not requiring cofactors for their activity, such as hydrolases, can remain active for a short period in the extracellular soil environment unless they are adsorbed by clay minerals or entrapped into humic molecules.^[10,11] Enzymes can be located in the soil matrix by combining ultracytochemical tests with electron microscopy. Unfortunately, it is problematic to apply these techniques to soil because of the presence of minerals, which are naturally electron-dense; the other problems of these techniques are reactions of the counterstaining compounds, such as OsO₄, with humic molecules or aspecific reactions with the heavy metal component of the enzyme-specific medium.^[8] In spite of these limitations, Forster and collaborators were capable of detecting acid phosphomonoesterase, succinic dehydrogenase, peroxidase, and catalase in microorganisms of rhizosphere soil.^[8,12] In addition, acid phosphomonoesterase was also detected in roots, mycorrhizae, and fragments of small (7 × 20 nm) microbial membranes.^[8,12,13]

The enzymes adsorbed by clay minerals or entrapped into the humic matrix can remain active even under unfavorable conditions for microbial activity, because they are more resistant to thermal and pH denaturation than the microbial enzymes.^[9,11] A role for these extracellular stabilized enzymes in microbial ecology has been hypothesized; indeed, their presence ensures the extracellular degradation of a series of substrates and decreases the need of microbial cells to synthesize and release extracellular enzymes to carry out these reactions.^[10] It is noteworthy to say that soil is an inhospitable environment for extracellular enzymes because nonbiological denaturation, adsorption and inactivation, and degradation by proteases all conspire to end the life of the free extracellular enzyme.

A better interpretation of changes in enzyme activities in the rhizosphere soil requires to distinguish the activity of the enzyme stabilized by soil colloids and that of free extracellular or intracellular enzymes.^[11] Unfortunately,

the present assays do not allow distinguishing both enzyme activities.

METABOLISM OF RHIZOSPHERE SOIL AS AFFECTED BY MICROFLORA AND MICROFAUNA INTERACTIONS

The plant uptake of nutrients such as N depends on the interactions between microflora and microfauna. Microbial growth in rhizosphere soil is promoted by the release of organic materials by plant roots; since the C/N ratio of the root-derived C is higher than the C/N ratio of microbial biomass, a substantial amount of N is immobilized during microbial growth.^[6] This can result in a temporary decrease in the amount of plant-available N. According to Clarholm,^[14] this microbial N immobilization is followed by a stimulation of the N mineralization promoted by protozoan grazing, with the release of ammonium, which is taken up by the plant root. The release of ammonium occurs because protozoa have a higher C/N ratio than bacteria. This series of events seems to be confirmed by the increase in protease and deaminase activities observed in the rhizosphere soil.^[6]

Plants can take up and assimilate several N sources (ammonium, nitrate, urea, amino acids), but the particular form taken up depends on the plant species; thus, tomato growth is inhibited if the ammonium concentration is too high.^[6] Competition between nitrifiers, heterotrophs, and plants occurs in the rhizosphere soil and can be particularly evident in N-limited systems such as forests. In this case, nitrifiers converting ammonium to nitrate may limit the amount of N immobilized by heterotrophs and favor the N uptake by plant species preferring nitrate to ammonium as a N source.

CONCLUSIONS AND FUTURE RESEARCH NEEDS

Rhizosphere metabolism includes pathways of animal, microbial, and plant cells. However, the overall metabolism of the rhizosphere soil is peculiar because it reflects the complex interactions among microflora, plant roots, and microfauna. Another distinctive characteristic of rhizosphere soil is the presence of a variety of compounds released from plant roots, microorganisms, and microfauna affecting these complex interactions. The most well-known molecular cross talk is that between legumes and rhizobia. However, future research is needed to understand exchanges of molecular signals between the various microorganisms and plant roots, among microbial cells of the same and different species, and between microbial cells and microfauna. It is also needed to study the effect

of surface-active colloids on the exchange of these molecular signals. Future research should also be directed in setting up enzyme assays, which allow the distinction of the activity due to enzymes stabilized by soil colloids from that of enzymes present in active animal, microbial, and plant cells.

Rhizosphere: Microbial Populations

James M. Lynch

Forest Research, Farnham, Surrey, U.K.

INTRODUCTION

The rhizosphere—the field of action of plant roots—can be viewed as a trinity whereby the biotic and abiotic factors from the soil, plant, and microbial population interact to determine the population structure and composition of the rhizosphere. The microbiota includes bacteria, fungi, actinomycetes, algae, protozoa, nematodes, and some small mites. This diverse assemblage can be influenced by agricultural practices and is influential in determining the sustainability of agricultural systems. The rhizosphere is the powerhouse of soil microbiological activity and offers major opportunities in soil biotechnology. A major research problem is that only about 5% of bacteria are culturable, and the fungi that are isolated often derive from spores that do not represent the negative states of the organism.

DISCUSSION

The bacterial population of the rhizosphere differs from that in the bulk soil, in terms of both population numbers and composition.^[1–4] It contains large numbers of Gram-negative nonspore formers with a higher proportion of chromogenic and motile forms, and more ammonifiers, nitrifiers, denitrifiers, and aerobic cellulose decomposers. However, it sustains fewer Gram-positive cocci and organisms capable of utilizing aromatic acids than found in the bulk soil.^[5] Short Gram-negative rods respond most to rhizosphere conditions, and invariably make up a greater percentage of the rhizosphere microflora than that in the bulk soil population. The three genera *Pseudomonas*, *Achromobacter*, and *Agrobacterium* are examples of the Gram-negative rods that are highly stimulated within the rhizosphere.

Given that rhizosphere exudations and secretions—components of rhizodeposition—serve to enhance and maintain a higher population than that found in the bulk soil, it must also be assumed that there is a high level of microbial competition within the rhizosphere. This in turn enhances selection pressure to select for those microorganisms most suited to the rhizosphere environment. Selection of bacteria whose growth is enhanced by amino acids is a reflection of the amount of amino acids in the

rhizosphere environment in comparison to in the environment of bulk soil. In general terms, bacterial populations within the rhizosphere are considered less fastidious than those found outside.

In contrast to the quantitative rhizosphere effect on bacteria, the nature of the effect for fungi is more qualitative with little effect on fungal numbers but an enhanced stimulation effect for certain genera. The imperfect fungi *Fusarium* spp, which are often pathogenic, are prominent members of the rhizosphere and a common example of this phenomenon, although numerous other genera are represented. There can also be an ecological link between fungal components and the bacterial components of the rhizosphere. The symbiotic mycorrhizal fungi, which can be ectotrophic and endotrophic, are particularly important in effectively increasing the root's absorbing power to promote the uptake of phosphorus and water.^[6]

ROOT COLONIZATION

It is generally understood that the organisms associated with seeds (such as the common fungi (*Penicillium* spp, *Aspergillus* spp)) and bacteria contribute very little to the established rhizosphere. The young seedling is first colonized by chance bacteria that first encounter the influence of the developing root, with a more species-stable population establishing as the root matures. The developing root tip and root hairs are commonly free of microorganisms, with bacteria colonizing at sites of lateral root emergence from the main root stem. The rhizosphere effect then increases with the age of the plant, reaching a peak at the height of vegetation and declining as senescence approaches. This is, however, a generalization; specific plant species display peaks at alternative times during their life cycles, with crop species generally exhibiting greater rhizosphere effects than do trees. The most pronounced population increases involve the amino acid-requiring bacteria and other organisms with simple nutritional requirements and rapid growth rates.^[7] The dominance of specific bacteria in certain plants is another a phenomenon that has been noted (Fig. 1).

The nature of secretions changes through a root's life cycle; consequently, the microorganisms that it can

Fig. 1 The rhizosphere trinity: The interacting factors that determine the environmental conditions of the rhizosphere. (Based on Ref. 1.)

support change. It is considered that most root colonization is triggered as the root tip advances through the soil, with the root tip performing as a slowly advancing source of substrate that serves to stimulate the growth and activity of dormant bacteria within the sphere of its influence. The process of root colonization can be conceptually divided into a series of steps: migration toward plant roots, attachment, distribution along the root, and growth and establishment of the microbial population. A number of microbial traits involved in these steps has been postulated, including chemotaxis, agglutinability, the use of flagella, and the ability to utilize complex carbohydrates. The phenomenon of rhizosphere competence describes the ability of microorganisms to associate with roots; the quantitative measurement of this is the colonization potential. The challenge is to stimulate organisms beneficial to the plant rather than those that are harmful, such as toxin producers and pathogens. In this respect some rhizosphere-competent strains of *Pseudomonas*^[8] and *Trichoderma*^[9] have proven particularly beneficial in disease control and growth stimulation.

NUTRIENT CYCLING

The rhizosphere is an environment created and maintained by the plant at cost to the plant. What benefits does the plant receive from this input of energy? The acquisition of nutrients is the preliminary goal of the investment that plants make in their environmental modifications. Interactions with the microbial populations of the rhizosphere

enhance the availability and uptake of nutrients that might otherwise have been unavailable to the plant root system. This happens in a number of ways and for a number of nutrients. Probably the most important nutrient in terms of plant growth is nitrogen, the discussion of which will serve here to also exemplify the importance of other nutrients.

Plant roots and the microbial populations that inhabit them are highly integral to the nitrogen cycle. The microbial population of the bulk soil is involved in the conversion of nitrogen through its various forms in the nitrogen cycle, as well as in fixing free nitrogen from the atmosphere (free-living nitrogen fixers). The enhanced populations within the rhizosphere provide the host plant with nitrogen in a readily available form for immediate utilization and subsequent release when the plant dies or is consumed. Far more nitrogen passes through this link in the cycle than does from the bulk soil.

Nutrient cycling in soil is extremely dependent on the supply of energy to the soil biota. Given that the source of this energy is carbon from organic compounds, it can be seen that the nitrogen and carbon cycles are inextricably linked, with carbon as the impetus.

MINERALIZATION AND IMMOBILIZATION

The decomposition of plant material and accompanying mineralization and immobilization of the organic N it contains are key processes in the soil–nitrogen cycle. Once incorporated into the soil matrix, plant residues will bring about a rapid increase in microbial biomass as the material is colonized. In the case of heterotrophic microorganisms using organic material as a source of combined carbon for both respiration and cell synthesis, the progressive decomposition of nitrogen-containing compounds will result in ammonium for use by the organism itself, with the excess released as waste. If insufficient nitrogen is contained within the substrate, then the organisms will draw upon the soil mineral nitrogen, resulting in nitrogen immobilization. The balance between release of nitrogen and immobilization depends on the carbon-to-nitrogen ratio of the material under decomposition, the energy efficiency of the organism, and the carbon-to-nitrogen ratio of the cells being synthesized. The carbon-to-nitrogen ratio of the substrate is the most influential of these factors, with materials varying from 5:1 for animal wastes to 100:1 for cereal straws. The ratio at which nitrogen is neither released nor immobilized has been shown to be approximately 35:1. This highlights the importance of this microbial-mediated process as it supplies nitrogen to the plant in what can be considered its preferred form (which is a less susceptible form than leaching) as well as providing the raw material for the nitrification sequence.

Given that ammonifying bacteria have a higher rhizosphere population than the bulk soil or R:S ratio (in excess of 50:1), it would be expected that there would be greater mineralization of organic matter within the rhizosphere. In the field situation, however, less mineralization can be shown to have occurred in soil under crops than in fallow soil, even allowing for the nitrogen taken up by the plants. This anomaly can be explained by ^{15}N studies that have shown that, although the net amount of mineralization in cropped soil is only half that in fallow soil, the total quantity mineralized is greater under cropping. The difference between the two soil types is due to the rapid assimilation of the mineralized matter by the microbiota within the rhizosphere of the crop.

This illustrates that the availability of nitrogen to the plant is a result of the opposing processes of mineralization and immobilization and on the plant's ability to compete for the available nitrogen. This suggests that the overall microbial effect in the rhizosphere is detrimental as often as it is beneficial. However, experimental comparisons of rhizosphere and nonrhizosphere soils have demonstrated that the rhizosphere effect on the net N mineralization from indigenous soil organic matter is positive in many cases but not in all.^[10] The actual microbial N immobilization generated by root-derived carbon seems to be counterbalanced by stimulation of nitrogen mineralization by promoted grazing of protozoa and the consequential release of ammonium by assimilation, as well as a higher microbial turnover of soil organic matter. It is hypothesized that the effect can also be beneficial, as a consequence of the nitrogen form involved (nitrate), and because the continual cycling of the nitrogen compounds via the microbial components prevents their loss from the system through leaching, thus providing a more constant supply to the plant.

Pseudomonas fluorescens is a very common soil bacterium; some strains can increase the mineralization of nitrogen in the pea rhizosphere, but reduce it in wheat.^[11] The likely interpretation is governed by the differential effects in the two rhizospheres on the bacterial-feeding nematodes and protozoa.

DINITROGEN FIXATION

The biological fixation of molecular nitrogen is carried out by several free-living bacterial genera, some of which are rhizosphere-associated, such as other *Azotobacter* and *Azospirillum*.^[12] In terrestrial systems, however, the largest contribution of combined nitrogen comes from the symbiotic fixation of dinitrogen by rhizobia, with fixation rates often two to three orders of magnitude

higher than those exhibited by free-living bulk soil dinitrogen fixers. It is the increase in plant-available nitrate that is the most consistent effect on soil nitrogen levels brought about by both crop and pasture legumes. A combination of conserved soil nitrogen, greater mineralization potential, and the return of fixed nitrogen explain why the benefits of crop legumes to nonlegume crops can be considerable.

The best studied examples of symbiotic nitrogen fixation are the soil bacteria of the genera *Rhizobium*, *Bradyrhizobium*, and *Azorhizobium*, collectively referred to as rhizobia. These organisms have the ability to induce the formation of nodules on the roots of leguminous plants. In these nodules the host plant provides the bacteria with their nutrient requirements and an environment conducive to nitrogen fixation. In return, the bacteria fix dinitrogen in excess of their requirements. The dinitrogen is subsequently released as ammonia and taken up by the plant.

While the rates of N_2 fixation for free-living bacteria are relatively low in comparison to those in a symbiotic or mutualistic relationship, the bacteria that conduct fixation under such conditions are widespread in soils, so do contribute to soil nitrogen inputs. This said, the rate of free-living bacteria such as *Azotobacter* and *Azospirillum* is increased under rhizosphere conditions, due to increased efficiency as a result of more readily available organic compounds exuded from roots. Consequently, it can be seen that the symbiotic fixing of N_2 in the rhizosphere brings substantial benefit to the plant system's ability to acquire and utilize nitrogen.

CONCLUSION

The rhizosphere community is a very complex structure that has great metabolic diversity. Some of this diversity can be beneficial to plants and the environment, although other facets are harmful. The population can now be investigated at the molecular level by determining nucleic acids present. The challenge is to link conventional population biology and metabolic diversity to this genetic capability. The study of the functional genomics of the rhizosphere provides tantalizing prospects for the future.

Rhizosphere: Modeling

Peter R. Darrah

University of Oxford, Oxford, United Kingdom

INTRODUCTION

The rhizosphere is the region of soil surrounding a length of root that is modified physically, chemically, or biologically by the activity of the root. Root activity may include water and mineral nutrient uptake, release of water-soluble organic solutes, production of mucilage, sloughing of plant cells, etc. Uptake/release perturbs the “steady-state” concentrations in bulk soil and generates gradients leading to transport through the soil matrix. The rhizosphere, in modeling terms, is therefore defined as an approximately cylindrical region of variable radius, encompassing a concentration gradient of the solute(s) of interest. Rhizosphere models simulate the often complex and dynamic changes in the chemistry and microbiology of this region that occur over time.

MODELING SOLUTE TRANSPORT IN THE RHIZOSPHERE

The common feature of all mechanistic rhizosphere models is the simulation of the transport processes that move solutes around the rhizosphere. The physical processes involved are diffusion and convection, and the former is normally the dominant process.^[1]

Diffusion of Solutes

The development of the theory of solute diffusion in soils was largely due to the work of Nye and his co-workers in the late 1960s and early 1970s^[2] who adapted the Fickian diffusion equations to describe diffusion in a heterogeneous porous medium. Fick’s law describes the relationship between the flux of a solute (mass per unit surface area per unit time, J_L) and the concentration gradient driving the flux. In vector terms

$$J_L = -D_L \nabla C_L \quad (1)$$

where D_L is the diffusion coefficient in pure water at the ambient temperature and pressure, and C_L is the concentration of the solute in solution. For a solute diffusing in soil, three additional factors must be taken into account:^[2] firstly, diffusive movement is only significant in the solution phase and only concentration

gradients in the soil solution drive diffusive movement; secondly, the cross-sectional area available for diffusion is reduced because the solute can only move in the solution phase; thirdly, an empirically determined tortuosity factor (f : range 0–1) is required to reflect the increased pathlength for diffusion in soil. To account for these factors, which all act to reduce the rate of diffusion in soil compared to water, Fick’s law is modified:

$$J = -D_L \theta f \nabla C_L \quad (2)$$

where θ is the volumetric moisture content and C_L defines the soil solution concentration of the solute.

In most cases C_L is not known directly but is a secondary, derived parameter, and to solve Eq. 2, it must be related to a known variable. This introduces a complication because many solutes exist in several forms in soil and some do not contribute directly to diffusion. Conventionally, all phases that can equilibrate with soil solution over a time-scale comparable with diffusion (seconds–minutes) are defined as available solutes (C_a) and are considered to contribute to diffusion. This would include most anions in most soils and uncharged organic molecules such as glucose. Many solutes display positive charge and will interact electrostatically with the negatively charged surfaces found in most soils, whereas others, such as phosphate, may interact with surfaces via ligand exchange mechanisms. Such inner and outer sphere surface complexes,^[3] jointly termed exchangeable solutes, are normally included as available solutes.

The reciprocal of the buffer power, b , defines the fraction of the available solute which is in soil solution at a particular concentration, i.e.,

$$b = \frac{\partial C_a}{\partial C_L} \quad (3)$$

Substituting for C_L in Eq. 2 gives

$$J = -\frac{D_L \theta f}{b} \nabla C_a \quad (4)$$

The relative rate of movement of individual solutes in soil is therefore dominated by the value of their buffer power. Buffer power is normally derived experimentally by adding different amounts of solute to a soil, allowing a brief equilibration period, and then determining the new soil solution concentration: b is then the gradient of the

resulting buffer curve. For mineral ions,^[4] the values for b vary enormously between soils, but typical values might be 100–2000 for phosphate, 3–30 for K and NH_4 , while for anions such as NO_3 and Cl , which exist wholly in the solution phase, $b = \theta$. Organic solutes show similar ranges. As a consequence phosphate may diffuse $5000 \times$ slower than nitrate in the same soil.

Convective Transport

Water, moving through the soil pores in response to water potential gradients, moves with it the solutes dissolved in soil solution. In a rhizosphere context, water moves radially toward the root to replace water taken up by the roots for transpiration. The flux of solute due to water movement (J_w) is simply the product of the rate of water flow at that point and the concentration in soil solution.^[2]

$$J_w = v C_L = \frac{v}{b} C_a \quad (5)$$

In a cylindrical system, because equal amounts of water are being transported across successive concentric radial increments, the rate of flow of water must vary across the rhizosphere, with the fastest flows at the root surface. It is conventional to use a single parameter for rhizosphere water flow, v_0 , which is defined as the water flux (volume per unit area per unit time) at the root surface, r_a .

Continuity Equation for Solute Transport

To describe the movement of solutes in the rhizosphere, where concentration gradients change with space as well as time, t , mass conservation is invoked with the spatial geometry appropriate for the cylindrical root:^[2]

$$\frac{\partial C_a}{\partial t} = \frac{1}{r} \frac{\partial}{\partial r} \left[r \frac{D_L \theta f}{b} \frac{\partial C_a}{\partial r} + \frac{r_a v_0}{b} C_a \right] \pm \frac{\partial S}{\partial t} \quad (6)$$

$$r_a < r < r_b$$

Here the spatial coordinate, r , defines the radial position in the cylinder of soil surrounding the root. This parabolic, second-order partial differential equation describes how the concentration of available solute at an arbitrary point in the rhizosphere changes with time in response to the concentrations on either side of it. Note that this equation is effectively one-dimensional because concentration gradients along the root length can be neglected on the basis that roots are long and thin and concentrations around the root are assumed to be radially symmetric.^[1] If concentration gradients along the root are thought to be important, then two-dimensional equations and solutions are required.^[5]

Transfers between available and unavailable solutes are modeled via the $\partial S / \partial t$ source-sink term: these could include dissolution of sparingly soluble mineral phases;

the mineralization of soil organic matter forms of the solute or the immobilization into microbial biomass.^[1–3]

BOUNDARY CONDITIONS

Eq. 6 describes how solutes will move in response to concentration or water potential gradients formed when the rhizosphere is perturbed by the activities of the root. These activities need to be mathematically described and form one of the two boundary conditions required to solve the initial-value problem: two examples are given below. The first is commonly used to simulate the uptake of mineral nutrients^[6] and equates root uptake (I_{\max} = maximum rate of uptake per unit surface area of root, K_m = affinity constant for uptake, E = rate of loss of nutrient to the soil per unit surface area) to the diffusive flux at the root surface.

$$I_{\max} \frac{C_L}{C_L + K_m} - E = \frac{D_L \theta f}{b} \frac{\partial C_a}{\partial r} \quad \text{at } r = r_a \quad (7)$$

The second describes the efflux and subsequent influx of glucose from roots that forms part of the rhizodeposition of root C that leads to microbial accumulation around roots.^[2]

$$-P(C_{\text{cyt}} - C_L) + V_{\max} \frac{C_L}{C_L + K_m} = D_L f \frac{\partial C_a}{\partial r} \quad (8)$$

$$r = r_a$$

Here, efflux depends on diffusion (C_{cyt} and C_L are the glucose concentrations in the root cytoplasm and soil solution, respectively, and P describes the permeability of the root to glucose). Reuptake of C is described in terms of Michaelis–Menten parameters.

The outer boundary condition defining the limit of the rhizosphere at $r = r_b$ is normally of the form:

$$\frac{\partial C_a}{\partial t} = 0 \quad r = r_b \quad (9)$$

SOLUTION OF THE EQUATIONS

The partial differential equations (PDE) given in Eqs. 6, 7 or 8, and 9 together form an initial-value problem, and initial values for all parameters and concentrations in the region r_a to r_b must be specified at the start. Most equations are then solved numerically using finite difference or finite element methods.^[5]

Several commercial mathematical packages now offer PDE solvers although some may impose restrictions on the type of boundary condition that can be specified. In some cases, approximate boundary conditions can be specified which allow for an analytical solution.^[1,2]

MORE COMPLEX SYSTEMS

The rhizosphere is a complex environment with multiple simultaneous interactions occurring between roots, soil, and microbes.^[2,7,8] As the rhizosphere develops, microbe numbers and individual species abundance may change markedly, the soil environment in terms of structure and chemistry, e.g., soil pH may be modified, and the levels of mineral nutrients, water, and organic compounds will change. This in turn may affect other processes leading to multiple feedback effects. Rhizosphere models accommodate this complexity by including several process variables, each with their own continuity equation and boundary conditions, which interact with each other through source-sink terms. The set of equations is then solved simultaneously. For example, the transport and uptake of Ca, Mg, K, NO₃, Cl, and SO₄ were simulated simultaneously to predict soil pH change in the rhizosphere resulting from imbalanced cation and anion uptake.^[9]

SCALING

A plant root system may extend several tens of kilometers and may take months to develop. The extent, deployment, and architecture of the root system will depend in part on the mineral nutrition resulting from the integrated uptake from each root segment and its local rhizosphere. Rhizosphere models of growing plants must therefore integrate from the local rhizosphere level to the whole plant scale. This may simply involve integrating influx over the growing root system if mineral nutrients do not limit growth.^[1,6] However, increasingly, the rhizosphere model is a subprocess model within a larger simulation of whole plant growth where root parameters depend on nutrient uptake history,^[2,10] although most whole plant or crop models currently simplify the rhizosphere model.

CONCLUSION

The biological members of the rhizosphere trinity show enormous capacity for adaptive “plastic” responses to changing environmental conditions. Plants under nutrient stress can show a variety of plastic responses including changing root allocation, architecture, physiology, and

biochemistry,^[7] many of which have not been comprehensively modeled. Attempts to manipulate the microbiology of the rhizosphere^[8] depend on favoring one or two species to achieve biological control, yield promotion, or bioremediation: modeling of microbial dynamics at the species level will represent a considerable challenge in the future.

Rhizosphere: Nutrient Movement and Availability

Philippe Hinsinger

INRA-ENSA. M, Montpellier, France

INTRODUCTION

The absorption of nutrients by plant roots is the process by which nutrients enter root cells across the plasma membrane. For soil-grown plants and most nutrients, it is considered that the limiting step in plant nutrition is not the absorption, but rather the processes occurring in the rhizosphere prior to absorption, namely nutrient mobilization and movement. The acquisition of nutrients embraces all these major steps, which depend on physical, chemical, and biological processes and factors.

BIOLOGICAL PROCESSES AND FACTORS INVOLVED IN NUTRIENT ACQUISITION

The acquisition of nutrients by plants combines three strategies. The first strategy is to increase the surface of absorption, which is essential for the acquisition of poorly mobile nutrients such as P and micronutrients.^[1,2] The architecture of the root system is one of these means: Its diversity and plasticity among plant species show that this strategy is differently exploited. The actual surface of absorption is not simply the external surface developed by root system: Root hairs are extensions of epidermal cells that can considerably extend the surface of absorption and the actual volume of soil prospected by roots. Their quantitative influence on the acquisition of P has been clearly demonstrated.^[2] In addition, nutrients such as Ca and Mg move through the apoplasm of root cortex before actually being absorbed. Thus, the surface developed by the apoplasm should be taken into account,^[3] although it does not contribute to enlarge the volume of prospected soil. Another extension of the surface of absorption is provided by the symbiosis with mycorrhizal fungi, which is a widespread feature as more than 90% of plant species can form such symbiosis.^[1,4] Mycorrhizal hyphae have much finer diameter than roots and root hairs and can extend several centimeters from the root surface, providing access to nutrients that would otherwise not be spatially available to the root. Their importance for the acquisition of poorly mobile nutrients such as P has been demonstrated.^[4] The actual volume of the rhizosphere therefore depends on these complex features of the geometry of roots and mycorrhizae.

The second strategy involved in the acquisition of nutrients relies on the physiological equipment of the absorbing surface,^[1] i.e., transporters and ion channels of the membranes of root hairs, epidermal and cortical cells, and those of mycorrhizal hyphae in mycorrhizal plants. Their density and absorption characteristics largely determine the plant's capability to acquire nutrients. For many nutrients that occur at rather low concentrations in the soil solution, uptake systems exhibiting a high affinity and able to function at low concentrations are crucial for the plant's acquisition efficiency.^[2,5] The absorption is, however, often considered to be nonlimiting, compared with the physical and chemical processes involved in the mobility of nutrients in the soil. The third strategy of the plant for acquiring nutrients relies indeed on physical and chemical processes that affect the availability of nutrients in the rhizosphere.

PHYSICAL PROCESSES AND FACTORS OF NUTRIENT MOVEMENT

Plant roots are taking up mineral nutrients dissolved in the soil solution. Therefore, in the absence of any movement of nutrients in the soil, the roots can access only a minor amount of nutrient from soil solution in the immediate vicinity of roots. This process, called root interception, is therefore considered to contribute only a minor proportion of the overall acquisition of most nutrients (Table 1). In addition to this process, the uptake of water by roots results in a movement of water from the bulk soil towards the root surface, along a gradient of water potential. As the soil solution contains water and dissolved nutrients, the uptake of water by roots generates a convective movement of solutes, i.e., mass-flow. The corresponding flux of nutrient depends on the flux of water and nutrient concentration in the soil solution.^[2,6] For those nutrients that are present at elevated concentrations in the soil solution, which is typically the case of nitrate in many agricultural soils, mass-flow can contribute a major proportion of plant acquisition (Table 1). For Ca and Mg, it can even exceed the actual flux of nutrients absorbed by the plant, thereby resulting in a buildup of their concentration in the rhizosphere (Fig. 1). This may ultimately result in a precipitation of Ca salts around roots, such as CaCO₃ in calcareous soils.^[7]

Table 1 Estimated contributions of interception, mass-flow, and diffusion to the acquisition of nutrients by a maize crop yielding 9500 kg of grain yield per ha

Nutrient	Acquisition			
	Interception	Mass-flow	Diffusion	
	kg ha ⁻¹			
Nitrogen	190	2	150	38
Potassium	195	4	35	156
Phosphorus	40	1	2	37
Calcium	40	60	150	0
Magnesium	45	15	100	0
Sulfur	22	1	65	0

(Adapted from Ref. 6 by permission of John Wiley and Sons, Inc.)

On the contrary, for those nutrients that are present at low concentrations in the soil solution compared with the plant's requirement, such as K and P (Table 1), root absorption results in a decrease in concentration in the rhizosphere (Fig. 1). The resulting concentration gradient in the rhizosphere is the driving force for diffusion. The diffusive flux of nutrient also depends on the diffusion coefficient.^[2,6] The actual diffusion of any nutrient in soils is, however, much slower than in water, because of physical and chemical interactions with the soil solid phase.^[8] The soil water content, tortuosity, and buffer

power (ability of soil solid phase to replenish the soil solution) determine the effective diffusion coefficient in soils.^[2,9] Table 2 shows that whereas the diffusion coefficient in water is fairly similar for ions such as NO₃⁻, K⁺, and H₂PO₄⁻, their diffusion coefficient in soils is different because of the lower mobility of K⁺ ions, and more so of H₂PO₄⁻ ions compared with NO₃⁻ ions. Such differences are essentially due to differences in buffer power that arise from chemical interactions with soil constituents. H₂PO₄⁻ ions are prone to strongly react with soil solid phase, via a whole range of precipitation/dissolution and adsorption/desorption reactions, while NO₃⁻ ions are not. The buffer power of soils for H₂PO₄⁻ ions is thus much larger than for NO₃⁻ ions, and hence their effective diffusion coefficient is much smaller (Table 2). Therefore, the radial distance from which a nutrient can diffuse towards the root surface considerably varies among nutrients and soils (Table 2)—from centimeters for NO₃⁻ ions and millimeters for K⁺ ions to a fraction of a millimeter for H₂PO₄⁻ ions (Fig. 1). The physical factors that influence the movement of nutrients towards the root surface via both mass-flow and diffusion are soil water content, porosity, tortuosity, viscosity, and temperature. All but the last can be altered by roots (Fig. 2).

Percentage of bulk soil concentration

Fig. 1 Typical profiles of nutrient concentrations (expressed in % of the concentration in the bulk soil solution) in the rhizosphere showing an accumulation of Ca and Mg and a more or less steep depletion of N, K, and P. (View this art in color at www.dekker.com.)

CHEMICAL PROCESSES AND FACTORS INVOLVED IN NUTRIENT AVAILABILITY

The acquisition of nutrients is much dependent on chemical processes and factors that determine the actual concentration and speciation of nutrients in the soil solution and the soil buffer power. These vary with nutrients, soil types, and properties and as a consequence of root and microbial activities in the rhizosphere.

The uptake activity of the root can result in considerable changes in nutrient concentrations, which can either increase or decrease in the rhizosphere (Fig. 1).

Table 2 Diffusion coefficients of some major nutrient ions in water (D_w), range of values of effective diffusion coefficients in soils (D_e), and corresponding radial distances of diffusion (Δx) within one week ($t = 604,800$ s), according to the equation: $\Delta x = \sqrt{(\pi D_e t)}$

Nutrient ion	D_w	D_e	$\Delta x = \sqrt{(\pi D_e t)}$ (m)
	(m ² s ⁻¹)		
NO ₃ ⁻	1.9 10 ⁻⁹	10 ⁻¹⁰ –10 ⁻¹¹	4.4–13.8 10 ⁻³
K ⁺	2.0 10 ⁻⁹	10 ⁻¹¹ –10 ⁻¹²	1.4–4.4 10 ⁻³
H ₂ PO ₄ ⁻	0.9 10 ⁻⁹	10 ⁻¹² –10 ⁻¹⁵	0.1–1.4 10 ⁻³

(Adapted from Ref. 2 with kind permission from Marcel Dekker, Inc.)

Fig. 2 Schematic diagram of the physical, chemical, and biochemical interactions between roots and soil components that determine the movement and availability of nutrients in the rhizosphere. Note that the microbial activities that are stimulated by root exudation themselves comprehend physical (e.g., aggregation), biochemical (e.g., mineralization), and chemical (e.g., chemical reactions related to microbial respiration or release of acids) processes. Although of equal importance, they have not been drawn for the clarity of the diagram. (View this art in color at www.dekker.com.)

This will have a dramatic effect on all the reaction equilibria governing the dynamics of nutrients in soils.^[7] It has been estimated that the concentration of K decreases 100– 1000-fold in the rhizosphere, shifting dramatically the equilibria of adsorption/desorption of exchangeable K and even fixation/release of nonexchangeable K.^[10] This explains the rapid depletion of exchangeable K and substantial contribution of nonexchangeable K to K availability in the rhizosphere (Fig. 3), which would not occur under bulk soil conditions.^[10]

The availability of many nutrients such as P and metal micronutrients (Fe, Mn, Zn, Cu, etc.) is strongly pH-dependent, as protons are implied in their speciation

and in many reactions, e.g., precipitation/dissolution at the soil solid–soil solution interface. Roots and rhizosphere microbes can be responsible for considerable changes of pH and, hence, of the availability of nutrients such as P.^[5] The origins of root-induced pH decrease are as follows: 1) primarily proton release to counterbalance an excess of cation over anion uptake; 2) release of organic acids; and 3) release of CO₂ via respiration, which leads to a buildup of rhizosphere concentration of H₂CO₃, which dissociates in all but acid soils.^[7] The availability of Ca phosphates can be much increased as a consequence of the lower rhizosphere pH found in ammonium-fed plants than in nitrate-fed plants.^[5]

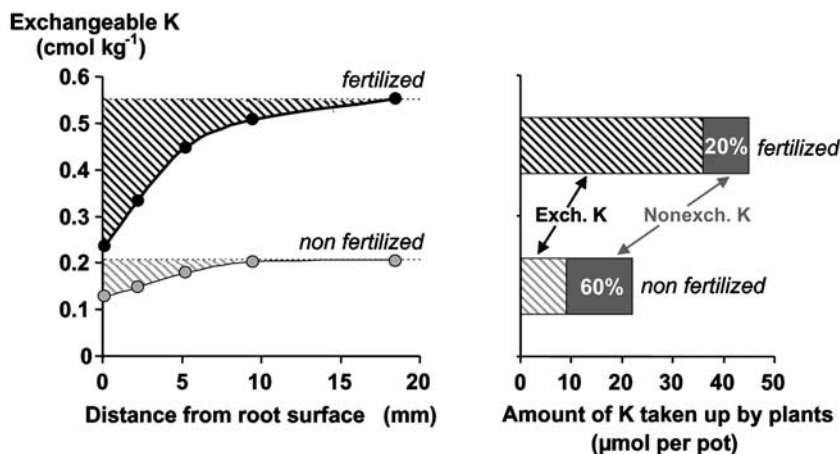

Fig. 3 Depletion of exchangeable K in the rhizosphere of oilseed rape after four days of growth in a fertilized and nonfertilized soil sampled at the long-term fertilizer trial of Gembloux, Belgium. The extension and intensity of the depletion zone were used to calculate the amount of exchangeable K depleted by the plants. Subtracting this value from the actual amount of K taken up (determined by plant analysis) provided an estimate of the contribution of the release of nonexchangeable K within the four days of the pot experiment.

The availability of many metal micronutrients is also governed by redox reactions and complexation processes, which can be considerably affected by the activities of roots and microbes in the rhizosphere.^[7] Complexing compounds released by roots and rhizosphere microbes have been shown to potentially increase the availability of metal nutrients.^[11] Grasses are capable of releasing Fe-chelating compounds called phytosiderophores.^[1,7] This process is enhanced under Fe deficiency and is thus part of an efficient strategy to acquire Fe in soils where its availability is minimal, such as calcareous soils. These root exudates can also strongly chelate other metal micronutrients such as Zn and Cu and thereby increase their availability.^[1,7] Carboxylic anions have also been extensively studied for their role in the dynamic of nutrients such as P. Their effect is based on the complexation of metal cations that play a major role in binding phosphate ions in soils, such as Ca, Fe, and Al, but can also rely on ligand exchange reactions that promote the desorption of phosphate ions from soil constituents.^[5,12] In many plant species, the rate of release of such exudates may be too low to be of any significance, though. Some species of plants and ectomycorrhizal fungi have been shown to exude large amounts of citrate, malate, or oxalate and significantly increase the availability of soil P.^[5,12] Some major nutrients can occur in the soil as organically bound nutrients, such as N, P, and S. These organic molecules will require biochemical processes such as enzymatically controlled hydrolysis to evolve into smaller molecules and ultimately release N, P, and S. Plant roots can exude some enzymes that will catalyze such breakdown processes, as shown for phosphatases that help plants make use of organic P compounds.^[1,11] However, soil microorganisms play a major role in these processes, through a variety of enzymatic pathways. Their stimulation by root exudation definitely contributes an enhanced release of organically bound nutrients in the rhizosphere (e.g., phosphatases, proteases, aminases produced by ectomycorrhizal fungi).^[4,11] Fig. 2 summarizes the numerous root-mediated, biochemical, and chemical processes and factors that determine the availability of nutrients in the rhizosphere.

CONCLUSION

Measuring the peculiar properties of the rhizosphere is challenging because of its spatial and temporal dynamics. Considerable advances in the identification of the factors and processes that determine the availability of nutrients in the rhizosphere have been made in recent decades, though. Comparing model outputs with actual measurements often shows large discrepancies, which suggest that there is still a need to better quantify the processes involved in nutrient acquisition.^[3] Another challenge for future research is to make better use of such knowledge

to determine how to manage those rhizosphere processes to improve a plant's acquisition efficiency, growth, and health. Both microbial and plant components are important tools to do so, in order to minimize the inputs of fertilizers and pesticides and increase the sustainability of plant-based productions.

Rice

Takuji Sasaki

National Institute of Agrobiological Sciences, Tsukuba, Ibaraki, Japan

INTRODUCTION

Rice is one of the most important cereal crops in the world because it is the main staple for about half of the world's population. Rice is also one of the most extensively analyzed plants in terms of its molecular biology, genetics, and nearly complete genome sequence and is thus considered a model plant for the cereal crops. Recent technological advances in genome analysis, such as high-throughput genome sequencing and genomewide analysis of transcripts, have paved the way for the characterization of many of the genes expressed in response to various environmental stresses. These innovations are expected to accelerate the breeding of new rice varieties with high yields and adaptability to unfavorable environmental conditions, thereby ensuring sufficient food to feed a burgeoning population, particularly in Asia and Africa. For this purpose, a thorough understanding of the rice plant's complex biological pathways, such as the genetic mechanisms of reproduction and physiological mechanisms of flowering time, is of utmost importance. In this article, the recent progress in rice molecular genetics is reviewed with emphasis on the development of rice genomics and its applications in the future.

MAPPING THE RICE GENOME CLONE-BY-COLNE

A molecular genetic analysis of rice has been undertaken to dissect the rice genome using DNA markers such as RFLP (Restriction Fragment Length Polymorphism), SSR (Simple Sequence Repeat), AFLP (Amplified Fragment Length Polymorphism), or CAPS (Cleaved Amplified Polymorphic Sequence). As a result, a high-density and precise genetic map with RFLP markers is now available,^[1] and soon these markers will be converted to PCR-based markers using the genome sequence information to facilitate wider applications. In addition, a new kind of marker based on SNP (Single Nucleotide Polymorphism) or In/Del (Insertion or Deletion of nucleotide) generated by comparison of nucleotide sequences among rice varieties or rice subspecies will also become available soon using the genome sequence data. DNA markers are extremely useful in determining the precise allocation of

target genomic region within the genome, particularly in gene isolation by map-based cloning.^[2] Also, DNA markers are indispensable in ordering large insert clones for construction of a sequence-ready physical map of the genome.^[3]

Physical maps of the rice genome have been established using genomic DNA fragments cloned in YAC (Yeast Artificial Chromosome), BAC (Bacterial Artificial Chromosome), or PAC (P1-derived Artificial Chromosome). At the Rice Genome Research Program (RGP), a YAC-based physical map covering 80% of the whole rice genome has been constructed by combining the results of RFLP marker and EST (Expressed Sequence Tag) screening.^[4] Initially, a skeleton YAC physical map with 63% coverage was constructed using 1439 RFLP markers in the genetic map.^[5] Thereafter, the 3' untranslated, unique sequences of rice ESTs were used as PCR primers to screen the YAC library and assign corresponding clones to previously mapped YAC contigs. As a result, YAC clones that carried both mapped and unmapped ESTs were newly allocated on the chromosomes so that the YAC contigs were extended and the genome coverage was increased to 80%.^[4] By mid-2002, this YAC-based physical map contained 6591 ESTs, and it is highly informative for map-based cloning. For example, the gene corresponding to rice dwarfism, *dl*, is one of the genes that has been cloned and characterized by this approach.^[6]

The rice physical map for genome sequence analysis has been constructed with BAC or PAC clones using methods for identifying overlaps and contiguous clones. In order to assign the clones to specific regions of the chromosome, fingerprinting by restriction enzymes is generally used. The fingerprint data obtained by electrophoresis is then analyzed by an fpc (fingerprinted contigs) program^[7] under an empirically adopted condition to make correct assignments of clones and overlaps. In this method, it is necessary to confirm the true overlaps by two parameters involved in fpc, namely, tolerance and cutoff values. These two parameters determine whether the contigs are reliable or not. A rice physical map based on fingerprints has been constructed at Clemson University Genomics Institute.^[8]

Clones were first assigned to their chromosomal positions by using the DNA markers described above. The availability of many PCR-based DNA markers

facilitated accurate anchoring of BACs/PACs by PCR prior to fingerprinting. The RGP screened Nipponbare PAC and BAC libraries with EST markers assigned on each of the 12 chromosomes. For example, in the case of chromosome 1, about 900 kinds of PCR primers were used for screening, and the fingerprint data of the anchored BACs/PACs were used for estimation of the overlaps among them. By this procedure, about 80% of chromosome 1 has been covered by BACs/PACs.

The physical map can be further refined using sequence information of the anchored clones. For this purpose, a database of BAC/PAC end sequences was established. CUGI has sequenced both ends of 92,000 BAC clones^[9] to help select the next target clone for sequencing among the aligned and mapped clones. This procedure is also useful to fill gaps on the RGP's physical map. Additionally, the accuracy of the physical map is determined by the consistency of the sequences of aligned clones.

Rice genome sequencing is performed by an international consortium, the International Rice Genome Sequencing Project (IRGSP), in which 11 countries contribute to generate a high-quality sequence (99.99%) of the 12 rice chromosomes.^[10] The genome sequence data are accessible through a centralized database named INE (Integrated rice genome Explorer) working by Java applet.^[11,12] Users of INE can find a PAC/BAC clone mapped to its chromosomal location by DNA markers and see the result of the annotation of the corresponding PAC/BAC sequence. Annotation of the sequence is performed using an automated annotation system, RiceGAAS (Rice Genome Automated Annotation System),^[13,14] which combines the results of both gene prediction and similarity search programs to assign the location of predicted gene and its function. Manual curation is also performed to come up with the most plausible gene model. The annotation map for each sequenced clone can be viewed graphically through INE, and each predicted gene is shown with the complete coding and protein sequence as well as a list of similar genes with information from the nonredundant protein database of NCBI. Two other databases, Oryzabase^[15] and Gramene,^[16,17] have been developed to show rice genetic resources and morphology and to integrate cereal genome information based on annotated rice genome sequence and associated biological information, respectively.

WHOLE-GENOME SHOTGUN SEQUENCING

In contrast to the clone-by-clone strategy of constructing a physical map to organize the DNA sequence, an alternative inexpensive and rapid strategy has been recently applied to the rice genome.^[18,19] This is called a whole-genome shotgun sequencing and involves the sequence

analysis of a large number of randomly chosen, small-insert clones to provide enough data for assembling the entire genome. However, because of the high complexity of the rice genome, it is impossible to make the correct assignment of a large number of short contigs without additional information, such as positional information of specific markers. Furthermore, many repetitive sequences in the genome were not assembled, and the gaps between contigs would be difficult to fill with this strategy. Therefore, supplemental data such as BAC-end sequences and a reference to the standard genome sequence by IRGSP are indispensable to raise the quality of sequence data obtained by a whole-genome shotgun method.

GENETIC AND REVERSE-GENETIC METHODS

Functional analysis of rice genes is mainly by genetic and reverse-genetic methods and is greatly aided by genome sequence data. So far, about 500 phenotypes have been assigned to 12 linkage groups, and about 200 of them have been genetically positioned on 12 chromosomes.^[20] In addition, many mutants generated by chemical mutagens, such as N-methyl-N-nitrosourea,^[21] and by rice endogenous retrotransposon, such as *Tos17*,^[22] have been used as resources for gene isolation. Among the agronomically important genes isolated using these strategies are the bacterial blight resistance genes, *Xa1*^[23] and *Xa21*,^[24] the rice blast resistance genes, *Pib*^[25] and *Pi-ta*,^[26] the gibberellin-insensitive dwarf gene, *d1*,^[6] the constitutively gibberellin-responsive slender rice gene, *slr1*,^[27] and the viviparous mutant genes, *Osabal* and *Ostatc*.^[28] In particular, *Tos17* is an advantageous tool because it has a high probability of being inserted into gene-rich regions,^[22] and the insertion site sequences are easily identified by analyzing the flanking sequence of the *Tos17* insert with suppression PCR.^[29] The disrupted gene sequence can be easily identified by referring to the genome sequence, and the data of resultant phenotype indicate the disrupted gene function. The insertion lines containing *Tos17* are also used for reverse-genetics methods to identify gene function. PCR screening of large populations of *Tos17* insertional mutants by gene-specific primers often find out target mutant. This strategy has been successfully used to identify the function of rice homeobox gene, *OSH15*,^[30] and phytochrome A.^[31]

The genes isolated as described above have strong phenotypes to facilitate isolating the responsible gene. However, most genetic variation seen in the field doesn't show such disruptive phenotypes. Natural variants show differences in most plant traits including flowering time, clum height, grain weight, and number of seeds. These

traits are generally important in agronomy and are called quantitative trait loci (QTL) or polygenic traits. Before the introduction of molecular tools for genetic analysis, it was difficult to isolate genes responsible for these traits. However, a combination of marker-assisted selection and advanced backcrossing methods makes it possible to isolate each component of a target QTL as a single Mendelian factor similar to the isolation of the mutant genes described above.^[32] This strategy has been used for the identification of genes identified as a QTL for rice flowering time.^[33,34] At least 14 loci were detected as QTLs of flowering time using progenies derived from a cross between a japonica variety, Nipponbare, and an indica variety, Kasalath. Among them, seven loci were identified as photoperiod sensitivity genes, and the structure and function of three of these genes were elucidated by map-based cloning followed by transformation. They are homologues to zinc-finger protein *CONSTANS*,^[35] protein kinase *CK2 α* ,^[36] and flowering time *FT*^[34] genes found in *Arabidopsis*. However, these homologous genes appear to have opposite functions: Flowering is triggered under short day-length conditions in rice and under long day-length conditions in *Arabidopsis*. This indicates the existence of a clock gene in both plants, yet to be identified.

CONCLUSION

With its small genome size, rice is considered the prototypic cereal genome. Recent findings show that because of the considerable syntenic relationships between all the cereals, the homologues of rice genes can be anticipated to be found at analogous chromosomal positions in other grass species.^[37] Recognition of these relationships has led to the exciting prospect that rice can be used to understand much of the genomic arrangement of the economically important cereals. However, a more detailed comparison of genomic sequences and gene function is necessary to clarify the syntenic relationships among cereal crops. Since the birth of the ancestral cereal plant about 60 million years ago, each species has diverged to its present nature by modifying the ancestral genes to fit its lifestyle. Understanding the similarities and differences among cereal genes using rice as a reference plant may be the key in establishing how gene families diverged and how biological pathways have been modified in the course of evolution.

Rice Blast

Purdue University, West Lafayette, Indiana, U.S.A.

INTRODUCTION

Rice blast is considered to be the most important disease of rice throughout the world. The disease occurs in 85 countries and can be very destructive when environmental conditions are favorable. Despite the extensive use of resistant cultivars and various fungicides, disease epidemics continue to occur in most rice-growing areas, and the annual loss to rice blast is estimated to be about US\$5 billion worldwide. As rice remains the major food crop for about half of the world's population, rice blast is recognized as one of the main pathological threats to world food supplies. A better understanding of the processes and mechanisms of pathogenesis will be helpful for an effective control of the disease.

DISEASE SYMPTOMS

The fungus can infect and produce lesions on most above-ground parts of the rice plant, including the leaves, stems, nodes, panicles, and grain. Leaf blast and neck blast are two major symptoms severely affecting plant growth and grain yield. Lesions formed on rice leaves are typically diamond-shaped, with a gray or white center and a brown or reddish brown border, and are 10–15 mm long and 3–5 mm wide (Fig. 1A). Newly formed lesions may have a white or grey-green center and a darker green border. During epidemics, leaf blast at seedling stages (1 month after sowing) can kill young plants completely (Fig. 1B). Blast in developing panicles can result in the complete loss of all rice seeds by causing premature death of the panicles. Later infections may cause incomplete grain fill and poor milling quality.

CAUSAL ORGANISM, DISEASE DEVELOPMENT, AND CONTROL METHODS

Rice blast is caused by the fungus *Magnaporthe grisea* (Hebert) Barr (anamorph *Pyricularia grisea* Sacc). *M. grisea* also causes disease on many other grass species,

including economically important crops, such as barley, wheat, and millet,^[1] although individual isolates have limited host range and race specificity. The disease cycle of rice blast involves three distinct phases: penetration, colonization, and sporulation (Fig. 2). The cycle begins when a conidium lands on the leaf surface, germinates, and forms a highly specialized penetration structure known as an appressorium. Turgor pressure that develops within the appressorium physically forces a penetration peg through the plant epidermis. After penetration, infectious hyphae grow intracellularly and intercellularly in rice plants and eventually result in lesion development (Fig. 2). Five to 7 days after infection, the fungus produces abundant quantities of conidia that are dispersed by wind or raindrops. Under favorable moisture and temperature conditions, multiple blast disease cycles occur in one growing season and have devastating effects on a susceptible rice crop.

The rice blast disease may progress through several phases starting with leaf blast and followed by collar, panicle, or node blast. Leaf blast usually is more severe earlier in the growing season but declines as leaves become less susceptible later in the season. Several environmental factors affect the progress of rice blast. Long periods of high humidity and moderate temperatures (63–73°F) are favorable to blast disease development. Conidia are produced and released under high relative humidity. The disease is also favored by excessive nitrogen fertilization, aerobic soils, and drought stress.

Integrated management programs have been applied to control the disease. However, due to the cost and environmental damage of fungicides, the use of resistant cultivars has been the most economical and effective method in most rice-growing countries. Many new varieties with high levels of resistance have been developed in the past. Unfortunately, many cultivars lose resistance within 3–5 years after their release because of the high degree of variability in natural populations of *M. grisea*. Analysis of the population dynamics of the rice blast isolates at the molecular level should provide new insights into their genetic variation and be helpful to prolong the life of newly released resistant cultivars.

Fig. 1 Disease symptoms in resistant and susceptible rice plants and the rice blast infection in the field. (A) Rice plants carrying the *Pi9(t)* resistance gene and the recurrent susceptible parent were inoculated with Philippine isolates PO6-6. Leaves were taken from both resistant (two leaves at left) and susceptible (two leaves at right) plants 7 days after inoculation. (B) Rice blast infection on susceptible plants (middle rows, arrow indicated) in a blast nursery in the Philippines. (View this art in color at www.dekker.com.)

MOLECULAR BIOLOGY OF THE RICE BLAST FUNGUS

The rice blast fungus can be cultured on various media and is amenable to classical and molecular genetic manipulations. Advances in genetic and cell biological studies of this pathogen during the past decade have made the *M. grisea* rice pathosystem an excellent model for investigating fungal–plant interactions.^[2] Several efficient protocols and selectable markers are available for fungal transformation.

Both forward and reverse genetic approaches have been used to study fungal pathogenesis in *M. grisea*. Several laboratories have generated or are generating a large number of random insertion mutants by using restriction enzyme-mediated integration (REMI) or *Agrobacterium tumefaciens*-mediated transformation (ATMT) approaches. These collections of transformants have been screened for mutants that are defective in different stages of infection. In the past decade, over 20 *M. grisea* genes necessary for fungal virulence or fitness have been identified by characterizing insertional mutants isolated. Gene disruption and gene replacement approaches have been used successfully to evaluate candidate genes that are likely to be important for fungal pathogenesis. However, the generation of targeted disruption or deletion mutants of specific genes is time-consuming. The transposon-arrayed gene knockout (TAGKO) approach utilizes bacterial transposon mutagenesis to generate cosmid clones with randomly inserted transposons that can be used for sequencing and fungal transformation.^[3] Application of other approaches that may be suitable for large-scale analysis of gene functions in *M. grisea* such as

RNAi silencing has been discussed by Sweigard and Ebbole.^[4]

In recent years, several groups have made significant progress in understanding the molecular mechanisms of appressorial turgor generation and signaling systems regulating infection-related morphogenesis. Major genes

Fig. 2 The infection cycle of the rice blast fungus. The infection cycle is initiated by attaching three-celled conidia to the rice leaf surface. Germ tubes produced from conidia differentiate into melanized appressoria. *M. grisea* uses the enormous turgor pressure generated in appressoria to penetrate the underlying plant surface. Once inside the plants, infectious hyphae grow in and between plant cells. Eventually, lesions develop and release more conidia to reinitiate the infection cycle.

involved in the melanin biosynthesis, such as *BUF1* and *RSY1*, have been characterized. The melanin layer is essential for lowering the porosity of the appressorial wall and generating hydrostatic turgor pressure. The turgor pressure that develops in melanized appressoria can be as high as 80 bar through the accumulation of glycerol. Mobilization of energy reserves for glycerol synthesis, such as glycogen and lipids, may be regulated by the cAMP signaling pathway, but their utilization is dependent on a mitogen-activated protein (MAP) kinase *PMK1*. Although the *PMK1* pathway regulates appressorium maturation and penetration, the cAMP signaling pathway is involved in surface recognition and initiation of appressorium formation. Both of these signal pathways are critical for infectious hyphal growth after penetration.^[2]

Recently, significant progress also has been made in the genetic analysis and isolation of genes controlling host and cultivar specificity. To date, several “avirulence” (*AVR*) genes have been isolated, including *PWL2*, *AVR-Pita*, and *AVR-CO39*. Interestingly, these genes do not share any conserved domains. *AVR-Pita* is the only gene whose corresponding resistance gene (*Pita*) in rice has been cloned and whose direct interaction with *Pita* has been demonstrated.^[5] Sequence analyses revealed that there were frequent spontaneous mutations in the genomic region of the cloned *AVR* genes. In the case of the *AVR-Pita* gene, instability is correlated with its location adjacent to a telomere, whereas the unstable *PWL2* gene resides in a chromosomal region rich in repetitive DNA. It is still unclear whether the instability of these *AVR* genes contributes directly to overcoming the effectiveness of the corresponding resistance genes in the host. As additional *AVR* genes are cloned in *M. grisea*, knowledge of their chromosomal locations and contexts will be a valuable resource for studying the genetic variability of the pathogen and its relationship with the durability of host resistance genes in rice.

GENOMICS STUDIES

M. grisea has seven chromosomes and an estimated genome size of ~40 Mb. A high-density genetic map consisting of 203 markers spanning approximately 900 cM was constructed by integrating markers from several laboratories.^[6] Small syntenic regions containing highly conserved genes have been identified in *M. grisea* and *Neurospora crassa*.^[7] A physical map consisting of BAC contigs assembled by fingerprinting analysis has been constructed for all seven chromosomes and integrated with the genetic map of *M. grisea*. MagnaportheDB is a federated database with the BAC end sequences and the physical and genetic map data.^[8]

Random clones from different *M. grisea* cDNA libraries have been sequenced as expressed sequence tags (ESTs) in several laboratories. Currently, there are over 28,000 *M. grisea* ESTs in GenBank. The largest *M. grisea* EST dataset was generated in Ebbole's laboratory at Texas A&M University by sequencing cDNA libraries constructed with RNA isolated from appressoria, conidia, mating cultures, *pmk1* mutant germlings, and mycelia grown on minimal, complete, nitrogen-deficient, and rice cell wall media. The EST sequencing approach has also been used to identify *M. grisea* genes expressed in infected rice leaves.

In 2003, the Whitehead Institute/Massachusetts Institute of Technology Center for Genome Research has generated over 6× coverage of the *M. grisea* 70-15 genome by the shotgun approach. Information about sequencing, assembly, and annotation is available to the public at www-genome.wi.mit.edu/annotation/fungi/magnaporthe. It is worth noting here that 70-15 is a strain generated by backcrossing three times to Guy11, which is the first hermaphroditic *M. grisea* isolate pathogenic to rice and is widely used in earlier genetic studies. Although 6× sequencing may be not adequate for assembling the whole genome, it has provided much needed sequence information for functional genomic studies. Microarrays of genes predicted from the rice blast genome sequence are under development and will be very useful to generate expression profiles of *M. grisea* genes in different mutants and plant infection stages.

FUTURE PERSPECTIVES

Functional genomic studies of *M. grisea* are likely to be the focus for the next few years and will lead to the identification of genes important for different developmental and plant infection stages. When additional genomes of fungal pathogens and model fungal organisms become available, comparative studies will be helpful to discover genes specific for fungal pathogens or specific for different infection mechanisms. With the availability of the rice and rice blast genome sequences, functional genomics of the rice–rice blast interactions will be more and more accessible as a model and will provide fundamental insights into rice blast disease.

CONCLUSION

In the last few years, considerable progress has been made towards understanding the molecular mechanism of the pathogenesis of the rice blast fungus. Several important genes controlling key steps in the development and infection have been well characterized. Few major

genome projects have contributed greatly to characterization of rice blast genome by providing numerous ESTs and the whole genome sequence. Fully understanding the function of the identified genes from the genome projects will be a daunting challenge for rice blast scientists. New tools and technologies will play more vital roles for the studies of the rice blast genes and the development of novel strategies to effectively control the disease.

RNA-Mediated Silencing

Karin van Dijk
Heriberto Cerutti

University of Nebraska, Lincoln, Nebraska, U.S.A.

INTRODUCTION

RNA-mediated silencing involves various epigenetic mechanisms—apparently triggered by double-stranded RNA (dsRNA)—that result in suppression of gene expression. These mechanisms can lead to the degradation of homologous RNAs, translational repression, heterochromatin formation, and DNA methylation. Epigenetic phenomena induced by dsRNA have been observed in many eukaryotes and they may have evolved as defense responses against transposable elements and viruses. Recently, it has become apparent that the basic machinery required for these processes is also involved in the control of development. Moreover, links between RNA-mediated silencing and DNA and chromatin modifications are also starting to emerge. For more on this, the reader is referred to several recent reviews. This article discusses the basic processes leading to RNA silencing, the putative triggers, some of the key plant proteins involved in these pathways, and some potential applications of RNA silencing.

RNA-SILENCING BY RNA DEGRADATION

Posttranscriptional gene silencing (PTGS), cosuppression and RNA-mediated virus resistance in plants and algae, RNA interference (RNAi) in animals, and quelling in fungi are all examples of RNA-mediated silencing. Although these phenomena may differ in the details, central to them appears to be a molecular machinery that processes long dsRNA into smaller dsRNAs—called small interfering RNAs (siRNAs)—which are then used as guides to target homologous RNA molecules for degradation. In the late 1980s and throughout the 1990s, RNA-mediated silencing processes were observed in many eukaryotes. However, it was not realized until the late 1990s that these seemingly different processes are mechanistically related.^[1–5] In plants, the initial observation came from research in the Jorgensen lab when an attempt was made to enhance the purple color of petunia flowers by overexpressing chalcone synthase.^[4,5] Instead, the reverse happened. The expression of both the transgene and the native gene were diminished, and many flowers lost their pigment. This phenomenon was named

cosuppression, and was later found to occur at the posttranscriptional level, hence the name posttranscriptional gene silencing. In the fungus *Neurospora crassa*, a similar phenomenon was observed, named quelling. Around the same time, researchers working on the nematode *Caenorhabditis elegans* found that they could successfully interfere with gene expression by injecting antisense RNA. However, to their surprise, injections with sense RNA could also suppress gene expression. We now know that the gene silencing observed in these cases was triggered by the presence of dsRNA, a contaminant produced during the preparation of sense or antisense RNA.^[5] This strategy of using dsRNA to silence a target gene is called RNA interference. Researchers have for many years used yet another RNA-mediated silencing process—antisense technology—to interfere with specific gene expression. To achieve this, transgenic organisms are engineered to produce RNA complementary to the target transcript. Although the precise mechanism by which antisense RNA works remains elusive, in at least some cases dsRNA is likely involved as an intermediate.^[3]

THE BASIC RNA-MEDIATED SILENCING MACHINERY

The combination of genetic and biochemical evidence from different organisms is starting to reveal the molecular machinery involved in the dsRNA-induced degradation of cellular RNAs. This process can be divided into an initiation and an effector step (Fig. 1).^[1,2] In the initiation step, the ATP-dependent dsRNA nuclease DICER (Table 1), initially described in *Drosophila melanogaster*, chops the dsRNA molecule into siRNAs of about 21–23 nucleotides. In the effector step, the siRNAs are transferred to an enzyme complex—the RNA-induced silencing complex (RISC)—which has an endonuclease activity distinct from DICER. RISC is proposed to unwind the double-stranded siRNAs, and use the antisense strand to identify complementary messenger RNAs (mRNAs). Target mRNAs are then cleaved across from the center of the siRNA-mRNA hybrid and further degraded (Fig. 1). In some eukaryotes, an amplification step appears to be required for efficient silencing (see following discussion).

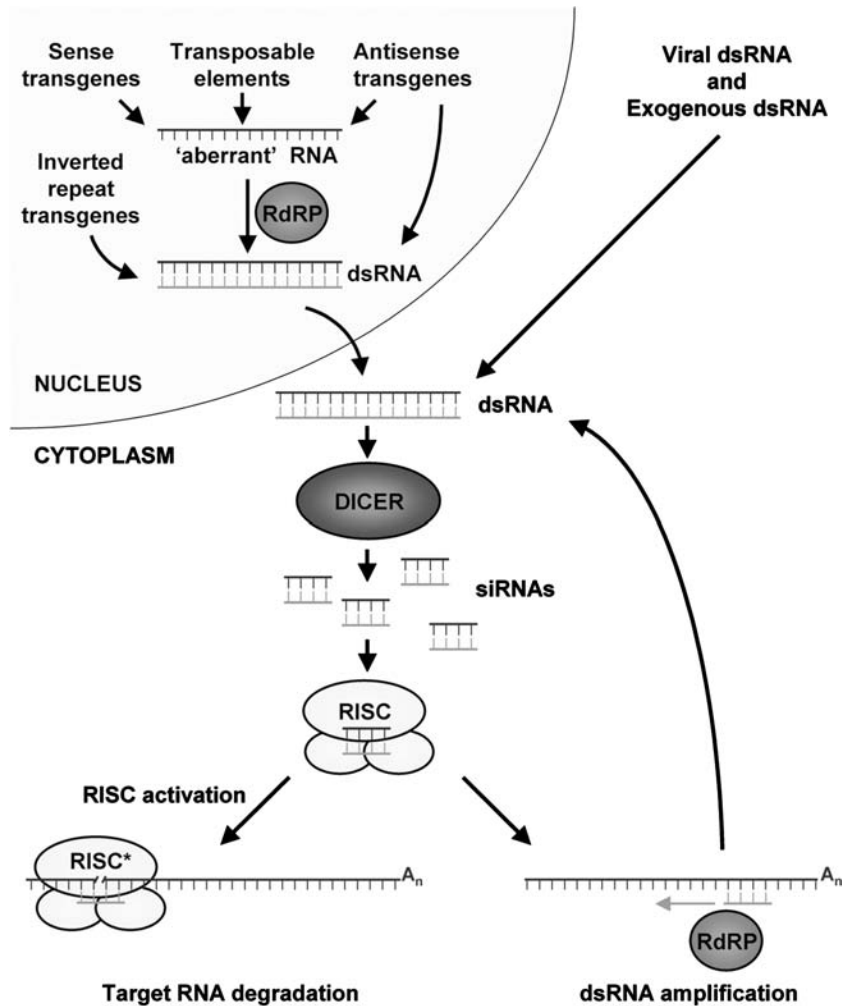

Fig. 1 Model for RNA-mediated silencing resulting in the degradation of target RNAs. Silencing is induced by double-stranded RNA (dsRNA). The dsRNA can be introduced exogenously, produced during viral replication, or transcribed from inverted repeat transgenes. In the case of transposable elements and sense or antisense transgenes, dsRNA can be synthesized by an RNA-directed RNA polymerase (RdRP) that uses aberrant RNA as a template (see article), or it can result from the annealing of single-stranded transcripts to RNA of opposite polarity (not depicted). DICER processes the long dsRNAs into small interfering RNAs (siRNAs), which are transferred to a multiprotein complex, the RNA-induced silencing complex (RISC). Upon unwinding of the siRNAs, the activated RISC (denoted by an asterisk) identifies and effects the degradation of target mRNAs with sequence homology. The dsRNA trigger can also be amplified by an RdRP. (View this art in color at www.dekker.com.)

Moreover, there is also spreading of silencing throughout the whole organism. The exact mechanism is unclear, but in plants it involves a sequence-specific signal that travels between cells as well as through the phloem.^[6]

TRIGGERS OF RNA-MEDIATED SILENCING

Direct delivery of dsRNA (injected, fed, or the result of transcription from inverted repeat transgenes) can induce silencing in a variety of organisms, including plants. One of the fascinating aspects of RNAi, which is particularly

noticeable in *C. elegans*, is that minute amounts of dsRNA can trigger degradation of a vast amount of mRNA. Recent studies suggest that the initial dsRNA trigger needs to be amplified to effectively silence target genes.^[7] In this model, primary siRNAs are used as primers by an RNA-directed RNA polymerase (RdRP) to synthesize more dsRNA, using the target mRNA as a template (Fig. 1). DICER then cleaves the dsRNA to produce enough siRNAs to effectively target even abundant RNAs for degradation.

With sense and antisense transgenes, a major question is how dsRNA is produced. One model proposes that an

Table 1 Proteins implicated in RNA-mediated silencing in *Arabidopsis*

Protein	Proposed or known function
Carpel factory (CAF/SIN-1)	RNAse III and RNA helicase activity; homologue of <i>Drosophila</i> DICER
AGO1	Protein containing PAZ and PIWI domains; one <i>Drosophila</i> homologue is associated with the RISC complex
SDE1/SGS2	RdRP; dsRNA production and/or dsRNA amplification
SGS3 (SDE2)	Coiled-coil protein with unknown function
DDM1	Member of SWI/SNF family of chromatin remodeling proteins; required to maintain DNA methylation
MET1	DNA methyltransferase
SDE3	RNA helicase

RdRP synthesizes dsRNA from aberrant RNA^[1,3] (Fig. 1). What makes an RNA molecule aberrant is not known, but it may involve the production of prematurely terminated, nonpolyadenylated or misprocessed RNAs. Because these transcripts are most likely present in the nucleus, the synthesis of dsRNA by an RdRP is proposed to occur in the nucleus.^[1] In support of this model, *Arabidopsis* mutants in an RdRP, SDE1/SGS2 (Table 1), are defective in the PTGS of sense transgenes. In contrast, silencing induced by viruses, expressing their own RdRP, is not affected in this mutant background.^[3]

MicroRNAs, ANOTHER SMALL RNA SPECIES PRODUCED BY DICER

Additional layers of complexity are emerging as more is discovered about RNA-mediated silencing pathways. For example, DICER can produce another species of small RNAs called microRNAs (miRNAs). MicroRNAs are processed from endogenous precursor RNAs consisting of double-stranded hairpin structures that have regions of imperfect complementarity.^[8] MicroRNAs were first identified in *C. elegans* as products of the genes *let-7* and *lin-4*. These miRNAs are involved in regulating developmental timing by binding to the 3' untranslated regions and preventing translation of their target mRNAs. Thus, in this case, miRNAs induce translational repression rather than mRNA degradation.

Recently, a combined effort has resulted in the isolation of many miRNAs in both animals and plants. The regulatory targets of most of these are unknown, but what has become clear is that the distinction between miRNA and siRNA has become blurred.^[1] For instance, one of the *Arabidopsis* miRNAs has perfect complementarity with the transcripts of a group of transcription factors, and it has been implicated in controlling their expression through degradation of the mRNA.^[1,8] Intriguingly, many plant miRNAs have a higher level of complementarity with their potential targets than animal

miRNAs,^[8] and they may function by regulating transcript stability rather than translation. Moreover, in plants, many predicted targets function as developmental regulators, suggesting that miRNAs might play a role in coordinating growth and development.

RNA-MEDIATED SILENCING AND CHROMATIN/DNA MODIFICATIONS

In addition to effects at the posttranscriptional level, it is becoming apparent that RNA can direct DNA methylation and chromatin modifications. In several plant species dsRNA can target the methylation of homologous DNA. This RNA-directed DNA methylation (RdDM) was initially observed in viroid-infected plants, and has now been shown to also occur in plants expressing inverted repeat constructs or infected with replicating viruses containing sequences homologous to genomic DNA.^[9] When the RdDM occurs in promoter sequences, the target genes are silenced at the transcriptional level, i.e., no RNA is produced. Promoter-directed dsRNA is also processed into siRNAs, but it is not yet clear whether these are required to induce DNA methylation.^[1,9]

In plants, many posttranscriptionally silenced transgenes are also methylated, but in this case, methylation occurs within the coding regions. Interestingly, two *Arabidopsis* mutants, *met1* and *ddm1* (Table 1), initially isolated in a screen for reduced methylation of the genome, are also defective in their ability to post-transcriptionally silence transgenes.^[10] The relevance of this methylation is not clear, but it might be involved in the initiation or maintenance of silencing by affecting the production of aberrant RNA. In addition, RNA has been implicated in heterochromatin formation and maintenance in other organisms.^[1] For instance, in *Schizosaccharomyces pombe*, mutants defective in components of the RNAi pathway show reactivation of transgenes integrated in the centromeric (heterochromatic) regions. This correlates with the loss of histone H3 methylation, which is commonly associated with a repressive chromatin

structure.^[1] Thus, RNA-mediated processes may also play a role in chromosomal organization and transcriptional control.

APPLICATIONS OF RNA-MEDIATED SILENCING IN PLANTS

RNA silencing has become an important tool in molecular biology and has the potential to revolutionize functional genomics, because it is an effective way to knock down the expression of any gene.^[11] Moreover, since RNA-mediated silencing does not require complete sequence identity between the dsRNA trigger and a target gene, it is even possible to silence the expression of gene families. There are also clear applications of this technology to agriculture. For instance, an RNA-silencing strategy can be used to suppress undesirable traits in plants. As an example, tomatoes that have reduced levels of polygalacturonase (a protein involved in fruit ripening) have been produced by antisense technology.^[4] The resulting tomatoes stay firm while ripening on the tomato vine. In the past, the success rate of this technology was somewhat unpredictable. However, a greater understanding of the mechanisms involved in RNA silencing has allowed the design of better constructs. Effective silencing of a particular gene can now be accomplished with inverted repeat transgenes that produce hairpin RNAs (hpRNA)^[11] (Fig. 1). One success story, using hpRNA, is the production of cotton seeds with altered fatty acid content due to downregulation of expression of a fatty acid desaturase.^[11]

Root Membrane Activities Relevant to Plant-Soil Interactions

Zeno Varanini

University of Udine, Udine, Italy

INTRODUCTION

The plasma membrane of root cells plays a fundamental role in the complex interactions that occur at the soil-root interface, contributing to the transport of solutes into the cell and thus changing the composition of the rhizosphere. Clearly, the biochemical mechanisms regulating the plant-soil interaction must respond and adapt to the conditions both within the root cell and at the rhizosphere; the plant must therefore possess sensing mechanisms that can efficiently modulate transport and enzyme activities at the plasma membrane. There are several classes of membrane-bound proteins, the most important of which in the soil-plant relationship are proton pumps, carriers, channel proteins, and reductases.

PROTON PUMPS

The plasma membrane H^+ -ATPase (pmH^+ -ATPase) is an electrogenic enzyme, exploiting the energy released upon the hydrolysis of ATP to transport protons from the cytoplasm into the apoplast. This enzyme can catalyze the extrusion of over 10^2 H^+ ions per second: It is also extremely abundant, forming approximately 1% of the overall amount of proteins at the plasma membrane. Moreover, these levels can increase remarkably under certain conditions (discussed later), in particular in the layers of cells at the soil-plant interface (i.e., the epidermal and root hair cells).

The plant pmH^+ -ATPase is formed by a single polypeptide approximately 100 kDa in size. Its putative topology suggests that the enzyme possesses ten transmembrane regions and four cytoplasmic domains,^[1] the latter including the carboxy-terminal region (Ct), an important domain from a posttranslational viewpoint. The Ct has in fact been observed to have auto-inhibitory properties; its effect can however be cancelled when, once phosphorylated, it becomes the binding site for proteins of the 14-3-3 family.

Plant pmH^+ -ATPase is encoded by a multigene family; it is not yet clear if the various isoforms function under specific environmental conditions or are expressed in specific types of cells, tissues, or organs.^[1]

The pmH^+ -ATPase plays a fundamental role in the soil-plant relationship, supplying energy for nutrient transport and acidifying the rhizosphere in order to facilitate the roots' acquisition of certain mineral nutrients; it is also involved in the plant's response to abiotic stress and signals from the rhizosphere.

Energization of Nutrient Transport

The activity of the pmH^+ -ATPase creates a gradient of pH (more acidic outside the cell) and potential (more negative inside the cell) across the plasma membrane, which is then exploited for nutrient transport by means of carriers or channels (Fig. 1). Cations are attracted to the cell by the membrane potential and could simply enter into the cell through protein channels; anions, on the other hand, require carriers (symporters). This type of transport is an active process, and the energy is supplied by the accompanying inflow of protons. The activity of pmH^+ -ATPase seems to be modulated according to the plants' nutritional needs. In the case of nitrate, the enhanced uptake brought about by the roots' exposure to this nutrient (induction) is accompanied by higher levels and thus activity of the pmH^+ -ATPase, presumably to meet the greater demand for proton-driving force.^[2] Recent investigations also reveal that treatment with nitrate induces a differential expression of the various forms of the enzyme, thus suggesting that certain members of the pmH^+ -ATPase multigene family may respond specifically to nutrient uptake.^[3]

Nutrient Acquisition by Rhizosphere Acidification

By extruding protons into the apoplast, the root pmH^+ -ATPase acidifies the rhizosphere, with major consequences: The lower pH stimulates the release of cations from the exchange sites on the cell wall and the soil colloids, which then pass into the soil solution and reach the binding sites of the transporters on the outer surface of the plasma membrane. The level of rhizosphere acidification brought about by the proton pump can be modulated by processes of secondary transport, and in particular by the ratio of cations and anions taken up by

Fig. 1 Schematic representation of the major transport proteins operating at the root plasma membrane. (View this art in color at www.dekker.com.)

the root cells. When nitrogen, for example, is taken up as ammonium, rhizosphere acidification increases; the opposite occurs when it is taken up as nitrate.

The acidifying action exerted by the pmH⁺-ATPase has important consequences on the solubilization of essential nutrients characterized by low availability. A well-investigated case is that of iron. This element is mostly present in the soil as ferric ion (Fe³⁺), which is extremely insoluble at neutral or alkaline pH values. Dicots and nongraminaceous monocots (Strategy I plants) can, however, respond to Fe-deficiency by acidifying the rhizosphere—the extent of the process depending on the species—and thus solubilizing and rendering available

Fe³⁺. Plant species endowed with a greater ability to acidify can increase root pmH⁺-ATPase activity under conditions of Fe deficiency.^[4] Higher levels of the enzyme are present at the plasma membrane, in particular in the rhizodermis and in the root hairs of the subapical root sections.^[5]

Response to Abiotic Stress and Signals from the Rhizosphere

The activity of pmH⁺-ATPase can also change when anomalous conditions are encountered at the rhizosphere. Salt stress is a common case: Under these conditions, enhanced proton extrusion may help energize the Na⁺/H⁺

antiporter systems operating at the plasma membrane. Salt stress has been reported to induce pmH⁺-ATPase gene expression in specific tissues; in tomato plants, the response was ascribed to a single, specific isoform.^[6]

Recent studies moreover suggest that under conditions of osmotic shock, there may also be a posttranslational regulation of the enzyme: The interaction with 14-3-3 proteins would appear to increase the H⁺/ATP coupling ratio.^[7] Enhanced enzyme activity has also been observed in the roots of plants growing in acidic environments: Root pmH⁺-ATPase would therefore also play a fundamental role in preserving cytoplasm pH homeostasis.^[8]

Finally, pmH⁺-ATPase activity also appears to be modulated by other factors present at the rhizosphere, such as humified organic matter. Low-molecular-weight fractions (<3500) in particular can stimulate the activity of pmH⁺-ATPase with positive effects on ion uptake rates and the ability to acquire iron and other metal micronutrients.^[9]

CARRIERS

These membrane proteins can move solutes either up or down electrochemical gradients at a rate of 10²–10⁴ molecules per second. There are three different types of carriers: symporters, antiporters, and uniporters. Whereas the latter proteins move substances down a concentration gradient, symporters and antiporters can transport a compound against its concentration gradient by contemporaneously transporting a second substance (usually H⁺) down its electric and/or chemical gradient. Symporters in particular play an important role in the root-soil interaction, as their transport activity of oxoanionic and cationic macronutrients helps modify rhizosphere pH.

Carrier proteins (symporters) have a molecular mass of approximately 50–60 kDa. Their structure includes 12 membrane-spanning regions and in some cases, motifs on their cytoplasmic domains suggesting a posttranslational regulation of their activity via phosphorylation and dephosphorylation. Although no evidence has been found that such regulation may occur *in vivo*, it has been clarified that the expression of symporter-encoding genes is regulated by nutrient availability at the rhizosphere.^[10,11] The modulation of gene expression depends on the nutrient: Nitrate, for example, is taken up from the soil through low- and high-affinity transport systems encoded by *NRT1* and *NRT2* genes. Some of these transporters are constitutively expressed, whereas others (*NRT2.1*) are nitrate-inducible and are subjected to negative feedback regulation by the products of nitrate assimilation. On the other hand, the genes encoding high-affinity transporters for phosphate (*PT1*, *PT2*) and sulphate (*SHST1*, *SHST2*) are derepressed when plants are deprived of the nutrient. Potassium and ammonium are also taken up by symporters when present at the rhizosphere at low concentrations

(in a μM range). The carriers are encoded by such genes as *HKT1* (Na⁺/K⁺ symporter), *KUP* (H⁺/K⁺ symporter), and *AMT1* (H⁺/NH₄⁺ symporter), which are upregulated under conditions of potassium and ammonium deficiency, respectively. Positively-charged micronutrients are transported into the cell via uniport carriers. An example is *IRT1*, the expression of which is induced in the roots of Fe-deficient plants.^[5] The gene encodes a nonspecific Fe uniport carrier that is also capable of transporting other bivalent cations into the cell, including Cd.

CHANNEL PROTEINS

Channels are membrane-spanning proteins that contribute to the diffusion of water and ions down energetically-favorable gradients. Electric or chemical signals control the opening and closing of these proteins; when open, inorganic and organic ions and water molecules pass through them at very high rates (10⁶ to 10⁷ molecules per second). Channel proteins are involved in several physiological processes: mineral nutrition; cell osmoregulation, by allowing great ion fluxes across the plasma membrane over short periods of time; signalling, by amplifying and propagating electric signals or transporting secondary messengers such as Ca₂⁺; and the control of membrane potential. The most important channels for the root-rhizosphere interaction are those allowing the flow of potassium and water across the plasma membrane and the efflux of organic and inorganic anions from the root cells.

Various types of channel proteins for the influx and efflux of potassium have been identified at the root cell plasma membrane,^[12] but it has only been possible to ascribe a physiological role to *AKT1*, a protein that surprisingly displays both high- and low-affinity kinetics for this nutrient. The channel proteins involved in the efflux of anions (carboxylates and phytosiderophores) are key factors in the response to nutrient deficiencies and in the resistance to aluminum toxicity;^[13] in the latter case, it has been suggested that aluminum itself may be the signal triggering the opening of the channels.

As regards water transport, channel proteins called aquaporins (encoded by *PIPs*) have been found to be involved in this process. When open, they facilitate the passive movement of water molecules down a water potential gradient. The activity of at least some aquaporins appears to be regulated by processes of phosphorylation and dephosphorylation.

Up to now, 30 genes have been found in *Arabidopsis* for aquaporin homologues. Some of these genes are constitutively expressed, whereas others are known to be temporally and spatially regulated during the plant's development and in response to stress. Aquaporins are very abundant proteins, and appear to be involved not only in cytosol osmoregulation, but also in the bulk flow of water.

REDUCTASES

Various redox activities are present at the plasma membrane that can transport electrons from cytoplasmic donors (e.g., NADH and NADPH) to oxidized acceptors in contact with the outer surface of the membrane. Among these enzymes, there is the turboreductase, induced in the rhizodermal cells of dicots and nongraminaceous monocots under conditions of Fe-deficiency. Its physiological function is to reduce Fe^(III)-chelates present at the rhizosphere, thus allowing the transport of Fe²⁺ into the cell by the IRT proteins (discussed earlier). Recently, a ferric chelate reductase (FRO2) has been cloned: It belongs to the superfamily of flavocytochromes, a class of proteins that mediate the transport of electrons across the membrane, and appears to be strongly induced in Fe-deficient plants.^[5] The roles and electron acceptors of the other reductases that are constitutively expressed in the roots of all plant species and are distributed along the entire root axis are still unknown. Since they produce reactive forms of oxygen, they may be involved in the metabolism of cell wall production and in pathogen control. Other authors, highlighting the ability to reduce nitrate, have instead suggested they may also act as sensors in the regulation of nitrate uptake and assimilation.

CONCLUSION

Biochemical and molecular analyses have clarified many aspects of the structure and regulation of plasma membrane activities modulating the root-soil relationship. However, much remains to be learned, and not only with regard to those systems that have been less investigated (i.e., channel proteins and reductases), but also the sensing mechanisms involved in the perception of the environmental conditions. There are also other objectives in the research on proton pumps and nutrient-transporting carriers: to understand the specific role of each isoform and shed more light on the aspects relative to posttranslational regulation. It would be interesting to assess which are the major systems involved in the root-soil relationship in field conditions. This could be a useful parameter in selecting or obtaining genotypes that are more efficient in their interaction with the soil (e.g. greater ability to recuperate nutrients, greater adaptability to adverse conditions, etc.).

Root-Feeding Insects

Eli Levine

Illinois Natural History Survey, Champaign, Illinois, U.S.A.

INTRODUCTION

Belowground plant parts constitute a major portion (often >50%) of the biomass and primary plant production available to herbivores. Therefore, it is not surprising that many species of insects have taken advantage of this resource. Root feeding is used here to refer to consumption of all belowground plant parts, including roots, rhizomes, and other storage organs. Root-feeding insects can influence plant diversity, plant succession, competitive interactions among plant species, the susceptibility of plants to other herbivores and plant diseases, and crop yield.^[1] This article discusses adaptations insects possess to live in the soil environment, examines some of the diverse species of insects that feed on plant roots, and discusses the effects of root feeding on host plants with emphasis on corn rootworms.

ADAPTATIONS TO THE SOIL ENVIRONMENT

Organisms that spend at least some part of their life cycle underground are referred to in this article as edaphic organisms. Edaphic species that live on the soil surface or in the litter are referred to as epedaphic organisms, whereas those that inhabit mineral strata beneath the litter layer are referred to as euedaphic organisms. Distantly related species that have come to share similar soil habitats may have followed parallel or convergent evolutionary paths, and may appear similar in form.^[2] A major factor limiting insect occupation of the soil has been the ability of these organisms to move. Most insects are not small enough to travel through interconnected pore spaces and must therefore either tunnel through the soil (by pushing soil particles aside and squeezing through) or excavate it (removing the soil in front and moving it behind them). Burrowing insects are generally round in cross section, but may otherwise vary in shape. Insects that tunnel often have very small or no legs, and may be of two body forms. Wireworms (the larval stage of click beetles; Coleoptera: Elateridae) are often smooth, slender, and hard-bodied; using a serpentine motion, they are able to force their wirelike bodies through the soil. In contrast, corn rootworm larvae (Coleoptera: Chrysomelidae) are

soft-bodied and can use peristaltic movements to pass through the soil. Soil insects that move by excavating the soil are often armored and thick-bodied, and may display modified forelegs for digging, such as in mole crickets (Orthoptera: Gryllotalpidae) or nymphal periodical cicadas (Homoptera: Cicadidae). Wings are generally reduced in adult insects that spend much of their lives in the soil, and compound eyes are often reduced or absent. In contrast, tactile sense organs are generally well developed in euedaphic insects, and many of these insects are sensitive to carbon dioxide, which is often used to locate plant roots. In some species, such as the Japanese beetle, *Popillia japonica* (Coleoptera: Scarabaeidae), grubs can move vertically through the soil profile as seasonal soil temperatures change, and thus remain active and able to feed on plant roots.^[3]

DIVERSITY OF INSECTS THAT FEED ON PLANT ROOTS

Insects that feed on roots are represented in most of the larger insect orders. The burrower bug, *Cyrtomenus bergi* (Heteroptera: Cydnidae), is a serious pest of cassava, a very important crop in low-income, food-deficit countries. All five nymphal stages and the adult stage of these small oval bugs live in the soil. They damage this root crop by directly feeding on the roots. Fungal pathogens can enter these wounds, reducing both root yield and quality.^[4] Some root-feeding scale insects in the genus *Margarodes* (Homoptera: Coccidae) are given the common name of ground pearls, for the pearl-like appearance of the wax cysts of females. Ground pearls often cause injury to vine crops, turf, and sugarcane, and are very difficult to control because the insects are protected by the cysts. Encysted insects are also able to resist extreme temperatures and low moisture levels, and adult females have been able to prolong emergence for several years.^[5] Root-feeding insects may also facilitate the transmission of plant pathogens. For example, root feeding by larvae of the striped cucumber beetle, *Acalymma vittatum* (Coleoptera: Chrysomelidae), was found to increase the incidence and severity of *Fusarium* wilt of muskmelon.^[6] Other root feeders have intricate life histories with other insect

species. For example, eggs of the corn root aphid, *Aphis maidiradicis* (Homoptera: Aphididae), pass the winter in nests of ants in the genus *Lasius*. In the spring, when the eggs hatch, the ants carry the nymphs to roots of weeds where the aphids feed. Later, the ants transport the aphids to the roots of maize. All the while, the ants feed on honeydew produced by the aphids.^[3]

CORN ROOTWORM LARVAL FEEDING ON MAIZE

The western corn rootworm, *Diabrotica virgifera virgifera*, and the northern corn rootworm, *Diabrotica barberi*, are the most serious insect pests of maize in the major maize-producing states of the United States and Canada. Both species have a single generation per year. Adults are present in maize fields from July through frost, and feed on maize foliage, pollen, silks, and developing kernels. Oviposition takes place almost exclusively in maize fields from late-July through mid-September (since the mid-1990s, however, western corn rootworms have also begun to lay eggs outside of maize fields in east-central Illinois and northern Indiana, rendering crop rotation ineffective in the management of this species in those areas). Diapausing eggs spend the fall and winter in the soil until late May or early June when they hatch and the larvae begin to feed on maize roots (larvae can only complete development on maize and a few grassy weeds). Newly eclosed larvae feed primarily on root hairs and the outer tissue of roots, causing little significant injury. As the larvae grow, root tips may be pruned back and larvae may tunnel into larger roots. Growing points at root tips may also be killed; this often leads to fibrous secondary root production. Larval feeding disrupts root system function, reducing the amount of water and nutrients supplied to developing plants, which can in turn reduce grain yield. Larval feeding may also facilitate infection by root and stalk rot fungi, resulting in further damage. Brace roots may also be severely damaged, causing plants to lodge and stalks to gooseneck. Altered leaf orientation can reduce photosynthetic efficiency of the plant; difficulty in mechanically harvesting the lodged maize can result in additional yield losses.^[7] In some cases, rootworm injury has slowed plant development, leading to asynchrony between tassels and silks and resulting in a greater percentage of plants with barren ears.^[8]

Root-injury ratings have been used to assess larval injury by corn rootworms. Some investigators have estimated that a mean root-injury rating > 2.5 (on a 1-to-6 root-injury rating scale, where 1 = minor injury and 6 = three nodes of roots destroyed) would result in economic loss. Other workers showed that root injury

ratings were not consistent predictors of yield. Numerous factors influence the extent of damage and its impact on yield. Number and species of larvae, size of the root system, ability of the maize hybrid to regenerate roots, availability of soil moisture and nutrients, plant population, and weather are all involved in the amount of damage that may occur and the impact this damage may have on yield. If other stress levels are minimal, severe root damage may not result in significant yield losses, particularly if high winds do not cause lodging.^[7]

A recent four-year field study using 12 commonly grown maize hybrids and natural infestations of corn rootworms at two locations in Illinois showed that hybrid characteristics and environmental conditions—particularly soil moisture—can strongly affect the level of root injury needed to cause economic damage. During one year of the study when growing conditions were stressful (low soil moisture), economic damage occurred with some hybrids when the average root rating was only 2.5 (on the 1–6 root-injury rating scale). When growing conditions were more favorable, economic damage did not occur with the same hybrids until root-injury ratings were 4.0 or higher.^[9] The complex interactive effects that maize genotype, level of rootworm larval injury, and environment have on grain yield suggest that maize hybrids may differ in their ability to tolerate rootworm injury and partition biomass between vegetative and reproductive tissue. That is, injury to the roots can reduce (to varying degrees, depending on hybrid) the allocation of resources toward seed production as more of the plant's resources are allocated to replace injured roots.^[10]

CONCLUSION

For corn rootworm management alone, approximately 88% of nonrotated maize hectares (estimated at over a million hectares) in Illinois are treated with a soil insecticide.^[9] The introduction of genetically modified crops with activity against root-feeding insects will revolutionize the way these pests are managed. Although these new crops will likely reduce reliance on soil-applied insecticides, effects on non-target organisms and the development of resistant insect populations must be looked out for.

Rubisco Activase

Archie R. Portis

USDA and University of Illinois, Urbana, Illinois, U.S.A.

INTRODUCTION

Rubisco activase is a protein that is required in the higher plants to maintain and regulate the activity of Rubisco, the protein formally known as ribulose 1,5-bisphosphate carboxylase/oxygenase. Rubisco is a very important protein in photosynthesis because it initiates both photosynthetic carbon metabolism via its carboxylase activity and photorespiration via its oxygenase activity.^[1] The activity of Rubisco is a major factor limiting photosynthesis and thus the productivity of many of our major crops. The properties of Rubisco activase and the current understanding of the regulation of Rubisco by the activase will be discussed.

WHAT IS KNOWN ABOUT THE STRUCTURE OF THE ACTIVASE?

Rubisco activase is a member of the very large and diverse AAA⁺ protein family that contains related sequence domains forming a common structural motif, which binds ATP. AAA⁺ proteins use the energy provided by ATP hydrolysis to perform a wide variety of functions.^[2] For example, AAA⁺ proteins are involved in proteolysis, DNA synthesis, membrane fusion, and microtubule severing and trafficking. Thus they constitute a novel type of molecular chaperone, which acts to manipulate other molecular or macromolecular structures. In performing these functions, large multimeric complexes are often assembled, which may contain other proteins. The AAA⁺ proteins in these complexes contain one or more copies of the AAA⁺ motif and typically form ring structures consisting of six or seven AAA⁺ proteins.

Rubisco activase is highly self-associating and oligomerization of the protein is closely linked to its ATP hydrolysis activity.^[3] However, the exact structure of activase has not yet been determined and the types of macromolecular structures it can form remain unclear. Based on a wide variety of evidence, a working model for its activity has been proposed (Fig. 1). In this model the activase forms a ring around the Rubisco holoenzyme, which consists of eight large and small subunits that form eight active sites. ATP hydrolysis is proposed to

cause conformational changes in the ring, and thereby in Rubisco.

WHY DO PLANTS NEED ACTIVASE AND HOW DOES IT WORK?

The active site of Rubisco is capable of binding a wide variety of sugar phosphates (ligands) as well as its substrate, ribulose 1,5-bisphosphate (RuBP).^[1,3] In addition, the amine group of a lysine residue in the active site must be carbamylated by addition of an “activating” CO₂ molecule, in order for carboxylation or oxygenation of RuBP to occur. While only minor changes in the conformation of the enzyme occur with carbamylation, much more dramatic and similar changes occur with the binding of certain ligands to both the carbamylated and uncarbamylated forms of the enzyme.^[4] The binding of these ligands causes conformational changes that close off the active site so that the ligand is completely surrounded. This results in the ligand being bound very tightly, and its dissociation from the active site is very slow. Catalysis is possible only when RuBP binds to a carbamylated site. Physiologically, two of the more important ligands involved in inhibiting the activity of Rubisco in this manner are RuBP, which also binds to uncarbamylated active sites, and 2-carboxyarabinitol 1-phosphate, which prefers carbamylated sites.^[3] Either directly or indirectly, Rubisco activase appears to reverse the conformational changes that sequester these ligands, allowing them to leave the active site more quickly. The activase was named for its ability to rapidly restore activity to Rubisco that has RuBP bound to uncarbamylated sites. Thus, depending on its ATPase activity, the activase can maintain and regulate the activity of Rubisco at a level appropriate for photosynthesis when it is limited by other factors, such as when light intensity is limiting.

Reductions in Rubisco activity can also occur during catalysis.^[5] The reaction sequence is quite complex and various “mistakes” have been shown to occur.^[1] In several cases it has been shown that an aberrant sugar phosphate product remains tightly bound so that in the absence of Rubisco activase activity, catalytic activity decreases to a low level.

Fig. 1 A proposed model for the mechanism of Rubisco activase. Inhibitors bind (bottom half of the figure) to the open active sites (shaded ellipses) on the large Rubisco subunits (white) and close them off (dotted ellipses). Nucleotide exchange induces small changes in the conformation of the activase (only simulated here by a change in shape and shading, because the actual structure of activase is unknown), enhancing oligomerization and binding to Rubisco with the closed sites (left side), surrounding the holoenzyme in a ring structure. ATP hydrolysis in this supercomplex releases Pi and causes conformational changes in the activase and the ring structure (movement of active units relative to one another), resulting in the opening of the active sites (top half of the figure). The inhibitors can now dissociate more rapidly, and the changes in the activase-activase interactions result in disassembly of the ring and activase release from Rubisco (right side of the figure), restoring Rubisco to an active state. (From Ref. 3.)

The activity of the activase also plays another important role in photosynthesis by promoting a higher carbamylation state for Rubisco (and thus increased catalytic activity) than would otherwise be possible at atmospheric levels of CO_2 .^[3] Indeed, activase was discovered by characterizing a mutant of *Arabidopsis* that required high CO_2 for growth.^[6] Studies of the isolated enzyme showed that less than half-maximal carbamylation is possible with the physiological conditions in the chloroplasts where Rubisco is located. While ligand binding can either increase or decrease carbamylation, the bound ligands also prohibit the needed substrate, RuBP, from binding. A kinetic way out of this apparent conundrum was provided by modeling the effects of activase on ligand binding.^[7] The modeling shows that a steady-state level of nearly maximal carbamylation can result from a difference in the ability of activase to promote the release of RuBP from the carbamylated and uncarbamylated forms of the active site.

In addition to playing a critical role in the regulation of Rubisco in response to changes in light intensity and

source-sink balance, recent studies indicate that the activase may play an important role in the response of photosynthesis to high-temperature stress.^[8] A decrease in the activation state of Rubisco contributes to the reduced rates of photosynthesis at high temperatures. Current evidence indicates that as temperature increases, there is an increased rate of Rubisco inactivation and a reduced activity of the activase, which is quite temperature-labile compared to other photosynthetic enzymes.

HOW IS THE ACTIVASE (AND THUS RUBISCO ACTIVITY) REGULATED?

In most plants surveyed to date, Rubisco activase comprises two isoforms of 41–43 kDa and 45–46 kDa.^[1,3] These usually arise from one or more nuclear genes via alternative splicing, and after import and processing of the intermediate forms containing a chloroplast transit peptide. The larger isoform contains an additional domain at the carboxy-terminus, including two cysteine residues. These cysteines provide the ability to regulate the ATPase and Rubisco activation activities via light-induced redox changes mediated by thioredoxin-f, as shown by studies of Rubisco activation in transgenic *Arabidopsis* plants expressing mutant forms of the activase.^[9] Oxidation/reduction of these cysteines alters the response of the ATP hydrolysis and Rubisco activation activities to the ATP/ADP ratio in the chloroplast, such that the activase consumes little ATP in the dark when Rubisco activity is not needed. Regulation of the activase via the ATP/ADP ratio in the chloroplast also appears to provide a means to regulate Rubisco activity in response to source-sink changes that alter the demand for the products of photosynthesis. However, several species appear to contain only the smaller isoform, yet the regulation of Rubisco appears to be quite similar to that in the species with both isoforms.^[10] Obviously, understanding the regulation of Rubisco in these plants will require more study.

CONCLUSION

Rubisco activase is representative of a rapidly growing class of chaperone-like proteins that are specifically tailored to cover a diverse range of cellular activities requiring alterations of molecular or macromolecular structure. The target of the activase is Rubisco, for which the activase overcomes various problems Rubisco has in carrying out its functions and provides a means to regulate Rubisco activity in response to various environmental factors. Whether or not photosynthesis can be improved by modifying the regulation of Rubisco via the activase is

currently being investigated. Meanwhile, there clearly is considerable potential for modifying Rubisco or expressing foreign forms of the enzyme in order to improve crop productivity. In order to achieve this goal, proper interaction between Rubisco and the activase will have to be maintained.

Secondary Metabolites as Phytomedicines

Donald P. Briskin

University of Illinois, Urbana, Illinois, U.S.A.

INTRODUCTION

Throughout history, plants have provided a rich source for the development of human medicines. Given rising demand for phytomedicines, production of medicinal plants as alternative crops could provide important new opportunities in agriculture. This article briefly discusses the fundamental aspects of phytomedicinal chemical production by plant cells and surveys eight medicinal plants that have received considerable attention over the past decade.

HISTORY

From the earliest times of human history to the beginning of the 20th century, plant medicinal products represented a significant component in conventional medicine, but their use declined with the development of modern pharmaceuticals (e.g., aspirin and quinine) containing pure chemical compounds. Many of these modern pharmaceuticals may have been based on active chemicals isolated from plants, and the development of synthetic or semisynthetic derivatives led to drugs with a consistent dose and even higher levels of potency. Nevertheless, the enhanced dose of one or a few active chemicals in these modern pharmaceuticals frequently resulted in problematic side effects, and these modern pure drugs were often expensive.^[1]

Over the past decade there has been a strong resurgence in interest in and use of medicinal plants and phytomedicines, especially in North America. Recent surveys of phytomedicinal use by the American public have shown an increase from about 3% of the population in 1991 to over 37% in 1998.^[2,3] By 2002, the North American market for plant medicinal products had reached about \$4.1 billion/year.^[3] No doubt a major factor contributing to this great increase in phytomedicinal use in the United States has been the passage of federal legislation in 1994—the Dietary Supplement Health and Education Act (DSHEA)—that facilitated the production and marketing of phytomedicinal products.^[1,2]

PLANT SECONDARY METABOLITES AND PHYTOMEDICINES

The pharmacological actions of plant materials typically result from combinations of secondary metabolites that are present in the plant. The medicinal actions of plants are frequently unique to particular plant species; the combinations of secondary metabolites in a particular plant species or family are often taxonomically distinct.^[4,5] This is in contrast to primary metabolic products—such as carbohydrates, lipids, proteins, and nucleic acids—that are common to all plant species, and are involved in the fundamental biochemical processes of building and maintaining plant cells.^[5]

Although secondary products can have a variety of functions in plants, it is likely that their ecological roles may have some bearing on potential medicinal effects for humans. For example, secondary products involved in plant defense through cytotoxicity toward microbial pathogens could prove useful as an antimicrobial phytomedicine, if not too toxic to humans. Likewise, secondary products involved in defense against herbivores through neurotoxin activity could have beneficial effects in humans (i.e., as antidepressants, sedatives, muscle relaxants or anesthetics) through their action on the central nervous system. In order to fulfill functions in promoting the ecological survival of plants, molecular structures of secondary products have evolved to interact with molecular targets affecting the cells, tissues, and physiological functions in other competing microorganisms, plants, and animals.^[4,5] In this respect, some plant secondary products may exert their action by resembling endogenous metabolites, ligands, hormones, signal transduction molecules, or neurotransmitters, and thus have beneficial medicinal effects on humans due to similarities in their potential target sites.^[5]

BENEFITS OF CHEMICAL SYNERGISMS

In contrast to synthetic pharmaceuticals based on single chemicals, many phytomedicinals exert their beneficial effects through the action of several chemical compounds acting additively or synergistically at single or multiple

Table 1 Average sales of specific medicinal plants in the United States

Medicinal plant	% Average of total sales
<i>Ginkgo biloba</i>	20.8
St. John's wort (<i>Hypericum perforatum</i>)	17.1
Ginseng (<i>Panax ginseng</i> and <i>P. quinquefolium</i>)	12.6
Garlic (<i>Allium sativum</i>)	11.3
<i>Echinacea</i> sp./Goldenseal (<i>Hydrastis canadensis</i>)	9.7
Saw palmetto (<i>Serenoa serrulata</i>)	5.5
Kava (<i>Piper methysticum</i>)	2.5
Valerian (<i>Valeriana officinalis</i>)	1.4

(Based on data from Ref. 6.)

target sites associated with a physiological process. As pointed out by Tyler,^[1] this synergistic or additive pharmacologic effect can promote pharmacological effectiveness without the problematic side effects associated with the predominance of a single xenobiotic compound in the body. In this respect, Kaufman et al.^[5] extensively document how synergistic interactions underlie the effectiveness of a number of phytomedicines. This theme of multiple chemicals acting in an additive or synergistic manner likely has its origin in the functional role of

secondary products in promoting plant survival.^[4,5] For example, in the role of secondary products as defense chemicals, a mixture of chemicals having additive or synergistic effects at multiple target sites would not only ensure effectiveness against a wide range of herbivores or pathogens, but would also decrease the chances of these organisms developing resistance or adaptive responses.^[4,5]

MEDICINAL USES AND ACTIVE PHYTOMEDICINAL CHEMICALS OF SEVERAL FREQUENTLY USED MEDICINAL PLANTS

Whereas there are thousands of medicinal plants utilized in Western and non-Western medical approaches, a relatively small number have been the subject of considerable interest in the United States over the past decade.^[1,2] As shown in Table 1, eight medicinal plants have tended to dominate the total market for U.S. sales of medicinal plant products since 1998.^[2,3,6] In general, the medicinal plants shown in Table 1 have remained within the top 10–15 plants dominating medicinal plant sales, although their percentage of the market has varied from year to year.^[6]

Due to the extensive nature of their use in both North America and Europe, these eight medicinal plants have been the subject of considerable study with respect to their

Table 2 Medicinal properties and active phytomedicinal chemicals of eight medicinal plants used in the United States

Plant	Medicinal use	Active phytochemicals	Mode of action
<i>Ginkgo biloba</i>	Improves flow of blood to the brain and extremities	Gingolides A, B, C Bilobilide	Improves capillary wall elasticity via antioxidant activity
St. John's wort	Antidepressant	Hypericin, Pseudo-Hypericin, Hyperforin, Flavones	Increases serotonin levels via inhibition of reuptake and catabolism
Ginseng	Improves response to stress, increases energy	Ginsenosides	Unknown but may relate to effects involving the adrenal glands
Garlic	Decreases blood cholesterol, lowers blood pressure	Allicin	Decreases cholesterol by inhibiting HMG-CoA reductase, blood pressure decreasing effect unknown
<i>Echinacea</i>	Decreases duration and severity of upper-respiratory infections	Echinacoside, Cichoric Acid, Isobutylamines, Alkylamides	Increases blood levels of several types of white blood cells, increase phagocytic activity of monocytes
Saw palmetto	Reduces symptoms of benign prostatic hyperplasia	Phytosterols present in the berries of this palm tree	Inhibition of 5 α -reductase leading to a decrease in dihydrotestosterone levels in the prostate
Kava	Treats insomnia and anxiety	Kavapyrones	Binding to GABA _A receptors in a similar manner to benzodiazepine drugs (ex. valium)
Valerian	Treats insomnia and anxiety	Valepotriates (iridoids), Alkaloids?	Stimulation of GABA release and inhibition of GABA reuptake

biochemical characteristics and pharmacological properties. For each of these plants, Table 2 summarizes their possible medicinal actions, active phytomedicinal chemicals that have been identified, and pharmacological mode of action, if known. Detailed information regarding the phytochemistry, pharmacology, and toxicology of these medicinal plants can be found in works by Schultz et al.^[7] and Cupp.^[8]

CONCLUSION

Although medicinal plants have had long-standing use throughout human history and are of considerable interest as alternatives to synthetic pharmaceuticals, there is a paucity of basic knowledge and research on their physiology and biochemistry. It is clear that few widely used medicinal plants have received the extensive physiological, biochemical, and genetic characterization applied to food crops or model plant systems such as *Arabidopsis*. Although active chemicals have been identified in many medicinal plants, the pathways for their biosynthesis and the genetic and environmental factors regulating their biochemical production are in many cases unclear.

At present, a major concern over the use of phytomedicines regards the maintenance of consistent medicinal quality in botanical medicines.^[9] Whereas the focus has tended to be on quality control in herbal manufacturing practices (good manufacturing practices (GMP)), variation in phytomedicinal content due to environmental effects on secondary plant metabolism in plant material can also represent a significant factor in determining the quality of the plant material entering the botanical medicine production process and the efficacy of the resulting product. The use of molecular and biotechnological approaches to medicinal plants would also have wide application and promise, especially with regard to metabolic engineering of phytomedicinal chemical pathways and the *in vitro* production of phytomedicinals in large-scale tissue culture systems such as bioreactors.^[10]

Seed Banks and Seed Dormancy Among Weeds

Lynn Fandrich

Oregon State University, Corvallis, Oregon, U.S.A.

INTRODUCTION

The relationship between seed dormancy and success of a plant as an agricultural weed is significant. Holm et al.^[1] estimated that there are about 250 significant weeds in world agriculture. If the top 40 weeds classified as “serious” are selected by ranking them according to the number of countries in which they are considered “serious” weeds, it can be shown, without exception, that each one of the 40 species has dormancy. If weed seed were forever dormant, or simply nondormant, the complexities of weed management would be greatly reduced. However, weed seeds vary widely with respect to degree, duration, and source of dormancy. The existence of large populations of weed seed with varying degrees and states of dormancy is the basis for the annual weed problem. Dormancy allows a weed seed to avoid germination when conditions are not appropriate to complete its life cycle and prolongs population survival in the form of a soil seed bank.

CHARACTERISTICS OF THE SOIL SEED BANK

All of the viable seed present on the surface and in the soil is usually described as the soil seed bank. The number of seeds in the seed bank is determined by the rate of input in the seed rain, minus the losses resulting from disease, predation, and germination. The seed bank consists of new seeds recently shed by a parent plant, as well as older seeds that have persisted in the soil for several years. All of these seeds will vary in depth of burial and state of dormancy. Only a small proportion of seeds, varying between and among species, germinate when conditions are favorable. It is generally assumed that annual species contribute up to 95% of the seeds in the agricultural seed bank and only 2 to 10% of weed seeds emerge as seedlings each year.

Because most weeds are capable of producing a high number of seeds, especially compared to cultivated species, a few uncontrolled plants can rapidly increase the number of seeds in the soil seed bank. Data collected from plants grown in monoculture showed that wild oat (*Avena fatua*) produced 372–623 seeds,^[2] common lambsquarters

(*Chenopodium album*) produced 75,600–150,400 seeds,^[3] and Palmer amaranth (*Amaranthus palmeri*) produced 200,000 to 600,000 seeds **per plant**.^[4] It should be noted that biotic (inter- and intraspecific competition) and abiotic (climate) factors affect seed production, and most plants in agricultural situations do not often approach these high seed production values.

Large numbers of seeds are dispersed both horizontally and vertically in the soil. Plowing, chiseling, disking, and other forms of tillage are major ways that seeds are moved and covered with soil. After a number of years of soil disturbance, a relatively stable vertical distribution of seeds is reached in the tillage zone. Early estimates of seed numbers in agricultural soils exceeded 100,000 seeds per hectare in the tillage layer. Samples of soil on well-managed farms in Minnesota averaged 16 million seeds per hectare, and as many as 45 million per hectare have been counted.

PERIODICITY AND INTERMITTENT GERMINATION

Most weed species exhibit annual periodicity in germination and emergence restricted to certain times of the year. This behavior was part of the original evidence for annual cycles in the relief and imposition of seed dormancy. Observations on seed germination and seedling emergence from soil samples placed in the greenhouse revealed that there was a typical periodicity, as well as a period of maximum germination for more than 100 weed species.^[5] Exhumed seeds of corn spurry (*Spergula arvensis*) showed clear seasonal changes in dormancy during three successive years of germination tests.^[6] Often, seeds are conditionally dormant, i.e., the appropriate conditions for germination are not present; seeds of winter annual species will not germinate in late spring, and spring annual species will not germinate in late fall.

WEED SEEDS AND DEPTH OF BURIAL

Seed germination and emergence of seedlings from various depths below the soil surface depend on the degree of dormancy present and conditions of the immediate

environment. However, dormancy-breaking stimuli are most effectively encountered and germination is rapid when seeds remain at or near the soil surface. There is an overall agreement that the number of seedlings and rate of seedling emergence decrease proportionately with increases in the depths of seed burial. Examination of seeds recovered from 12 cm deep showed that approximately 85% were completely dormant.^[7] The results of these investigations also revealed a strong association between seed mass and maximum depth of emergence, with the heaviest seeds emerging from the greatest depths.

PERSISTENCE OF WEED SEEDS IN SOIL

It is quite common for seeds to be dormant when they are fully mature on the parent plant and for dormancy to be lost after they are shed. The term "after-ripening" has frequently been used to denote the interaction between environment and seed over time that leads to a loss of dormancy.^[8] The length of the after-ripening period varies between and among species and by seed location on the plant. Most weed species show one or two periods of high percent germination in seed produced during any given year, and the percent germination in subsequent years can be quite low. The mean length of the dormancy period in populations drives turnover in the seed bank. Grime^[9] makes a distinction between "transient" (complete turnover in less than one year) and "persistent" seed banks (some seed remains in the bank longer than one year). The term "aging" is sometimes used incorrectly to describe after-ripening. Aging reduces seed viability and seedling vigor.

ENVIRONMENTAL FACTORS THAT AFFECT SEED DORMANCY

Temperature

Temperature is the major environmental factor to cause a change in seed dormancy. Temperatures may break dormancy but also send seeds into dormancy when other environmental conditions are limited. Seeds of summer and winter annual weeds may be conditionally dormant due to temperature influences. Experimentally, the effect of chilling is tested through exposure of imbibed seeds to low temperatures, usually around 0 to 1°C, for a substantial period. Seeds of bur buttercup (*Ranunculus testiculatus*) germinated only at very cold incubation temperatures, and maximum germination occurred at 5°C.^[10]

Seeds of winter annual species must be exposed to high summer temperatures for several months to germinate at

fall temperatures. If lack of moisture prevents seeds of obligate winter annuals from germinating in the fall, low winter temperatures may induce dormancy. Consequently, viable seeds that fail to germinate in the fall cannot germinate in spring because they are dormant. Seeds of the winter annual Japanese brome (*Bromus japonicus*) were forced into dormancy with winter temperatures and would not germinate during the spring and summer, despite favorable germination conditions.^[11]

Under natural conditions in the soil, seeds are subjected to fluctuating temperatures. It has been observed that random fluctuations in temperature, in and above a low temperature, are as effective in promoting germination as exposure to constant low temperatures. It has also been found that seeds which remain dormant at constant temperatures may be induced to germinate by a diurnal fluctuation of temperatures. Thompson and Grime^[12] investigated the effect of fluctuating temperatures on the germination of 112 species of herbaceous plants. Forty-six of the species examined were found to have their germination stimulated by temperature fluctuations in the light.

Light

Exposure to light breaks dormancy in many weed species, but there may be situations in which light has no effect or even inhibits germination. Baskin and Baskin^[13] observed that among 142 species, germination of 107 was promoted by light, 32 were unaffected by the difference in light and dark conditions, and 3 were inhibited by light. Wesson and Wareing^[14] concluded that "under natural conditions in the field, the germination of buried seeds following a disturbance of the soil is completely dependent upon exposure of seed to light." Even a short exposure or "light break" was sufficient to significantly increase the total number of seedlings emerging from soil.

CONCLUSION

Understanding the processes of dormancy loss and germination is essential to the development of good weed management programs. Currently, most management programs aim to control emerged weed populations and affect the quantity of seed returned to the soil, but it should be recognized that almost all agronomic practices also affect weed seed dormancy and germination through manipulation of the soil environment. Because many agricultural weeds exhibit periodicity of emergence, tillage treatments, planting dates, and other cultural practices can be altered to follow peak germination times and

maximize depletion of the seed bank. A natural population of viable weed seeds in the field declined at a rate of approximately 50% per year with frequent cultivation.^[15] A review of the utilization of specific agronomic practices to manipulate weed seed dormancy and germination requirements for weed management is available from Dyer^[16] and others.^[17,18]

Seedborne Pathogens

S. B. Mathur

Danish Government Institute of Seed Pathology for Developing Countries, Copenhagen, Denmark

H. K. Manandhar

Nepal Agricultural Research Council, Khumaltar, Lalitpur, Nepal

INTRODUCTION

Seedborne pathogens are infectious agents, such as bacteria, fungi, mollicutes, nematodes, viroides, and viruses, that are associated with seeds and which can cause diseases in seeds, seedlings, and plants. These pathogens are capable of causing spots and discoloration in seed coat, change in seed size, loss in seed germination, and reduction in seedling vigor and of producing symptoms often leading to seedling death. Through seeds, such pathogens get transmitted to plants, causing symptoms and ultimately affecting production of seeds in terms of both quality and quantity. Seedborne pathogens can completely or partly replace seeds, such as occurs in ergot, smuts, bunts, and nematode galls.

Some seedborne pathogens can be exclusively seedborne and seed transmitted, while others can be both seedborne and at the same time soilborne or present in collateral hosts. Seedborne pathogens are found in seed lots as contaminations, present on the surface of the seed and/or located in the seed coat, pericarp, endosperm, and embryo. They get transmitted to plants of the next generation systemically, locally, or both locally and systemically.

Many seedborne pathogens are economically important as they are able to cause appreciable losses in crop yield. The losses are enumerated in several large publications that readers should consult because they give comprehensive accounts of different types of seedborne pathogens, mechanisms of seed infection, seed transmission, spread, survival in seeds, and control of diseases caused by such pathogens. Some crop-oriented publications are also of importance. The electronic version of the Crop Protection Compendium (2002) of CAB International provides useful information on a number of aspects of seedborne pathogens that cause diseases in agricultural, horticultural, and industrial crops, medicinal plants, and forest tree species.

IMPORTANCE OF SEEDBORNE PATHOGENS

Seedborne pathogens are important because they affect the planting value of a seed lot and the spread of the disease as seeds get transported from infested areas to noninfested areas. This is also a mechanism by which new races, strains, or pathotypes travel from one region to another region of a country and across international boundaries (Figs. 1–4).

The importance of seedborne pathogens is realized when infected seeds are sown in the field. Depending on seeding rate, even a trace seed infection can bring thousands of infected seeds in a one-hectare area of land, as seen in Table 1. These large numbers of infected seeds, when distributed uniformly in a randomized fashion in the field, increase their role in disease development.

Seedborne pathogens, including some commonly occurring saprophytic organisms, are able to spoil seeds and grains by producing toxins, especially in bad storage conditions. Such spoilage makes the grains unfit for human and animal consumption.

DETECTION OF SEEDBORNE PATHOGENS

Laboratory test methods are available for detecting seedborne pathogens. A recently published book^[4] and Seed Health Testing Methods, Annex to Chapter 7 of International Rules for Seed Testing, Edition 2003, published by International Seed Testing Association (ISTA), are essential resources for detecting fungi. Most of the sporulating fungi are detected by incubation methods (Fig. 5). Some fungi, which are located in the embryo, are detected only by the embryo count method.^[4]

Bacterial pathogens can be detected by plating of seeds on agar media; liquid assays; growing plants for symptom

Fig. 1 Mottling of soybean seeds induced by soybean mosaic potyvirus. (View this art in color at www.dekker.com.)

development; biochemical, serological, and molecular tests; and using bacteriophages. Viruses are detected by examining dry seeds, germinating seeds, or seedlings raised from seeds, followed by indicator plant test, serology, molecular tests, and electron microscopy.

Most nematodes present in seeds can be extracted using a simple Baermann-funnel technique and by direct inspection of seeds for wheat gall nematode.

CONTROL OF SEEDBORNE PATHOGENS

Pathogens found in seeds can be controlled using physical, chemical, and biological means. In general, it is advisable to grow crops by using, as far as possible, pathogen-free

Fig. 2 Chickpea seeds with reduced size (right) collected from plants infected by *Fusarium oxysporum*, a wilt fungus.^[1]

Fig. 3 Hypertrophied seed caused by *Protomyces macrosporus*, mixed with normal seeds of coriander, and hypertrophies of various grades (inset).

seeds, preferably of resistant cultivars, or seeds collected from fields and areas where either specific diseases do not occur or the disease pressure is low.

The choice of control measures depends on the types and nature of pathogens. Those pathogens that are exclusively seedborne are easy to control by appropriate seed treatments. The control, however, is difficult when the pathogens are both seedborne and soilborne or when they are also present in collateral hosts (weeds and hosts other than primary hosts).

As seeds infected by pathogens are often discolored, spotted, and lighter in weight, they can be removed to a great extent by seed-cleaning machines, by soaking in brine solution, by hand (manually), or by winnowing.^[5] Clean seeds thus obtained give seedlings of higher vigor and better plant stand (Fig. 6), and the yield from such plants is higher.

Fig. 4 Ears of wheat infected with loose smut fungus, *Ustilago tritici*: (A) a partially smutted ear; (B and C) completely smutted ears.^[2] (View this art in color at www.dekker.com.)

Table 1 Expected number of infected seeds to enter in a field of one hectare that are capable of producing disease

Percent seed infection	Seeding rate					
	125 thousand seed/ha	250 thousand seed/ha	500 thousand seed/ha	1 million seed/ha	2 million seed/ha	5 million seed/ha
0.1	125	250	500	1,000	2,000	5,000
0.5	625	1,250	2,500	5,000	10,000	25,000
1.0	1,250	2,500	5,000	10,000	20,000	50,000
2.0	2,500	5,000	10,000	20,000	40,000	100,000
5.0	6,225	12,500	25,000	50,000	100,000	250,000
10.0	12,500	25,000	50,000	100,000	200,000	500,000

Usually, the seeding rate is expressed in kg per hectare, but the number of seeds per gram can be calculated in the laboratory. This will help in calculating number of seeds per hectare.

The above table can be expanded. It will help in knowing the number of seeds that will enter a field, but the rate of transmission of seedborne pathogens will depend on the nature of the pathogen, susceptibility of the host, soil conditions, environmental conditions, cultural practices, etc.

(From Ref. 3.)

CONCLUSION

Seedborne pathogens are one of the major constraints in agriculture as they can affect physical appearance and nutritional value of seeds or grains, spoil grains by producing toxins, reduce germination, cause death of seedlings and plants, act as initial inoculum for disease development in the field, and move with seeds from infested areas to noninfested areas. Therefore, seedborne pathogens must receive due consideration in agriculture across the globe. Seeds must be tested before sowing by

internationally accepted seed health test methods. Infected seeds must be removed as far as possible from sowing or should be sown only after proper seed treatments.

Seed Dormancy

Alistair J. Murdoch

The University of Reading, Reading, U.K.

INTRODUCTION

Seed dormancy is most easily observed and measured as the absence of germination in an imbibed, viable seed. Its intrinsic nature is, however, less easily defined physiologically. Almost all seeds go through a dormant phase if only to prevent viviparous germination on the mother plant. Many crop species have been selected for low dormancy to ensure rapid and uniform crop establishment. Residual dormancy, however, causes problems for seed germination testing, volunteers in crops, and low germination in the brewing industry.

Prevention of immediate germination through either dormancy or quiescence is a crucial element in the regeneration strategy of many wild plants. The success of such a strategy depends on quantitative and sometimes qualitative differences in dormancy within seed populations.

Stimulation of germination of dormant seeds frequently occurs as a function of fascinating interactions of environmental or chemical stimuli with the annual dormancy cycle of seeds in the soil. These interactions lead to the periodicity of emergence. Quantifying differences *within* seed populations with respect to environmental factors is the key to predictive models for the germination and emergence of dormant seeds.

DEFINING DORMANCY

Dormancy is usually defined in the way it is most often measured and observed—negatively:

The failure of a viable seed to germinate given moisture, air and a suitable constant temperature for radicle emergence and seedling growth.^[1,2]

Attempts to define dormancy positively include “a seed characteristic, the degree of which defines what conditions should be met to make the seed germinate,”^[3] but how is the degree of an unspecified characteristic to be measured?

Seed dormancy is sometimes classified by the phenological stage when dormancy is induced or by the putative mechanism.^[4] A distinction of particular value is that between primary (innate) and secondary (induced) dor-

mancy. Primary dormancy develops during seed maturation on the mother plant, while secondary dormancy is induced after shedding.

DEFINING QUIESCENCE

Absence of one or more of the three prerequisites for germination of a nondormant seed (moisture, air, and a suitable temperature) usually reduces metabolism.^[5] Nongermination of nondormant seeds can, therefore, arguably be called quiescence, again defined negatively:

The failure of a viable seed to germinate due to shortage of water, poor aeration or an unsuitable temperature for radicle emergence and seedling growth (cf. Ref. 1).

Quiescence is frequently enforced by the environment as in air-dry seeds or in imbibed seeds below the base temperature for the rate of germination of nondormant seed.

Hardseededness, sometimes called physical dormancy,^[4] is strictly innate quiescence. Best known in the Leguminosae, hard seeds, which are impermeable to water, occur in several other plant families.^[1] Like innate dormancy, impermeability develops during maturation drying on the mother plant and it may increase after shedding in dry environments. Although hard seeds are easily made permeable by mechanical abrasion, some of the greatest longevities of seeds in the soil are achieved by such innately quiescent, hard seeds, which possess no primary dormancy.

MEASURING DORMANCY

Phytochrome is integrally involved in many photomorphological responses in plants, and seed germination is no exception.^[5] It has been speculated that the phytochrome molecule in its active, far-red-absorbing form binds to an unidentified receptor protein and that dormancy might be quantified directly by the amount of this protein present in the seed.^[3] Current research into the mechanisms and differences in gene expression between dormant and nondormant seeds is likely to revolutionize not only our

understanding of seed dormancy, but perhaps also the way we measure it.

At the time of writing, however, dormancy is usually measured by nongermination of imbibed viable seeds with adequate aeration and at a suitable temperature for seedling growth. If V is percentage viability of a seed

Fig. 1 After-ripening of A) caryopses and B) spikelets of *Cenchrus ciliaris* matured in different thermal, moisture, and fertility environments including 32°/27°C (13 h/11 h) drought stress (□), 27°/20°C drought stress (■), 32°/27°C no water stress (◇), 27°/20°C no water stress (◆), 32°/27°C nutrient (○), 27°/20°C nutrient (●) in Experiment 1. All plants were grown identically at 25°C until 5 d after anthesis on May 31, 1996. They were then transferred to maturation conditions with 13 and 11 h per day at upper and lower temperatures, respectively. Drought stress means a series of cycles in which watering was withheld until the first signs of wilting. Nutrient treatments were watered with a balanced solution containing 100 ppm nitrogen. Seeds were after-ripened as spikelets at 43% r.h., 40°C, and germinated in darkness at 25°C. Germination is plotted on a probability scale showing regression lines fitted by probit analysis. (From Ref. 7; reproduced with permission of CAB International.)

lot and G the percentage germination in such conditions, then the percentage dormancy is $(V-G)$. Germination and viability are both quantal responses since an individual seed is either viable or inviable and it either germinates or does not. By inference, the expression $(V-G)$ likewise but incorrectly quantifies dormancy as a quantal response since an individual seed has to be classified as either dormant or nondormant. In reality, it is only the expression of dormancy in the specific testing environment that is a quantal response.^[1] Bradford^[6] has proposed that dormancy in an individual seed is like

“a hill that seeds approach from one side (i.e. as the requirements to break dormancy are met) and then progress down the other, gathering momentum (increasing germination rate).”

The realism of this view is seen easily when considering the response of seeds as a function of the dose of a dormancy-breaking stimulus. Nondormant seeds in the population should germinate upon imbibition. The dormant seeds vary in dormancy: Some may respond to after-ripening for one week while others may need two (Fig. 1). It is well stated: “We do not yet know how to measure the depth of dormancy in individual seeds but its variation is reflected in the seed-to-seed variation in the expression of dormancy in a seed population.”^[1]

Seed-to-Seed Variation in Dormancy

Unless 0% or 100% of seeds germinate, the classification of viable seeds into two groups—those that germinate and those that do not—may be thought to imply polymorphism. But polymorphism should be deduced only if there is a discontinuity in dormancy periods or when developmentally or morphologically different seeds vary in the depth of primary dormancy. Polymorphic seeds may be produced on the same or different plants. In the classic case of *Xanthium pensylvanicum*, the two seeds in each capsule are dispersed together. The upper seed is much more dormant and germinates at least 12 months later than the lower one.^[2]

There is often, however, a continuum of variation in dormancy even within apparently uniform seed lots (Figs. 1 and 2). Similarly, seed-to-seed variation occurs in the dose of a dormancy-inducing and/or germination-inhibiting treatment required to induce secondary dormancy as in aerobic preconditioning of *Orobanchae* seeds (Fig. 2).

This seed-to-seed variation of dormancy responses in seed populations often approximates to the normal frequency distribution. The germination-dose curve is therefore quantified by its mean and variance, and the curves are linearized by transforming the germination or

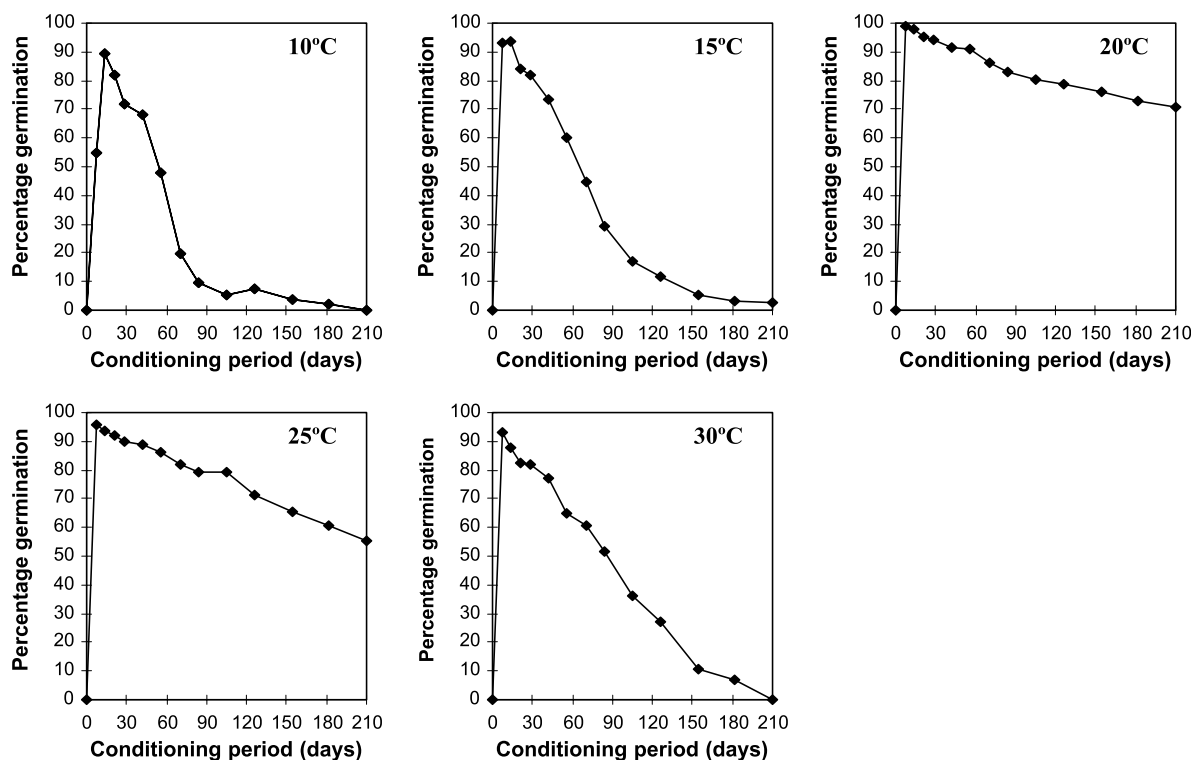

Fig. 2 Germination of *Orobanche aegyptiaca* seeds after conditioning (fully imbibed) for various periods at 10°C, 15°C, 20°C, 25°C, and 30°C. Seeds were surface-sterilized with sodium hypochlorite solution before conditioning for periods shown on the x-axis. Germination tests lasted ten days at 20°C with 3 ppm of GR24. GR24 is an analogue of Strigol—an exudate of cotton roots that stimulates germination of seeds of some parasitic plants. Loss of primary dormancy over the first 15 days (approx.) is followed by induction of secondary dormancy. Primary dormancy is lost most slowly and secondary dormancy induced most rapidly at 10°C. Secondary dormancy is induced most slowly above 20°C, the more rapid declines in germination at 25 and 30°C being due to loss of viability, which was most rapid at 30°C. (Drawn from data published in Ref. 8.)

dormancy percentages to probits (Fig. 1). This (probit) analysis gives a robust measurement of seed dormancy: The intercepts of the probit lines in Fig. 1 give far better estimates of dormancy levels of seeds produced in various maturation environments than the results of a single germination test. The reciprocal of the slope quantifies the standard deviation of the dormancy response to the applied treatment in the seed population, and these two parameters are the key to modeling responses of dormant seeds to environmental variables.^[7,8]

PRIMARY DORMANCY

Primary dormancy may simply occur because the embryo is immature so that germination is delayed pending further development as in the linear embryos of the *Ranunculaceae* and *Umbelliferae*.^[4] Other seeds are dormant due to a physiological block caused by the seed coat and/or the embryo.

Primary dormancy has two main functions: first, preventing precocious germination,^[9] a response linked to the presence of abscisic acid (ABA) during seed maturation; and secondly, assisting the temporal dispersal of seeds by preventing their immediate, synchronous germination. Very few species can therefore reproduce effectively without seed dormancy. One exception is recalcitrant seeds from the tropics. These seeds can neither be dried nor be chilled below 10–15°C without losing viability. Primary dormancy is absent and germination occurs on or before release from the inhibitory effect of the enclosing maternal environment.

Heritability of dormancy is complex because parts of the seeds differ genetically. For example, a diploid embryo may receive nutrients from a triploid endosperm (with two maternal and one paternal sets of chromosomes) and is surrounded by maternal tissues (testa and fruit structures).

Primary dormancy not only varies with genotype but also with maturation environment; in barley (*Hordeum vulgare*) and *Cenchrus ciliaris* (a perennial grass that

occurs in arid and semiarid environments), dormancy was greater for seeds produced under water stress, a characteristic which may be of adaptive value in plants growing in arid ecosystems (Fig. 1). The opposite effect of water stress occurs in *Avena fatua*.

Primary dormancy declines both prior to shedding and subsequently. When this loss of dormancy occurs in "air-dry" seeds, it is termed after-ripening (Fig. 1). The rate of after-ripening increases with temperature in a predictable manner, the Q_{10} for the relation usually being 2.5–3.8.^[1]

SECONDARY DORMANCY

Dormancy may be induced in dormant and in "quiescent" nondormant seeds after shedding. Secondary dormancy is induced rapidly by anaerobiosis and more slowly by prolonged moist aerobic treatments in which germination does not occur. Induction of secondary dormancy may be delayed or prevented by intermittent low-intensity laboratory light and nitrate.^[1] Rates of induction of secondary dormancy of *Orobanche* seeds were fastest at 10°C and decreased to a minimum above about 20°C (Fig. 2).^[8] By contrast, rates of induction in imbibed *Rumex crispus* seeds increased with an increase in temperature.^[1]

Are the mechanisms of primary and secondary dormancies the same? Dry after-ripening and the same chemicals may relieve both primary and secondary dormancy, implying some similarity. It is, however, interesting that while short periods of imbibition are associated with relief of primary dormancy, longer periods lead to secondary dormancy (Fig. 2). The final answer to this question may come when the expression of dormancy genes can be measured in seed lots varying in dormancy.

Annual cycles in which physiologically based dormancy is relieved and secondary induced during the course of a year occur in buried seeds of some annual plants in both temperate and tropical soil environments.^[4] Exposure to light, nitrate, and temperature treatments may be needed to relieve residual primary and secondary dormancy at times of low dormancy. Understanding how these physical and chemical factors affect seed populations with different levels of dormancy is crucial if

seedling emergence from persistent soil seed banks is to be predicted.^[10]

Seed Genebank: Functions, Acquisition Strategies, and Database Management

Adi B. Damania

GRCP, University of California, Davis, U.S.A.

INTRODUCTION

When American poet Edgar A. Guest bought a packet of seed it flashed through his mind that he had purchased “a miracle of life.”

The seeds were worth only a dime
but possessed a power no man could create,
a dime's worth of mystery, destiny, and fate.
—“*A Package of Seeds*”

In working with seeds, whether it is harvesting, cleaning, handling, storing, or transporting, it is essential to keep in mind at all times that inside the seed is a dormant miniature plant awaiting the opportunity to continue its life cycle. Crop genetic diversity can be conserved as DNA, clones, tissue culture, and living plants. This entry deals with genebanks that conserve genetic resources in the form of seeds only.

The principal reasons to conserve crop genetic resources in genebanks (genetic resources centers) are to save them for future use in plant breeding programs, to offer food solutions in times of famine or other natural disasters, and for biological research. Today, genetic diversity is under threat, whereas it was grown undisturbed for thousands of years. Habitats of wild progenitors of crop plants continue to be destroyed by unsustainable human activity in several places.^[2] Also, in some areas, high-yielding cultivars are replacing traditional varieties (called landraces) developed by farmers' selections over a millennium. As new varieties, with higher yields and greater disease resistance become available, landraces are displaced and lost forever if not collected and conserved in genebanks. This is especially ironic because all plant breeding is built on existing genetic diversity; hence, it is imperative that this diversity be conserved and remain available for present and future crop improvement programs and to ensure food security.

VAVILOV ESTABLISHES A GENE BANK IN SOVIET UNION

At various stages in human history, before there were genebanks, people have been collecting and conserving

plants for their economic or exotic values in botanic gardens or plantations. However, the activity of mounting targeted expeditions overseas to scientifically collect crop germplasm from areas where its diversity is the greatest was pioneered by the Russian botanist, geneticist, and plant breeder Nikolai Ivanovich Vavilov (1887–1943). In a series of adventurous expeditions, mainly between 1916 and 1933, Vavilov and his coworkers collected more than 250,000 plant accessions from centers of diversity all over the world for the betterment of Russian agricultural production.^[14] The collections that Vavilov made have been preserved by the N.I. Vavilov Institute of Plant Industry (VIR) in St. Petersburg, Russia. VIR houses one of the world's oldest and most comprehensive genebanks.

Among the most important crop genetic resources collections are those held by the International Agricultural Research Centers of the Consultative Group for International Agriculture Research (CGIAR). The materials in their genebanks are held “in trust” for the United Nations' Food and Agriculture Organization (FAO). More than 700,000 accessions are held at 11 CGIAR Centers, out of which 532,500 accessions are held “in trust.”

IN SITU AND EX SITU CONSERVATION

There are two basic technologies for storing seeds of crop genetic resources in situ, i.e., in its natural agricultural habitat, and ex situ, as stored seed samples or plants in a genebank.^[11] A crop genebank is a facility for conserving, managing, and reproducing the diversity of crop plant varieties and their progenitors and/or wild and weedy relatives. Not unlike the crops they conserve, genebanks come in different shapes and sizes from very large number of collection samples (also referred to as accessions) conserved in specially designed buildings with cold storage rooms or a household freezer to a field consisting of a few labeled plants. However, their primary purpose remains the same: the safe maintenance of plant diversity.^[6] A genebank may include the diversity of a single crop species and its wild relatives, for example, 35,500 or more samples of wheat and its wild relatives, gathered from around

the world are maintained by the Genetic Resources Unit of the International Center for Agricultural Research in the Dry Areas (ICARDA) in Syria. National governments also maintain genebanks, such as the United States Department of Agriculture (USDA), Agricultural Research Service (ARS), National Plant Germplasm System (NPGS) that has over 458,000 samples of more than 10,376 species belonging to 1622 genera of genetic resources in storage at various genebanks.^[10]

In the 1960s, the start of the genetic resources conservation movement consisted of but a handful of genebanks, mostly in the industrialized countries. Today there are nearly 1470 genebanks worldwide; nearly two-thirds of these are in developing countries.^[5] At least 100 countries maintain living plants in field genebanks, and about 60 have facilities to conserve germplasm *in vitro* (in test tubes). Collections of fruit trees, such as mango, avocado, pecan, lychee, sugar cane, annonas, and cacao are conserved as living trees, usually clonally propagated in clonal repositories. Among them, the world's genebanks maintain more than 6 million accessions. More than one-third of the total accessions are held by 15 national genebanks worldwide (for a comprehensive list see appendices in Ref.^[12]).

FUNCTIONS OF A MODERN GENE BANK

1. Acquires and documents genetic resources.
2. Conserves and generates/multiplies samples of genetic resources acquired through collections, exchanges and donations.
3. Promotes and supports research activities related to plant genetic resources conservation and utilization.
4. Maintains a query-friendly database and documentation of the collections through networking.
5. Distributes plant materials between national and international institutions and scientists.
6. Disseminates information on evaluation results and other research through publications.
7. Sponsors training and workshops.
8. Collects data on morphology and other constant traits or characterization.
9. Evaluates collections for agronomic and other economically useful traits.

A flow chart of activity in an active genebank is given in Fig. 1.

Meeting the germplasm requirements of breeders is one of the most important functions of genebanks, but increasingly genebanks are fulfilling bigger roles. In addition, genebanks resupply farmers, through

their local government or distribution system, with seeds collected previously from their own areas after a natural or man-made calamity. For example, repatriation of accessions to their country of origin is valuable in cases where local collections have been lost. This is the case in Iraq.

ACQUISITION OF GERmplasm TO START A GENE BANK

When a genebank is newly established, it usually builds up its collections by soliciting donations followed by exchange. Thus, when ICARDA decided to set up a genebank, it got material from the USDA as well as the National Research Council's (CNR) Germplasm Institute in Bari, Italy. Later, it sent out its own scientists on collecting missions and thus filled gaps, both geographical and morpho-types, in its collections. Materials are exchanged with other genebanks in both hemispheres. In recent years, the genebank at ICARDA and other international centers of the CGIAR have duplicated their collections at other international genebanks for reasons of safety. This is a standard practice among major genebanks known as safety duplication or "black box" conservation. Most genebanks also maintain a herbarium of plants or plant parts that are dried and preserved on herbarium sheets. These accessions are used to document the names and morphology of plants along with dates, detailed coordinates of the collection sites, and the names of collectors.

SEED STORAGE REQUIREMENTS

The most widely grown food crops, such as wheat, rice, and maize, have seeds that can be stored on a long-term basis. The major factors that influence the longevity of seeds in storage are temperature, moisture content, and oxygen concentration.^[13] These three factors have to be considerably reduced to maintain germination ability over a long period of time, i.e., several decades. Seed viability is not static and it depends on the conditions of initial storage. Viability, which is normally near 100% when seeds are first stored, declines over time, so that they must be regenerated by growing plants in the field or a greenhouse to provide fresh stocks. In addition, depleted stocks of seed due to fulfilling requests have to be replenished. Hence, they need to be rejuvenated and multiplied, preferably at the same time.

At a genebank, the seeds are initially cleaned and subsequently dried to less than 6% moisture content, and sealed in a jar or glass vials, or in an aluminum foil packet from which air has been removed by vacuuming.

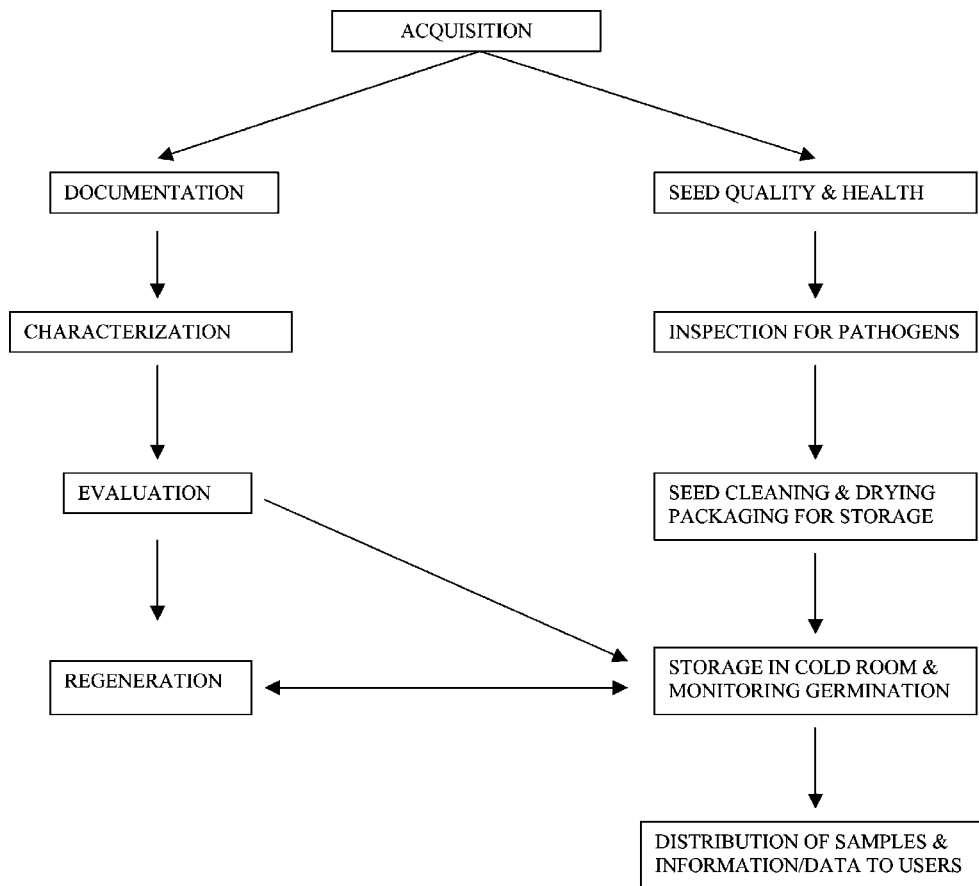

Fig. 1 Sequence of events in an active genebank.

Under what is called medium-term storage, the seeds are maintained at about 5°C and can remain viable anywhere from 10 to 30 years. In some cases, when samples are often requested by breeders or other scientists, the seed material may not be kept in hermetically sealed containers, and hence humidity control is needed. However, for long-term storage, which may extend up to a 100 years, they are kept at -18°C in air tight containers (e.g., sealed tins, glass ampoules, aluminum foil pouches, etc.). In this case, humidity is not controlled because the samples are hermetically sealed. For a list of procedures for handling seeds in a genebank see Refs.^[3,4,7]

Finally, a wide range of plants and particularly tropical trees produce seeds that are in various ways “recalcitrant.” They are so termed because they are very difficult to germinate and do not maintain viability like orthodox seeds under low humidity and below freezing temperatures. This is largely due to their thick seed coats. Hence, seeds from recalcitrant species require more elaborate methods of preservation, most often by maintaining living plants that must be tailored individually to their requirements. The principal characteristic difference between orthodox

and recalcitrant seeds lies in the physiology of their response to desiccation.^[1] Hanson^[7] prefers to use the more accurate terms “desiccation-tolerant” for orthodox seeds and “desiccation-sensitive” for recalcitrant seeds.

SEED HEALTH

Seed material acquired through collection in the fields or through donation from other genebanks may be infected with pathogenic organisms, and care must be taken that these pathogens do not cause problems in the country where the receiving genebank is located.^[8] Subsequently, the samples are tested for seed or plant health by germinating the seeds and observing the plants for diseases before being put in to long-term storage. If there are risks of introducing a disease, the genebank may be required to generate the seed in quarantine^[12]. In some countries, seed treatment by sterilizing in hot water or an antiseptic is done before the seeds can be entered into a genebank.

INFORMATION MANAGEMENT

Genetic resources are as useful as the amount and quality of the data related to them. Information on each accession in a genebank is maintained in computerized databases. These databases are queried to recover passport, descriptor, and evaluation data rapidly to make selections. Practically, all database systems in use are relational databases. Earlier, there were hierarchical databases and network databases, but nowadays we have mostly relational databases and a few object databases. Different types of relational database management systems (DBMS): Oracle, dBASE, FoxPro, Access, etc. are available. Genebank managers use different DBMS to implement desired applications. There is no common "application" for genetic resources databases. For example, the USDA Germplasm Resources Information Network (GRIN) is based on Oracle software, whereas ICARDA uses a system based on Visual FoxPro software. Also on Microsoft SQL server, many smaller national germplasm documentation systems are based on Access. This is not necessarily a problem since transfer of data from one DBMS to another is possible. The System-Wide Information Network for Genetic Resources (SINGER) system is a database periodically "populated" from various germplasm database systems used in different CGIAR Centers for the purpose of joint web publishing. In Europe, there are quite a number of diverse systems in use. All this makes the job of the documentation specialist at any genebank very difficult, especially when evaluation information needs to be exchanged.

There are practically little or no difficulties in sending so-called passport information with a set of requested or exchange samples. The passport data contain a few simple descriptors such as crop number; genebank number; Latin name (botanical name); country of origin; province; site (of collection), latitude, longitude, and altitude of collection; plus identifiers (local name of variety or landrace); accession number(s) of other genebank(s) if the sample was received as a donation from another genebank (Jan Konopka, pers. comm.). Three distinct points must be noted here: 1) adequate information must be acquired and easily accessible; 2) this database of information should be developed or processed for optimal use by breeders and other users; and 3) any decision making regarding the ex situ conservation in genebanks incorporates or takes into consideration this information.

Seed Production

Murray J. Hill

New Zealand Seed Technology Institute, Lincoln University, Canterbury, New Zealand

INTRODUCTION

In nature, seeds overcome three major problems for the plant. First, they are the method of multiplication, because a plant is often able to produce very large numbers of seeds. Second, seeds are a survival mechanism for plants because they often survive in the soil, even under adverse conditions, persisting until suitable germination conditions occur. Third, seeds help to disperse plants using agencies such as wind, water, or contact with animals or birds.

In agriculture, the aim of seed production is to multiply seed numbers by establishing a seed crop with sufficient plant density to produce seed to sow new plantings in the following season.

VEGETATIVE AND REPRODUCTIVE DEVELOPMENT

Plants are reproduced in two main ways for use in agriculture. Some are reproduced vegetatively (e.g., potatoes, cassava), although most produce seed by sexual reproduction (e.g., self-fertilization or cross-fertilization). A few crop species reproduce by apomixis, which is asexual but produces seedlike bodies that behave in all respects like normal seed (i.e., reproduction without fertilization)^[1] (Fig. 1).

Before seeds can be produced the plant must have the chance to flower. Some plants pass through the vegetative stage to the reproductive phase with no special requirement or stimulus. In other plants, there is a clearly defined transition between the two phases. The early stage (before the plant is receptive to an external flowering stimulus) is the juvenile phase. Attainment of the required physiological phase (“puberty”) is related to plant size (to leaf numbers in particular). At this stage, plants are often stimulated to become reproductive by day length (photoperiod) and/or by exposure to low temperature (vernalization). As a result, there are plants with no required climate stimulus (most annuals) and those that require precise things to happen in terms of low temperature (most perennials) and day length (long-day, short-day, or day-neutral plants).^[2] The timing and prediction of flowering in a range of crops is well discussed elsewhere.^[2]

Flower morphology, pollen formation and pollination, and fertilization are well described in field crops by Copeland and McDonald^[3] and in vegetable seed production by George.^[4] A schematic summary of the seed production sequence is shown in Fig. 2.

SEED DEVELOPMENT

In seed crops the sequence of seed development occurs in three stages.^[5]

- A growth stage, lasting about 10 days after pollination and characterized by rapid increase in cell division (but not elongation) in cell division, high moisture content, and nonviability (Fig. 3A).
- A food reserve accumulation stage, lasting 10–14 days and involving a great increase in seed dry weight that reaches a maximum at the end of the stage (Fig. 3B). The amount of water in seed changes little but the percentage water content falls rapidly. Seed becomes viable during this stage, which ends with seed becoming physiologically mature.
- A ripening stage, lasting 3–14 days, depending on climate. Seed dehydrates to a moisture content in equilibrium with the environment, resulting in seed that has reached harvest maturity.

SITE SELECTION AND CROP MANAGEMENT

Choice of a seed production site is a basic consideration. It is important because different areas vary in their suitability for seed production. The main requirements are to grow seed crops in areas that have a sufficiently long growing season and suitable day length and temperature to promote strong vegetative growth; strong stimulation of seed head development and flowering; and good climatic conditions during seed development, ripening, and harvesting.

In forage crops, plant breeders have been very successful in producing varieties that grow large amounts of herbage. This is done in many cases by breeding plants that remain vegetative (leaf producing) as long as possible before becoming reproductive (i.e., seed producing).

Fig. 1 Apical meristems of ryegrass and white clover. (A) Vegetative growing point of perennial ryegrass (*Lolium perenne* L.) showing leaf primordia ($\times 115$). (B) Reproductive growing point of perennial ryegrass (*Lolium perenne* L.) showing spikelet and floret initiation ($\times 75$). (C) Vegetative apical bud of white clover (*Trifolium repens* L.) showing expanding leaf initials and central dome ($\times 400$).

The objective in specialist seed production systems is to grow large plants, producing flowers and then seeds at as many of the available sites as possible.

Growers who produce seed crops with high yield and quality tend to be those who manage their seed crops to force plants to become more strongly reproductive.^[6] Seed management packages are recommended that involve judicious, well timed use of fertilizer (e.g., P and K in legumes and N in grasses); controlled use of water; cutting or grazing to encourage plant branching and provide more places on the plant for flower formation;

adjustment of sowing date and rate to take advantage of differences in climate (temperature and day length); specialist herbicides to remove specific weeds; and plant growth regulating chemicals.

CROP ROTATION AND PADDOCK HISTORY

Time intervals between related or similar crops are standard agronomic practice. The many reasons for crop

Schematic summary of seed production sequence.

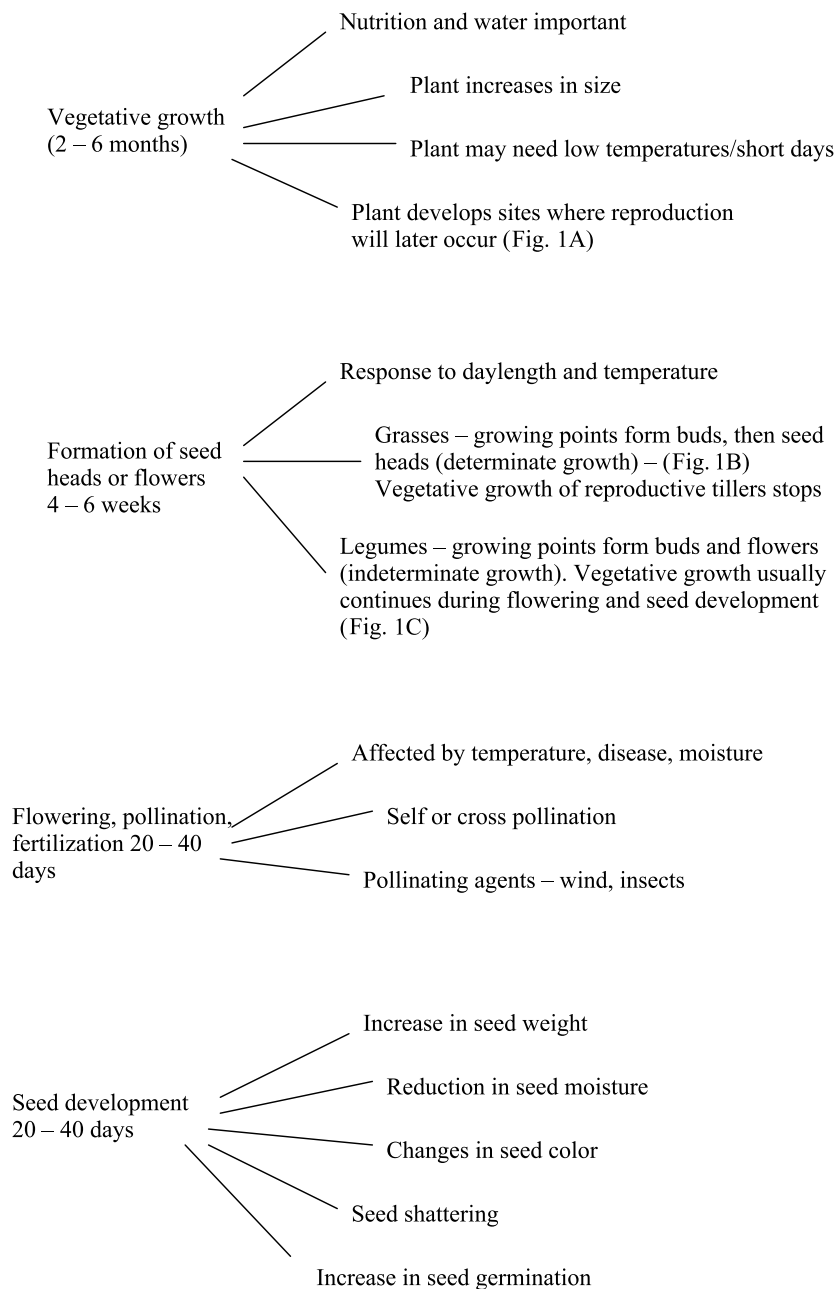

Fig. 2 Schematic summary of seed production sequence.

rotation include plant nutrition; maintenance of soil condition; reduction of disease, pest, and weed seed carryover; and, particularly in the case of seed production, to minimize the risk of plant residues and dormant crop and weed seeds remaining in the soil from previous potentially contaminating crops. Information on previous cropping history is an important consideration in seed production.

Maintaining the genetic purity of the seed crop is also important. This is usually achieved by crop growth regulation and good planning. The major factor is to minimize the possibility of cross-pollination between different crossing-compatible crops. This is done by ensuring that crops likely to cross-pollinate are not flowering at the same time or are planted an acceptably safe distance apart to prevent pollen crossover.

Fig. 3 Seeds of perennial ryegrass (*Lolium perenne*) during the growth stage (A) and food reserve accumulation stage (B) of seed development.

Seed fields, whether they involve an autumn- or spring-sown crop, may be established in rows or in solid stands. The former has the advantage of requiring lower seed sowing and fertilizer rates, and often ensures cleaner weed-free crops and longer stand productivity. Seeding rates lower than those for general crop production are often advocated when crops are sown for specialized seed production. Small seeded grasses such as bentgrass are often sown at 0.25 kg/ha, whereas larger cereals may be sown at 80–100 kg/ha.

PLANT POPULATION

In many seed crops the successful establishment of an adequate or optimum plant density is directly related to high seed yields. With increasing population, the yield of seed per hectare increases to a maximum point or plateau before declining. This parabolic relationship suggests that in seed production, the sowing rate should be sufficient to establish a crop that will produce a seed yield maximum.^[6]

Row spacing depends on plant growth habit and the lateral spread of the root system. Taller plants are often grown in wider rows than are shorter plants.

WEEDS

Weeds are objectionable in all crops because they compete for soil, water, and nutrients; smother the crop and cut out light; may delay harvesting; may impede cultivation and harvesting; and may be plant parasites (e.g., dodder (*Cuscuta* sp)) or hosts for pests and diseases. Their seed may ripen at the same time as the crop and be difficult to remove in seed cleaning (e.g., wild red rice in rice; wild oats in cereals).

Weed control measures include crop rotation, sowing into a clean seedbed, application of presowing or pre-emergence herbicides, inter-row cultivation, roguing, and sowing clean seed.

PESTS AND DISEASES

The incidence of diseases and pests in a seed crop is affected by climate, their presence in the soil or in the sown seed, and by the presence of alternate hosts growing nearby or in the field. Such control measures as crop rotation, burial of plant debris, seed treatment, foliar sprays (noting risks to pollinating insects if using insecticides), isolation, roguing, and postharvest hygiene all deserve consideration.

MOISTURE

Moisture stress can reduce seed yield. On the other hand, irrigation can ensure good establishment and vigorous vegetative growth, and ensure that the plant is not stressed for moisture during seed development. Despite this, the induction of some moisture stress immediately flower buds form can be helpful in reducing the protracted flowering period in indeterminate plants (e.g., in legumes such as white clover (*Trifolium repens*)).

HYBRID SEED PRODUCTION

The discovery of hybrid vigor in field crops such as maize in the early 1900s has probably contributed as much to seed production as any other single factor.^[1] A hybrid is produced by crossing inbred lines that have been developed by inbreeding and selection. This results in hybrid seed progeny with greater yield than nonhybrid crops. This occurs due to heterosis or hybrid vigor, due to an accumulation of a large number of dominant factors (genes) that favour growth. Hybrid seed production is now common in many field crops (particularly cereals) and in the production of vegetable seeds.^[4]

CONCLUSION

Perhaps the most surprising thing about many of the crops grown for seed is the low yields obtained, compared to the potential yield these crops could produce if all components were maximized.^[6]

As an example, the theoretical potential seed yield for alfalfa (*Medicago sativa* L.) is about 12 tonnes/ha and for Trefoil (*Lotus corniculatus* L.) about 2500 kg/ha. These can be compared with mean actual seed yields in New Zealand of 670 kg/ha (6% of potential) and 540 kg/ha (22% of potential).

This suggests many farmers still have a long way to go before realizing the production potential of the crops they grow for seed.

Seed Testing Methods

Daniel G. Curry

Iowa State University, Ames, Iowa, U.S.A.

INTRODUCTION

A similar group of seed that is stored together, is uniform in genetics, and has a similar production history is known as a seed lot. Each seed lot has a certain amount of value, depending on the amount of seed in the lot and its quality characteristics. Most of these characteristics cannot be determined by visual inspection. Therefore it must be tested using various procedures to determine the quality of the seed and, ultimately, its value. Seed companies rely on these tests to ensure they are selling seed that meets not only the government's minimum standards but also their higher standards of quality. Customers rely on these tests to determine if the seed is of good value.

SEED REGULATIONS

To ensure fair trade, most countries require that specific seed tests be performed and documented. For example, in the United States, the seed laws direct seed companies to label their seed when it is sold, communicating to the buyer pertinent information concerning its quality (Fig. 1).

Most seed laws require that only a minimum number of tests be performed and the results be reported on the label. However, many seed companies need additional information on quality characteristics that are beyond the minimum requirements to ensure customer satisfaction and loyalty. For example, vigor tests cause stress on the seed, and the results may indicate how well the seed lot will perform under environmental stress. This information is important to companies whose customers plant in cold or wet environments.

WHO TESTS SEEDS

Seed tests are performed by analysts at university, provincial, state, and federal government laboratories as well as technologists at commercial and private laboratories. Seed testing personnel analyze seed according to established rules that are based on past experience and scientific research. These rules are recorded and updated periodically by various organizations.^[1]

SAMPLING

It would be impractical to sample every seed in a lot, because frequently the seed is unusable afterward, and testing large amounts of seed would not be timely or economical. Therefore a sample of the lot is taken and submitted for testing. If the sampling technique is sound, the sample will represent the entire lot. The number of seeds tested depends on which test is being performed (Table 1).

TYPES OF SEED TESTS

Important quality characteristics of seed include germination (does it grow?), physical purity (what else but pure seed is in the lot?), seed health (are there pathogens in or on the seed?), varietal purity (is there more than one variety in the lot?), and genetic purity [does the seed contain genetically modified organisms (GMOs)?].

In seed laboratory practice, germination is defined as the emergence and development from the seed embryo of those essential structures which, for the kind of seed in question, are indicative of the ability to produce a normal plant under favorable conditions.^[2] While many factors affect germination, the most important are proper moisture, temperature, and sufficient oxygen^[3] (Fig. 2).

Documents that contain scientifically based methods of seed testing instruct analysts how to control factors that would induce the maximum germination. Seed is planted into a specified media, with proper moisture added, and placed in a germination chamber at the proper temperature for a specified number of days. Germination of most seeds takes from 7 to 28 days. At the end of this period, the seedlings are categorized as normal or abnormal, and the ungerminated seeds are categorized into dormant, hard, or dead seed. This information will be reported to the seed company. The germination result is given as a percentage (the average number of seedlings considered normal out of the entire number of seeds planted) and is valid for a period of months.

The purity test is performed by physically separating the pure seed from other crop seed, weed seed, and inert material. A magnifying lens or a microscope often is used to help the analyst view all components of the sample.

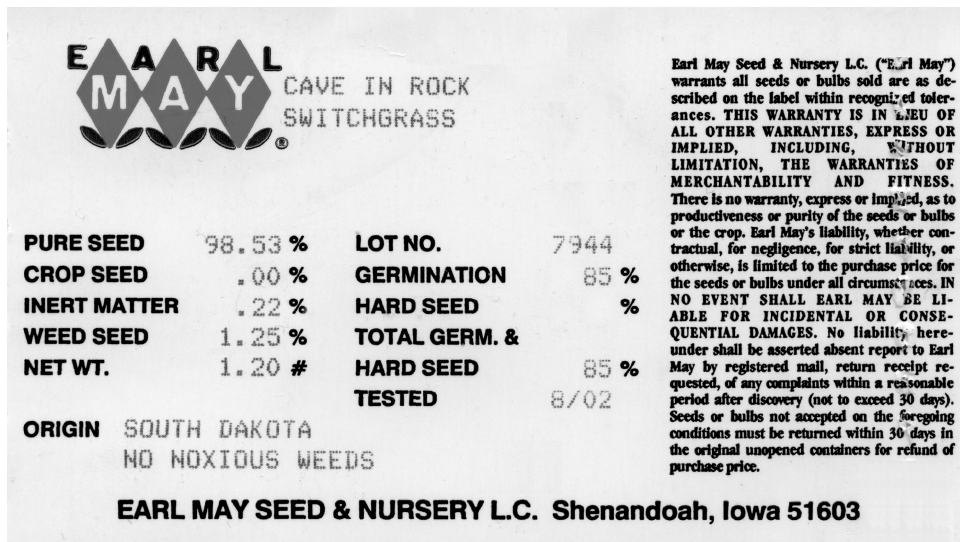

Fig. 1 Typical seed label. (View this art in color at www.dekker.com.)

Table 1 Seed tests and amount of seed tested

Type of seed test	Name of test	Amount of seed tested*
Required by law	Germination	400 seeds
	Purity	2500 seeds
	Noxious	25000 seeds
Vigor	Cold	200 seeds
	Accelerated aging	200 seeds
	Saturated cold	200 seeds
	Extended cold	200 seeds
	Cotton cool	200 seeds
Viability	Tetrazolium test	200 seeds
Miscellaneous tests	Moisture	250 g
	Test weight	250 g
	Protein, oil, starch	500 g
	Seed count	400 seeds
	Fast green	200 seeds
	Variety identification	Visual inspection
Hilum color		500 seeds
Hypocotyl color		400 seeds
Waxy corn purity		400 seeds
Peroxidase		100 seeds
Electrophoresis		100 seeds
PCR		4800 seeds
Phenol staining		200 seeds
Fluorescence		400 seeds
Health tests		Plate tests
	Blotter tests	400 seeds
	Wash test	400 seeds
	Soak test	400 seeds
	Virus test	400 seeds
	Grow-out test	400 seeds
	Trait test	Herbicide bioassay
Bt test		90 seeds
PCR test		3000 seeds

Compliments of the Iowa State Seed Testing Laboratory.

*The amount of seed tested varies, depending on the species of seed.

With forceps in hand, the analyst "works" the sample (about 2500 seeds) by dragging a few seeds away from the sample and separating the material into the four components. The weight of each component is recorded in the final report, and the percentage of each component will be on the label when the seed is sold.

With the noxious weed exam, the amount of seed tested is usually 10 times the purity weight. A noxious exam is similar to the purity test, except only noxious weeds are removed. The weed seeds to be extracted are determined either by local or federal governments. The number of noxious seeds found in the working sample will be reported to the seed company.

There are many other types of seed tests that provide information about some aspect of the seed that is important to the owner. Viability tests are used to determine whether the seed is alive. Even under ideal conditions, some live seed may not germinate because of dormancy or seed hardness. A viability test, such as staining seed with tetrazolium salts, allows the analyst to separate the live seed from the dead. This test is useful when seed is experiencing dormancy. Although the seed may not germinate during the testing process because of dormancy or seed hardness, the tetrazolium test will indicate its viability.

Vigor tests determine how well a seed lot will perform under stressful environmental conditions. High and low temperature extremes or low-oxygen/high-moisture extremes are used to stress the seed. Final germination results from vigor tests usually correlate with extreme field conditions.

Seed germination performance can be affected by certain pathogens such as fungi, bacteria, viruses, and nematodes. Seed health tests are usually performed for one of two reasons: 1) The seed company wants to ensure

Fig. 2 A seed corn germination sample of 400 seedlings. (View this art in color at www.dekker.com.)

that a particular pathogen is not present so it will not affect the customer's growing crop; or 2) the company wants to ship seed to another country. When shipping to another country, a certificate must be issued by the governmental phytosanitary offices of each exporting country. The certificate requires a declaration that states the seed is free of the importing country's list of banned pathogens. For example, Mexico will not allow corn seed into the country unless that lot of seed has been determined to be free of bacteria known as Stewart's wilt (*Erwinia stewartii*). Argentina will not allow imported corn seed into the country unless the seed is free of wheat streak mosaic (WSMV). More than 150 different tests can be performed to determine the presence of various pathogens in seed lots.

Three different methods are used to test genetic traits. For the first, a bioassay, detection is based on symptoms of the plants that are tested. Seeds or seedlings are made to absorb a chemical herbicide for a period of time. The seedlings are then evaluated for symptoms of the plant's reaction. If the seedlings do not react to the herbicide, no symptoms appear and the seedling is thought to have the herbicide-resistant trait. If the seedlings are not tolerant to the herbicide, they will show symptoms, such as restricted growth. A minimum of 400 seeds are usually tested, and a percentage of the amount of seed that is tolerant or nontolerant is reported.

A second test for genetic traits uses the enzyme-linked immunosorbent assay (ELISA) method, which is based on detection of specific proteins. Two application methods use the ELISA technology. The first uses a plastic plate with 96 wells that contain an antigen for the target protein. Tiny liquid samples from the seed or plant tissue are placed in the wells. If the target protein is present, the wells change color. If not, the solution washes out and there is no color change. This method works well in a lab environment, as it requires the use of a computer-controlled plate reader, a sterile environment, and lab equipment such as a multi-channel pipette.

The other ELISA method uses a lateral flow absorbent strip. When this strip is placed in a solution of plant material and water, it will detect whether a protein from a particular genetic trait is present in the sample. This system works well in nonlaboratory settings such as crop fields, farm elevators, and other points of commerce

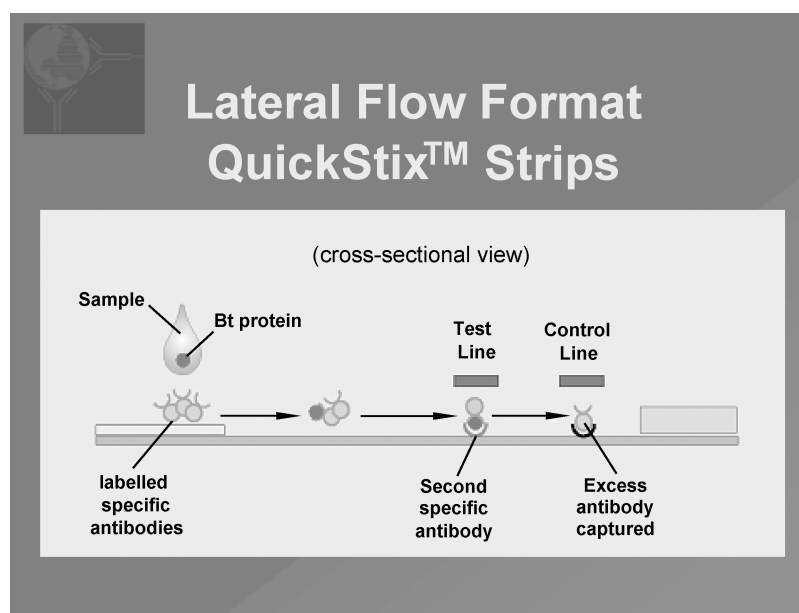

Fig. 3 Diagram of a lateral flow strip, courtesy of EnviroLogix. (View this art in color at www.dekker.com.)

where a quick, low-cost determination of GMO presence is needed (Fig. 3).

A third technique of detecting genetic traits is called the polymerase chain reaction (PCR) method. It amplifies a target sequence of genes that is present in the seed or seedling. If the sample contains a genetically modified gene, thousands of copies of the gene will be made, thereby allowing the analyst to detect the gene.

Variety tests are performed on seeds to ensure that the genetic integrity of the seed lot is secure. Plant breeders work to improve existing varieties of plants. The breeder starts with a small number of plants that have been genetically changed in some way. As each generation of plants is grown and the seed is produced, steps are taken to preserve the identity of the seed lot. Otherwise, seed tends to be commingled or contaminated by pollen from other seed lots. An example of a variety test is a hilum (point of attachment on the seed coat of a soybean seed) color test for soybeans. Five hundred seeds are compared with parent seed to ensure that the color of the hilum is similar in all of the seed.

CONCLUSION

As seed continues to be assessed for its quality characteristics, seed testing will remain an important part of agriculture. Germination, purity, noxious, and other similar tests will change little over the coming years. Genetic seed

testing will continue to evolve, however, as new traits of plants are produced by the biotechnology industry.

Seed Vigor

Alison A. Powell

University of Aberdeen, Aberdeen, U.K.

INTRODUCTION

The concept of seed vigor arose following observations that, despite having equally high laboratory germination, commercial seed lots of many species show large differences in field emergence, particularly in adverse field conditions. Failure of the germination test to predict differences in field emergence suggested that there is a further physiological aspect to seed quality, not revealed by laboratory germination. This is referred to as seed vigor. Seed lots having high germination but poor emergence are low-vigor seeds; those giving good emergence are high-vigor seeds. Differences in germination rate and storage potential are also indicative of vigor and are included in the definition of vigor accepted by the International Seed Testing Association (ISTA). Seed aging and imbibition damage influence vigor and can be reduced by careful storage and handling of seeds. An understanding of the causes of vigor differences can help to maintain high levels of seed vigor.

DEFINITION OF VIGOR

In 2001 the ISTA formally recognized seed vigor as an important aspect of seed quality when it added vigor as a chapter in the International Rules for Seed Testing.^[1] The ISTA definition of seed vigor is as follows:

“Seed vigor is a sum of those properties that determine the activity and level of performance of seed lots of acceptable germination in a wide range of environments.

Seed vigor is not a single measurable property, but is a concept describing several characteristics associated with the following aspects of seed lot performance.

- i. Rate and uniformity of seed germination and seedling growth
- ii. Emergence ability of seeds under unfavorable environmental conditions
- iii. Performance after storage, particularly the retention of the ability to germinate

A vigorous seed lot is one that is potentially able to perform well even under environmental conditions that are not optimal for the species.’’

The germination of low-vigor seeds is therefore asynchronous and slow and the seeds emerge poorly in unfavorable conditions, in contrast to the rapid uniform germination and good emergence of high-vigor seeds. Low-vigor seeds also have poor storage potential.

CAUSES OF DIFFERENCES IN SEED VIGOR

Aging

Seed deterioration, or aging, is the major cause of differences in seed vigor and can be described as the accumulation of deleterious changes within the seed until the ability to germinate is lost.^[2] The aging of a seed lot is described by the seed survival curve (Fig. 1). This illustrates that the germination of a population of seeds initially shows a very slow decline with time during which it is difficult to differentiate between the standard laboratory germination of samples of seeds at different points on the survival curve. However, as the population moves along the survival curve, the seeds are aging, i.e., deleterious changes are accumulating, until, at the end of the slow decline, the proportion of seeds within the population that are incapable of germinating increases and germination falls. At the beginning of the initial slow decline in germination, seeds are described as physiologically young or high-vigor seeds, whereas at the end of this phase they are physiologically old or low-vigor seeds.

Aging may occur before harvest, both during and after postmaturation drying. The degree of preharvest deterioration, frequently described as “weathering,” depends on the climatic factors temperature and moisture (humidity/rainfall). Most deterioration occurs after the seeds have dried down to harvest maturity as a result of delayed harvesting.

The greatest incidence of aging arises, however, during seed storage, commonly in commercial storage, but also during brief, temporary periods of storage—for example, after harvesting and before and during processing. The major factors that influence seed aging and hence a decline in vigor and subsequently germination are seed moisture content and temperature. Their effects are described in Harrington’s Rules of Thumb,^[3] which

Fig. 1. The seed survival curve.

state that a 1% increase in seed moisture content or a 5°C increase in storage temperature will double the rate of aging, i.e., halve the storage life. These relationships are described more accurately in the viability equation^[4] used to predict long-term storage of seeds in gene banks.

Imbibition Damage

Imbibition damage is a major cause of low vigor in grain legumes and arises when water rapidly enters the cotyledons during imbibition leading to physical disruption of membranes, cell death, and high solute leakage from the seeds, particularly at low temperatures.^[2] Imbibition damage highlights the role of the testa in protecting the cotyledons from the damaging effect of water uptake.^[2] In some species, an intact testa limits the incidence of imbibition damage. High-vigor seed lots have little testa damage, imbibe slowly, show little imbibition damage, and emerge well. Extensive testa damage is associated with rapid water uptake and low vigor.

In other grain legume species (e.g., *Phaseolus* sp., *Cicer ciceris*, *Vigna sesquipedalis*, *Vigna unguicularis*), there is a genotypic component to the susceptibility of seeds to imbibition damage. Cultivars having partially or completely unpigmented testae imbibe more rapidly and show greater levels of imbibition damage compared with cultivars having pigmented testae. As a result, the vigor of unpigmented cultivars is reduced, leading to poorer field emergence than is found in pigmented cultivars.^[2]

Interaction of Imbibition Damage and Aging

The two major causes of reduced vigor in grain legumes—aging and imbibition damage—also interact, aged seeds being more susceptible to imbibition damage.^[5,6] It has been proposed that the increased susceptibility of aged seeds to imbibition damage arises because membranes that have been weakened by physiological deterioration are more sensitive to physical damage during imbibition.^[5,6]

ASSESSMENT OF SEED VIGOR

A range of tests evaluate seed vigor, the theoretical basis of which lies in seed aging. Vigor tests can be divided into three categories: physiological tests, biochemical tests, and tests that apply the whole aging process.

Physiological tests divide into two groups. In the first group, there are those tests that measure the impact of aging on an aspect of germination and early seedling growth. These are essentially a modification of the germination test and reveal the reduced rate and uniformity of germination that is found in aged seeds. Vigor can be assessed as the rate of germination based on the first count from the standard germination test. The slower germination of aged seeds also leads to smaller seedlings, when seedling size is assessed at a particular point in time, as in the seedling growth test. In the second group of tests, such as the cold test for maize and the cool germination test for cotton, stresses that reflect the type of stress that may be encountered in the field are applied to the seed. Low-vigor seeds are revealed by the reduced tolerance of aged seeds to stress.

The second category of vigor tests includes biochemical tests. The Conductivity test uses the increase in solute leakage that occurs from aged seeds to identify seed lots of low vigor. This test is an ISTA-validated test for garden peas^[1] and can also be applied to a wide range of grain legumes.^[7] The Tetrazolium test indicates the decline in respiratory enzyme activity during aging through the reaction of a colorless solution of 2,3,5-triphenyl tetrazolium chloride with dehydrogenases to produce the red substance, formazan, in living cells.^[7] Dead cells do not stain.

The third group of vigor tests evaluates the effect of a period of aging on germination and is based on the manipulation of the rate of seed aging by holding seeds at a raised temperature and high relative humidity (Accelerated Aging test) or moisture content (Controlled Deterioration test). Seeds age rapidly and reductions in germination, normally seen over months or years, occur within days or hours. Both tests predict the field emergence and storage potential of seeds. The Accelerated Aging (AA) test is ISTA-validated for soybean,^[1] while

Controlled Deterioration^[8] tests the vigor of small seeded vegetable species and is an ISTA suggested test.^[7]

MAINTENANCE OF VIGOR AND VIABILITY

Seed moisture content influences the rate of seed aging more than the temperature of storage;^[4] therefore, efficient drying of the seed at or after harvest is important to reduce the rate of aging during subsequent storage and prevent a decline in vigor. However, dry seeds have a low water potential and hence high matric potential and readily absorb moisture from the air.^[9] Thus, control of the relative humidity of the store is important to maintain low seed moisture content and reduce aging. Alternatively high-cost, low-volume seed may be stored in sealed moisture-proof containers.

Low-vigor seeds show earlier and greater reductions in germination during storage than high-vigor seeds in all storage conditions. Application of the Accelerated Aging or Controlled Deterioration test before storage enables seed producers to identify these low-vigor seed lots with poor storage potential.

Minimizing the incidence of testa damage during harvest and processing can maintain seed vigor by reducing the incidence of imbibition damage. Testa damage is greater when seeds are harvested at low seed moisture content. Modification of harvest timing and handling procedures can reduce testa damage and help maintain seed vigor.

CONCLUSION

Seed vigor has a major effect on successful emergence and crop establishment. Careful harvest and processing of seed offers one approach to maintaining seed vigor. In addition, application of vigor tests during production can identify where any reduction in seed quality has occurred during the production process, whether this is when the seed is still on the plant (weathering), during harvest and

processing, or during storage. Thus, guidelines could be developed to minimize any reduction in vigor in subsequent years. In addition, companies may use vigor results in their in-house quality control. This could involve preventing the sale of particularly low-vigor seed or providing guidance regarding the storage potential of seed lots.

Seeds: Pathogen Transmission Through

Curgonio Cappelli

Dipartimento di Arboricoltura e Protezione delle Piante, Perugia, Italy

INTRODUCTION

Pathogen transmission through seeds occurs when pathogenic microorganisms spread from seeds to seedlings. A developing infected plant can show symptoms within a few days or develop asymptotically for a variable period of time. In some rare cases, pathogens present in infected plants survive, spreading from seeds to plants and from plants to seeds without causing any external symptom and inoculum production (i.e., *Neotyphodium*, grasses).

Most seed-transmitted pathogens (virus, bacteria, and fungi) in favorable conditions can cause very serious yield losses. For example, *Drechslera maydis* race T (southern leaf blight of corn) in the United States (1970) caused losses of about one billion dollars.

In plant pathology, seed transmission represents a possible mode of primary infection from which dangerous polycyclic microorganisms can start epidemic attacks. The early presence of a small quantity of infected plants (i.e., 0.05% of a crop) is sometimes sufficient for the development of destructive attacks (i.e., viral and bacterial diseases of legumes and vegetables). In some host-pathogen combinations seed transmission occurs every year because seeds represent the only possibility for the organism to survive (i.e., loose smut of wheat). In others this phenomenon occurs sporadically, because pathogens normally survive with other modalities (i.e., soil, other hosts, volunteers and wild plants, etc.). The different types of seed transmission are summarized using different criteria. Some of these diseases (i.e., ergot, bunt, and smut of cereals) were studied some centuries ago by plant pathology pioneers. With the increasing importance of seed pathology and the application of improved methodologies for microorganism detection in seed lots, more diseases were found to be seed transmitted.

MECHANISMS OF PATHOGEN TRANSMISSION AND REPRESENTATIVE EXAMPLES OF IMPORTANT DISEASES

Nine mechanisms of seed pathogen transmission are reported in Table 1.^[1] The first six are determined according to the three possible inoculum locations in the seed

(intraembrial, extraembryal, and contamination) and the two types of plant infection (local and systemic). The other three are represented by seed contamination with a particular nonparasitic stage of the pathogen in the soil before causing local, systemic, or organospecific infection of the plant.

1. Intraembrial infection causing systemic infection of plants. *Ustilago nuda*, barley (loose smut). When the seed germinates, the fungal mycelium located inside the embryo (mainly in the scutellum) moves to the growing point and then to the young tillers. The mycelium is carried up the plant with its elongation. The first symptoms of the disease appear during spike differentiation, when the teliospores of the fungus replace the seed and are released for the infections of healthy spikes. Embryo infection followed by systemic infection has been observed to be caused by other fungi (*Plasmopara helianthi*, sunflower, Fig. 1), viruses (i.e., Bean common mosaic virus, bean, Soybean mosaic virus, soybean), and bacteria [(i.e., *Xanthomonas axonopodis* pv. *phaseoli*, bean (Fig. 2), *Xanthomonas campestris* pv. *vesicatoria*, pepper (Fig. 3)].
2. Intraembrial infection causing local infection of plants. *Ascochyta pisi*, pea (anthracnose). The mycelium, localized in the embryo, causes lesions on the first true leaves where pycnidia develop under suitable humidity conditions. The spread of conidia by the wind causes the secondary infection of healthy plants.
3. Extraembrial infection causing systemic infection of plants. *Ustilago avenae*, oat (black loose smut). The mycelium, present in the pericarp, develops in the young seedling, causing systemic infection of the plant. During the flowering period, the behavior of the fungus is similar to *U. nuda* (see first mechanism). In *Xanthomonas arboricola* pv. *malvacearum*, cotton, the bacterium, localized mainly in the seed coat, causes systemic infections and the first symptoms on the cotyledons (Fig. 4).
4. Extraembrial infection causing local infection of plants. *Septoria apiicola*, celery (late blight). The pycnidia present in seed coat and pericarp produce conidia that spread to cotyledons and young leaves where local dark lesions may appear after about 10

Table 1 Principal mechanisms of pathogens' seed transmission

Inoculum location	Infection of plant	Example
1—Intraembrial infection	Systemic infection	<i>Ustilago nuda</i> —barley
2—Intraembrial infection	Local infection	<i>Ascochyta pisi</i> —pea
3—Extraembrial infection	Systemic infection	<i>Ustilago avenae</i> —oat
4—Extraembrial infection	Local infection	<i>Septoria apiicola</i> —celery
5—Seed contamination	Systemic infection	<i>Tilletia caries</i> —wheat
6—Seed contamination	Local infection	<i>Puccinia carthami</i> —safflower
7—Seed contamination followed by a period of saprophytism or a dormant stage in the soil	Local infection	<i>Sclerotinia sclerotiorum</i> —sunflower
8—Seed contamination followed by a period of saprophytism in the soil	Systemic infection	<i>Fusarium oxysporum</i> f.sp. <i>callistephi</i> —aster
9—Seed contamination by particular structures of infection of the pathogen followed by nonparasitic phase	Organospecific infection	<i>Claviceps purpurea</i> —cereals

days. In favorable conditions, the fungus may produce new pycnidia for the prosecution of its life cycle. A similar mechanism has been recently observed on *Alternaria linicola*, linseed (Fig. 5) and on *Stemphylium herbarum*, red cichory (Fig. 6).

- Seed contamination causing systemic infection of plants. *Tilletia caries*, wheat (common bunt). Teliospores of *Tilletia caries* are localized on the surface of healthy wheat seeds, where they overwinter. At the time of grain germination, teliospores germinate, producing a dikaryotic hypha that penetrates into the cells of the emerging coleoptiles, reaching the base of the first and second leaves and then the area below the growing

point. The infection cycle proceeds asymptotically, until the production of an ear with kernels that contain the teliospores.

- Seed contamination causing local infection of plants. *Puccinia carthami*, safflower (rust). Safflower rust is

Fig. 1 Sunflower plants showing typical symptoms of downy mildew (stunt and chlorosis) caused by *Plasmopara helianthi* introduced into the soil by infected seeds of the previous sunflower crop. (Photos courtesy of L. Tosi and A. Zizzerini.) (View this art in color at www.dekker.com.)

Fig. 2 Foliar symptoms caused by seedborne inoculum of *Xanthomonas axonopodis* pv. *phaseoli* in bean plants. (Photos courtesy of R. Buonauro.) (View this art in color at www.dekker.com.)

Fig. 3 Pepper cotyledons showing symptoms caused by *Xanthomonas campestris* pv. *vesicatoria*. (Photos courtesy of R. Buonauro.) (View this art in color at www.dekker.com.)

a rare seedborne rust disease transmitted directly from seed to seedling. Teliospores that contaminate the surface of seeds are responsible for the infection of seedling tissues, causing hypertrophy and hyperplasia of hypocotyls (Fig. 7). The inoculum produced above ground spreads to the leaves, where it causes the typical rust symptoms (pustules).

7. Seed contamination followed by a period of saprophytism or by a dormant stage in the soil and then by local infection. *Sclerotinia sclerotiorum*, sunflower (basal stalk rot and head rot). Sclerotia of the fungus, introduced into the soil by the seed, can produce hyphae that can either infect the developing host or generate apothecia, asci, and ascospores. The ascospores resealed in the environment are responsible for local infection of different part of the host, including the head.
8. Seed contamination followed by a period of saprophytism in the soil and then by systemic infection.

Fusarium oxysporum f.sp. *callistephi*, aster (wilt). Conidia and mycelium of the fungus, carried into the soil by the seed, grow saprophytically in the soil, increasing the inoculum level. In favorable conditions, the fungus attacks the roots of young seedlings and develops inside the plant, causing vascular wilt. In *Fusarium oxysporum* f.sp. *gladioli*, saffron (Fig. 8), the same mechanism has been observed.

9. Seed contamination by structures from organospecific seed infection followed by an extramatrix non-parasitic phase and later by direct organospecific seed infection. *Claviceps purpurea*, cereals (ergot). Sclerotia of the fungus, transported into the soil by the

seed, remain inactive until the spring when they produce several club-shaped perithecial stromata containing asci and ascospores. Ascospore dispersal occurs during the flowering period of the host when the ovary is susceptible to the fungus, prior to fertilization.

FACTORS AFFECTING THE TRANSMISSION OF SEEDBORNE PATHOGENS

The presence of pathogens in seed lots does not always involve microorganism transmission to the plant in the field and disease development. Research carried out in different host–pathogen combinations showed the importance of some parameters that influence the infection of young seedlings until the development of the first symptoms. A number of factors such as host, pathogen, environmental conditions, and crop management may affect the transmission rates of seedborne pathogens.^[2–5]

1. **Host Genotype.** The development of seedborne infection in the field depends on the genetic constitution of the host cultivar. In plant-resistant genotypes, the activation of defense mechanisms in germinating infected seeds can prevent disease transmission to the plant. Resistance of wheat to loose smut fungus occurs through the reaction of the embryos, which are completely resistant to infection. In other host–pathogen combinations, some cultivars

show less susceptibility than others because they require a major quantity of inoculum with respect to the susceptible cultivars (i.e., *Tilletia tritici*, wheat).

2. **Quantity of Inoculum.** The inoculum level can affect pathogen seed transmission because too little or too much inoculum can result in nontransmission of the disease. For example, in *Tilletia caries*, wheat, infections of seedlings in susceptible cultivars occur when the number of teliospores contaminating the seeds is more than 100 per seed. The quantity of inoculum associated with the seed depends on the different situations occurring during seed differentiation. For example, late flower infections may result in low superficial contamination of seeds only (i.e., *Septoria* spp.). On the other hand, early infections of flowers may cause severe infections of developing seeds, reducing seed vitality: Seeds fail to germinate and do not transmit the disease (e.g., poor quality of cereal seeds infected by *Fusarium* spp.). Between these two extreme situations, cultivar resistance, germination capacity of seeds, and environmental conditions at sowing time determine the amount of inoculum necessary for seed transmission.
3. **Inoculum Vitality.** Inoculum vitality depends on the longevity of the peculiar structures produced by the pathogens and on the characteristics of each seed lot (Table 2). Mycelia, sclerotia, chlamydospores, oospores, teliospores, virus particles, and bacterial cells that contaminate or infect seeds can maintain their vitality for some years (i.e., 5–10 or more). Often, vitality depends on the quantity of inoculum present in each seed lot and can be reduced by soil microflora (or other factors) when seeds are sown.

Fig. 8 Abnormal development of saffron shoots caused by *Fusarium oxysporum* f.sp. *gladioli*. (a) Young infected plants in the field. (b) Corms during germination. (Photos by C. Cappelli.) (View this art in color at www.dekker.com.)

Table 2 Examples of longevity of some important seedborne pathogens

Pathogen	Host	Viability (years)
Fungi		
<i>Alternaria brassicicola</i>	Cabbage	7
<i>Ascochyta pisi</i>	Pea	7
<i>Botrytis alli</i>	Onion	3.5
<i>Botrytis cinerea</i>	Linseed	3.3
<i>Diaporthe phaseolorum</i>	Soybean	2.5
<i>Drechslera avenae</i>	Oat	10
<i>Drechslera oryzae</i>	Rice	10
<i>Drechslera sorokiniana</i>	Wheat	10
<i>Phoma lingam</i>	Cabbage	1.1
<i>Septoria apiicola</i>	Celery	3
<i>Tilletia caries</i>	Wheat	9
<i>Ustilago nuda</i>	Barley	11
Bacteria

<i>Xanthomonas campestris</i> pv. <i>campestris</i>	Cabbage	3
<i>Xanthomonas arboricola</i> pv. <i>malvacearum</i>	Cotton	4.7
<i>Xanthomonas axonopodis</i> pv. <i>phaseoli</i>	Bean	15
<i>Pseudomonas syringae</i> pv. <i>tomato</i>	Tomato	20
<i>Xanthomonas axonopodis</i> pv. <i>vesicatoria</i>	Pepper	10
Viruses		
Alfalfa mosaic virus	Alfalfa	3
Barley stripe mosaic virus	Barley	3
Bean common mosaic virus	Bean	30
Cucumber mosaic virus	Cucumber	1
Soybean mosaic virus	Soybean	2

4. Type of Inoculum. Seed transmission can be influenced by the type of inoculum in seeds because not all the pathogenic structures present in the seed lots can infect the developing seedlings. Safflower seeds by contaminated uredospores of *P. carthami* produce healthy seedlings, whereas teliospores produce the typical symptoms of the disease.
5. Inoculum Location in the Seed. Often, seed transmission occurs only if the inoculum is located in a particular position of the seed. Most viruses, for example, are transmitted to the seedlings only if they are located in the embryo.
6. Soil Microflora. The microflora present in the soil can reduce the transfer of vital inoculum from seeds to seedlings, especially when the contaminating inoculum can be influenced by the presence of an antagonistic microflora in the soil. There are

suppressive soils in which some soilborne *F. oxysporum* causing vascular diseases reduce their activity for the presence of antagonistic bacteria present in the rhizosphere.

7. Environmental Factors. Host development is often strongly influenced by environmental conditions. Moisture and temperature are the most important factors and both may affect seed and spore germination, seedling infection, and the first steps of disease development. Common bunt of wheat requires the teliospores to germinate at the same time as the grain, being too short a period of seedling susceptibility. In this case, soil temperatures affect spore germination, and seed transmission rates of the fungi can vary considerably. Teliospores located on the seed surface germinate optimally at 10–15°C, whereas at higher temperatures (20–25°C), germination is reduced. For this reason seeds of the same seed lot used in areas of different climatic conditions produce different percentages of infected plants. Internally localized pathogens normally produce infected plants and there are no significant effects of soil environment on pathogen transmission. Sowing date or geographic crop location do not change the incidence of loose smut of wheat (*Ustilago tritici*) or other similar host–pathogen combinations. In general there are particular geographic and climatic pattern and, temperatures and humidity strongly associated with fungal, viral, and bacterial seed-transmitted diseases. The establishment of infection is favored if, after sowing, the temperatures cause a slow development of seedlings.
8. Cultural Practices. Sowing data, sowing depth, soil type, soil pH, seeding rate, and fertilizers, etc. may affect pathogens seed transmission by having some direct or indirect effects on host, pathogen, and environment. Early sowing and shallow planting of wheat, for example, cause the reduction of bunt transmission, whereas deep sowing may cause the extension of the germination period and consequently seedling susceptibility.

CONCLUSION

Seed lots today move around the world more frequently than in the past. As a consequence, there are more opportunities for the spread of new pathogenic microorganisms in seed crops, as evidenced by the many new seedborne diseases recorded in the last ten years.

According to the practices of “Integrated Pest Management,” it will be very useful in the future to increase the use of seed health tests that can forecast the amount of inoculum transmitted to plants in different climatic conditions.

Sex Chromosomes in Plants

M. Ruiz Rejón

Universidad de Granada, Granada, Spain

INTRODUCTION

Unlike the situation in the animal kingdom, most plants are hermaphrodites. In fact, only about 5% of the 250,000 species of flowering plants are dioecious, having separate females and males. In less than a dozen of these dioecious species, sex is determined by chromosomes such as the X and Y that are so well known in animals. Despite their low number, plant species with sex chromosomes enable investigations of the origin and evolution of these chromosomes, and also advance the genetic improvement of commercial plants.

THE ORIGIN AND EVOLUTION OF SEX CHROMOSOMES

Currently, the most widely accepted hypothesis on the origin of sex chromosomes is that they first arose when a pair of nondifferentiated chromosomes joined together the genes that control male and female sex (i.e., genes that inhibit the development of either female or male sex organs). Second, at some point, differentiation occurred in the zone bearing these genes, which suppressed recombination in this area. Third, suppression of recombination was extended to more areas of the sex chromosomes, followed by a degeneration of the Y chromosome and the appearance of dosage-compensation mechanisms in the X chromosome.^[1] In short, this evolutionary process appears to have proceeded in three stages (Fig. 1).

This hypothesis is based on the very old sex chromosomes of animal species, normally in the last stages of this evolutionary process. However, dioecious plants, being at different stages in the process of chromosome differentiation (Table 1), offer a unique opportunity to investigate this process.

The First Stage: Asparagus

In asparagus (*Asparagus officinalis*), males as well as females have 20 chromosomes (Fig. 2A), and sex is controlled by two regulatory genes—the male activator (M) and the female suppressor (F). The males are heterozygous (MF/mf) and the females homozygous (mf/mf).

These genes are located in chromosome 5, which has a similar morphology in both males and females.^[2]

This similarity indicates that dioecism is of very recent origin in asparagus, and that chromosome 5 can be considered as an example of an incipient sex chromosome.

The Second Stage: White Campion

In the white campion (*Silene latifolia*), females have 22 autosomes (chromosomes with similar morphology in males and females) and two X chromosomes, whereas males have 22 autosomes as well as one X chromosome and one Y chromosome.

The origin of the sex chromosomes in the white campion is recent (some 20 million years ago (M.Y.A.) versus some 100 million years ago in mammals). Thus, although a differentiated sex-chromosome system developed with restriction of recombination in some regions, the process has not advanced to extensive degeneration of the Y and dosage compensation of the X.

The sex chromosomes are the largest chromosomes of the karyotype, with the Y larger than the X. Pairing occurs only during meiosis in one terminal region (Fig. 2B), indicating the suppression of recombination over much of their length.

The Y chromosome became differentiated from the X chromosome in at least three interstitial regions. These regions are thought to contain regulatory genes similar to those mentioned in asparagus. The white campion, however, may have three types of regulatory genes—one gene that suppresses the development of the carpels (female flower parts), and two genes that promote the development of anthers (male flower parts, one early and one late).^[3]

At the molecular level, the gene that suppresses the development of the carpels and the gene that promotes the (late) development of anthers are distally located at the ends of the nonrecombinant region of the Y chromosome, whereas these two genes are closely linked in the X.^[4] This differential disposition may have come about through chromosome rearrangements such as inversions and/or translocations. These rearrangements have suppressed recombination between the two chromosomes, thereby avoiding breakage of the two allele combinations that determine male or female in the sex-controlling genes.

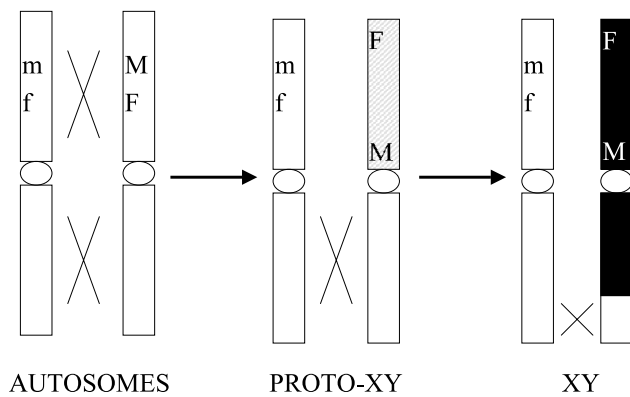

Fig. 1 Hypothesis concerning the origin of sex chromosomes. First stage: Establishment in an autosome pair of two linked genes, one a male activator (M) and the other a female suppressor (F). Second stage: Chromosomal rearrangements can prompt differential disposition of these genes between the proto X and Y chromosomes, suppressing the recombination between them. Third stage: Finally the recombination occurs only in a small region, the Y is degenerated, and some dosage-compensation mechanism appears in the X.

The white campion has no signs of degeneration of the Y chromosome; it is not heterochromatic (i.e., it does not show differential staining with respect to the remaining chromosomes), nor does it possess specific satellite DNA (a kind of repetitive DNA that may lack any function). In addition, although a functional gene has been found in the X chromosome for which its homologue in the Y is degenerated,^[5] two other functional genes have been found in the X chromosome for which their copies in the Y are not degenerated.^[6,7] The fact that some diplohaploid

YY plants (plants obtained by duplication from a haploid male cell with a Y chromosome) are viable and fertile indicates that the process of degeneration of the Y has not been completed for many genes.

With respect to the appearance of dosage-compensation mechanisms in the X chromosome, the data for *S. latifolia* are not conclusive. In females, the two X chromosomes differ in replication time and appear to be differentially methylated (marked with a CH₃ group in the cytosine of CG dinucleotides), but there are no signs of facultative heterochromatinization (reversible heterochromatin) in one of the two X chromosomes in the females.

The Third Stage: Sorrel

Sorrel (*Rumex acetosa*) females have 14 chromosomes, two of which (the large pair) are the X chromosomes. The males have 15 chromosomes, including 12 autosomes, one X chromosome, and two Y chromosomes of different sizes (Y1 and Y2). Y1 and Y2 are the largest chromosomes of the karyotype after the X chromosome. This composite chromosome system is believed to have arisen from a simple XX/XY by translocation between the X and an autosome, giving rise to the new X, with the primitive Y being Y1 and the homologue of the autosome being Y2.

In meiosis, the two Y's pair with the end of each arm of the X; thus, there is no meiotic recombination between the two Y's nor with the majority of the X (Fig. 2C). The Y's show clear signs of degeneration, are heterochromatic (Fig. 2D), and are rich in at least two satellite-DNA families with respect to the X and the autosomes, one of these satellites being specific to the Y's.^[8,9]

Table 1 Sex chromosomes in representative plant species

Family	Species	Sex chromosomes	Sex determination mechanism
<i>Asparagaceae</i>	<i>Asparagus officinalis</i>	5th chromosome pair	Active-Y
<i>Actinidiaceae</i>	<i>Actinidia deliciosa</i>	Undifferentiated	Active-Y
<i>Cannabidaceae</i>	<i>Cannabis sativa</i>	♀XX/♂XY	Active-Y
	<i>Humulus lupulus</i>	♀XX/♂XY	X/A ratio
	<i>Humulus japonicus</i>	♀XX/♂XY ₁ Y ₂	X/A ratio
<i>Cariaceae</i>	<i>Carica papaya</i>	Undifferentiated	Active-Y
<i>Caryophyllaceae</i>	<i>Silene latifolia</i>	♀XX/♂XY	Active-Y
<i>Chenopodiaceae</i>	<i>Spinacia oleracea</i>	Undifferentiated	Active-Y
<i>Cucurbitaceae</i>	<i>Coccinia indica</i>	♀XX/♂XY	Active-Y
<i>Dioscoreaceae</i>	<i>Dioscorea tokoro</i>	Undifferentiated	Active-Y
<i>Euphorbiaceae</i>	<i>Mercurialis annua</i>	Heterocigotic male	Active-Y
<i>Polygonaceae</i>	<i>Rumex acetosa</i>	♀XX/♂XY ₁ Y ₂	X/A ratio
	<i>Rumex hastatulus</i>	♀XX/♂XY o ♀XX/♂XY ₁ Y ₂	X/A ratio
<i>Rosaceae</i>	<i>Fragaria sp.</i>	Heterogametic female	?
<i>Vitaceae</i>	<i>Vitis</i>	♀XX/♂XY	Active-Y

Fig. 2 Sex chromosomes in male cells of some plant species. A: Diplotene of *Asparagus officinalis*. B: Metaphase I of *Silene latifolia*. C: Diplotene of *Rumex acetosa*. D: Mitotic metaphase of *R. acetosa* stained with the blue fluorochrome DAPI. (Note the intense signal of the Y chromosomes indicating its heterochromatic nature.) (View this art in color at www.dekker.com.)

The X's show no clear signs of dosage compensation. In females, there is no heteropicnosis (differential staining) of one of the X chromosomes. The genetic-control system in sorrel, however, depends on the ratio of X:autosomes (for this ratio, the females have a value equal to 1 and the males 0.5), in which the compensation, if it occurs, would lead to gene hyperactivity in the X chromosome of the males rather than to the inactivation of an X of the females.

Plants such as *R. acetosa* constitute the third stage in the evolutionary process of the origin of the sex chromosomes characteristic of many animal species. In fact, in the Y chromosomes of sorrel, in addition to the previously mentioned satellite DNA, genes also control male fertility, as is also the case in humans. In this sense, sorrel plants with an X:autosome ratio of 0.5 but without Y's are sterile males.

CONCLUSION

Despite the facts that research on sex chromosomes in plants has lagged behind that in animals and that enigmas persist, recent accelerated investigation using molecular tools is enabling the testing of the general hypothesis for

the origin of sex chromosomes. In fact, the different stages proposed by this hypothesis have been found in plants, thus confirming that sex chromosomes originated as a mechanism to avoid breakage of the two alternative combinations that give rise to males or females in sex-determining genes.

The role of the genes themselves in determining the sex of plants and whether they are located in the sex chromosomes or in the autosomes need clarification. For the moment, the genes identified in the sex chromosomes of plants (e.g., the case of the functional genes of *Silene latifolia* discussed above) do not intervene directly in the control of sex. In different dioecious species, genes involved in floral development are not associated with the sex chromosomes nor with sex control.

All these findings are of great interest from scientific and applied standpoints. In scientific terms, the analysis of dioecious plants in which the development of one of the sexes is halted will enable an understanding of the development of hermaphroditic plants in which both sexes appear. From an applied perspective, all these findings are of interest in areas of genetic plant improvement such as early determination of plant sex in crops that benefit from only one sex, in developing single-sex populations, in manipulating the reproductive systems of plants by converting them from dioecious to hermaphroditic and vice

versa, and in controlling pollination for the production of hybrid seeds.

Shade Avoidance Syndrome and Its Impact on Agriculture

Garry C. Whitelam

University of Leicester, Leicester, U.K.

INTRODUCTION

The ability to acquire information about their surroundings and use this information to modify behavior or development is a characteristic of all living organisms. Being sessile organisms that are not able to choose their environment, plants need to be especially plastic in their development in order to optimize their growth in response to environmental change. Since plants depend upon light as an energy source for the process of photosynthesis, they are especially sensitive to variations in the light environment. Plants monitor a range of light signals such as intensity, quality, and direction, and use this information to modulate a wide range of developmental and physiological process ranging from seed germination, seedling establishment, shoot architecture, the onset of flowering, and fruit development. Three principal families of signal-transducing photoreceptors have been identified in higher plants: the red/far-red (R/FR) light-absorbing phytochromes and the UV-A/blue light-absorbing cryptochromes and phototropins.^[1] In light-grown plants, R/FR light signals acting through the phytochromes enable plants to detect nearby vegetation and to evoke the shade avoidance syndrome of responses.

PROPERTIES OF PHYTOCHROMES

The phytochromes are biliproteins that absorb maximally in the R (600–700 nm) and FR (700–800 nm) regions of the spectrum. The phytochromes exist as a homodimer of two subunits that each consists of a polypeptide (ca. 1200 amino acids) and a linear tetrapyrrole chromophore attached via a thioether linkage to a conserved cysteine residue in the N-terminal globular domain of the protein. Light-induced interconversions between Pr and Pfr involve isomerization of the tetrapyrrole chromophore, accompanied by reversible conformational changes throughout the protein moiety. Phytochromes can exist in either of two relatively stable isoforms: a R light-absorbing form (Pr) with an absorption maximum at about 660 nm, or a FR light-absorbing form (Pfr) with an absorption maximum at about 730 nm. The Pfr form of phytochrome is generally considered to be biologically active, and Pr is considered to be inactive. The absorption spectra of Pr and

Pfr show considerable overlap throughout the visible light spectrum, and so under almost all irradiation conditions phytochromes are present in an equilibrium mixture of the two forms that tends to reflect the relative proportions of R and FR wavelengths.

Higher plants contain multiple discrete phytochrome species that make up a family of closely related photoreceptors, the apoproteins of which are encoded by a small family of divergent genes. The size of the phytochrome family varies among different plant species. In dicotyledonous angiosperms, including the model species *Arabidopsis thaliana*, five apophytochrome encoding genes (*PHYA-PHYE*) have been characterized. Apophytochromes A, B, C, and E are evolutionarily divergent proteins, sharing only 46–53% sequence identity, whereas *PHYD* encodes an apoprotein that shares 80% sequence identity with apophytochrome B. Molecular phylogenetic analysis supports the occurrence of four major duplication events in the evolution of phytochrome genes. An initial duplication is believed to have separated *PHYA* and *PHYC* from *PHYB/D/E*. The subsequent separation of *PHYA* from *PHYC* and *PHYB/D* from *PHYE* resulted in three subfamilies: *A/C*, *B/D*, and *E*.^[2]

PHYTOCHROMES AND SHADE AVOIDANCE

Phytochromes play a major role in regulating seed germination and early seedling establishment. In light-grown plants, the phytochromes mediate two principal responses: photoperiodic perception, leading to floral induction in some species, and proximity perception, leading to the shade avoidance syndrome. The shade avoidance syndrome, one of the best-studied examples of adaptive phenotypic plasticity in plants, is a suite of developmental responses initiated by the reflected/scattered light signals generated by neighboring vegetation.

The daylight spectrum has more or less equal proportions of R (600–700 nm) and FR (700–800 nm), but the selective absorption of blue and R wavelengths by the chlorophylls causes the radiation that is reflected/scattered by green leaves to be relatively enriched in the FR (Fig. 1). This FR-rich light signal (i.e., a reduction in R:FR ratio) is detected by nearby plants as a change in the equilibrium between Pr and Pfr and provides a unique and

Fig. 1 The spectral photon distributions of daylight and of the radiation reflected from a dense wheat canopy. The R:FR ratio of daylight (600–700 nm:700–800 nm) is 1.10 and the R:FR ratio of the reflected light is 0.28.

unambiguous signal that potential competitors are nearby. The magnitude of the reduction in R:FR ratio is quantitatively related to the proximity and density of the neighboring vegetation. In response to low R:FR ratio signals many plants evoke competitive reactions, including increased elongation of internodes and/or petioles, reduced leaf growth, and increased apical dominance,^[3,4] in an attempt to avoid being shaded. In many competitive plant species, such as arable weeds and a number of crops, internodes are especially sensitive to the low R:FR ratio signal. This correlates well with the finding that the reflected low R:FR ratio signal is particularly intense in internodes. The importance of the internode response was demonstrated in field experiments in which individual internodes of *Sinapis alba* or *Datura ferox* were screened for the low R:FR ratio signal by annular cuvettes containing copper sulphate solution, which absorbs strongly in the FR. Such “blinded” internodes failed to elongate in response to the proximity signal generated by growing plants at high densities.^[5] In some species, prolonged exposure to the low R:FR ratio signals evokes a survival reaction, the acceleration of flowering.

The roles of individual phytochromes in regulating shade avoidance responses have been largely inferred from studies of mutant plants deficient in one or more of the phytochromes. In a number of plant species, deficiency of phytochrome B has been shown to result in plants constitutively displaying phenotypes comparable to those

of the shade avoidance syndrome.^[6] This indicates a major role for phytochrome B in the perception of the R:FR ratio signal. However, the retention of some sensitivity to low R:FR ratio signals in mutants that are null for phytochrome B indicated the involvement of other phytochromes in shade avoidance. Phytochromes D and E were subsequently shown to play a role in R:FR ratio perception.^[7,8]

SHADE AVOIDANCE IN AGRICULTURE

When plants grow in close proximity to one another, the shade avoidance syndrome is invoked. These responses are likely to be of benefit to individual plants growing in mixed communities, by providing a means of competing for light through the reallocation of resources. In an agricultural setting, however, shade avoidance represents an undesirable trait that diverts resources into increased stem and petiole elongation to support competitive growth, and away from agriculturally important activities such as root, leaf, and seed/fruit growth. Despite the strong selection for high yield in monocultures that has characterized the breeding of modern crops, many crop plants have retained the shade avoidance response to nearby vegetation and so show increased stem elongation when grown at increasing densities.

Crop productivity is a complex function of the acquisition and distribution of resources. Shade avoidance responses lead to dramatic alterations in resource allocation that can severely limit harvestable biomass in monocultures. Thus, it can be predicted that by rendering individual plants insensitive to the low R:FR proximity signal, the wasteful allocation of resources into competitive growth should be reduced, with a concomitant increase in harvestable yield. This notion has been tested in an elegant field experiment in which a transgenic approach was used to suppress shade avoidance responses. Tobacco plants were genetically engineered to overproduce phytochrome A, a member of the phytochrome family that normally plays a major role in seedling development in response to FR signals. When overexpressed, phytochrome A antagonizes the action of phytochrome B (and presumably phytochromes D and E), so that the plants do not display increased stem elongation in response to the low R:FR ratio signal. When such plants are grown in the field at different densities, in contrast with wild-type plants, they do not show proximity-induced increases in stem elongation. In fact, they show proximity-conditional dwarfing. Significantly, the transgenic plants display increased harvest index compared with wild-type tobacco plants.^[9] It is anticipated that suppression of shade avoidance would have similar benefits in a range of crops.

CONCLUSION

By perceiving the FR-rich light signals reflected from leaves, the phytochromes enable plants to detect the presence of neighboring vegetation and to initiate competitive growth responses: the shade avoidance syndrome. Although beneficial to individuals growing in mixed communities in the competition for light, shade avoidance in many crop plants leads to a wasteful redirection of resources that reduces harvestable biomass. Experimental approaches are being developed that may lead to suppression of shade avoidance in crops, with attendant increases in yield.

Social Aspects of Sustainable Agriculture

Frederick H. Buttel

University of Wisconsin, Madison, Wisconsin, U.S.A.

INTRODUCTION

Agriculture—conventional and sustainable, “traditional” and “modern”—is intrinsically social (or sociotechnical) in nature. The social character of agriculture is particularly apparent, particularly widely recognized, and particularly crucial in the case of sustainable agriculture. Not only must any reasonable definition of sustainable agriculture include both social and economic as well as technological and ecological components, the roots of unsustainability and the pathways to sustainability are fundamentally social processes. This chapter will provide an overview of the most fundamental social dimensions of sustainable agriculture.

THE DEFINITION OF SUSTAINABLE AGRICULTURE

It is widely agreed that sustainable agriculture is intrinsically a joint social and ecological construct. Thus, for example, Ikerd^[1] stresses the “anthropocentric” as well as “ecocentric” nature of agricultural sustainability, noting that the essence of sustainable agriculture is that “we [in sustainable agriculture] are concerned about sustaining agriculture for the benefit of humans, both now and into the indefinite future.” Sustainable agriculture is an agriculture that is “ecologically sound, economically viable, and socially responsible.”^[2] Allen similarly emphasizes that a conception of sustainable agriculture that fails to recognize the role of people, social actors, social institutions, and social movements is a limited one.^[3]

Sustainable agriculture and organic farming are very closely related but are not exactly coterminous. Organic farming systems tend to be highly sustainable systems according to the ecological and social components of the definition of sustainable agriculture, and are often quite economically viable as well.^[4,5] Many in the sustainable agriculture community, however, feel strongly that sustainability improvements in mainstream or conventional agriculture are as important as the expansion of organic farming and organic agro-food systems.

STRUCTURAL CAUSES OF THE LACK OF SUSTAINABILITY

Agricultural sustainability is not only a vision of the long-term goals for agriculture, which imply measuring sticks for or indicators of its achievement.^[6] Sustainability also implies a critique of or a set of concerns about “conventional” agriculture—that mainstream agriculture has shortcomings in terms of environmental soundness, economic soundness, and social justice—and suggests that there have been trends over time that jeopardize the achievement of these three ends.

The historical U.S. pattern of abundant land, limited and/or relatively expensive rural labor, and a strong tendency toward overproduction and low commodity prices has encouraged a capital-intensive, chemical-intensive monocultural system with a very high degree of enterprise and spatial homogeneity (or specialization). Commodity, trade, and public research policies have historically reinforced these tendencies to monoculture, specialization, and heavy reliance on chemicals, leading to an agriculture that has significant shortcomings on all of the criteria implied in the definition of sustainable agriculture.^[7]

SUSTAINABILITY AND THE CORPORATE-INDUSTRIAL AGRICULTURAL ECONOMY

Agricultural sustainability cannot be considered apart from the globalized and highly concentrated corporate economy within which sustainable agriculture, and agriculture as a whole, is enmeshed. Corporate concentration on input provision, food processing, and retailing limit the choices available to sustainable and other farmers. Corporate control over agriculture is increasing through processes such as the disappearance of “open markets” for agricultural products; the extension of vertical integration and contractual relationships; and the ever closer alignment of multinational chemical and seed companies on one hand, and food processors, manufacturers, and global trading companies on the other.^[8] There is evidence that the increased corporate domination of

agro-food systems has negative implications for achieving agricultural sustainability. Farmer contractees, for example, are typically directed contractually by “integrators” to use particular practices which, more often than not, are unsustainable.

It should be stressed, however, that corporations—often small ones, but also large firms—have been major agents in extending the scope of organic food production and organic marketing. There are two major nationwide organic chain grocery stores, and a number of corporations have been very successful in producing organic products such as potatoes, grapes, fresh fruits and vegetables, and so on. The corporate organization of the organic food industry represents a major dilemma for proponents of agricultural sustainability. Highly successful sustainable agriculture ideas will be attractive to private corporations, which will often be successful in diffusing products and practices. At the same time, corporate agricultural sustainability practices may undermine certain aspects of the sustainability agenda (e.g., large-scale monocultural production of organic potatoes in the Northern Intermountain states is associated with a considerable threat of soil erosion and loss of biodiversity).

There is considerable debate in the sustainable agriculture community as to whether the best indicator of the growth of sustainable agriculture is the national market share of organic food—much of which is due to the activities of very large corporations such as Whole Foods—or whether the extent of sustainable agriculture is most accurately measured by the prevalence of community-supported agriculture (CSA), farmers markets, local co-ops, community gardens, and direct marketing of food. Those with the strongest commitments to sustainable agriculture are also most likely to see food system localization and the re-creation of more local “foodsheds” as the heart and soul of a genuine and enduring sustainable agriculture.^[9]

SUSTAINABILITY AS A SOCIAL MOVEMENT

Agricultural sustainability is as much a social movement as it is a set of technologies and production practices. Social definitions of sustainability—that is, the concerns, views, ideologies, and agendas of movement participants—are as or more important in shaping what sustainability is as ecological or biological indicators such as soil erosion rates, levels of soil organic matter, biodiversity, levels of runoff, and so on. What has put sustainability on the national and global agenda is primarily the organization and activities of three major types of groups: farmer-driven sustainable agriculture organizations and movements, consumer-driven or consumer-oriented sustainable agriculture initiatives (such as

many CSA farms and most food co-ops and local food councils), and national and global environmental groups. Environmental groups have arguably done the most to increase the visibility and persuasiveness of the overall notion of sustainability, and of the particular concept of agricultural sustainability, though farmer-oriented groups do not always agree with environmentalists’ agendas for agricultural sustainability.

Each of the three main types of sustainable agriculture organizations, however, agrees on the main components of the movement agenda: the need for more public research on sustainable practices, the need for public policy incentives for sustainability, the desirability of family farming, and the imperative to improve the environmental performance of agriculture. Increasingly, this consensus has extended to issues such as opposition to major trade liberalization agreements (the World Trade Organization and NAFTA) and opposition to genetic engineering of crops and foods.^[10]

PUBLIC POLICY AND THE FUTURE OF AGRICULTURAL SUSTAINABILITY

Three necessary but insufficient conditions for the continued advance of sustainable agriculture are the development of improved sustainable technology; the presence of a vigorous and dynamic sustainability movement; and the development of a public policy environment that reduces the public policy disincentives to an environmentally sound, socially responsible, and economically viable agriculture. Of these three conditions, the public policy environment of agricultural sustainability is arguably the most important over the long term, even though the macro-public-policy environment is difficult to redirect, and there are areas of public policy disagreement among farmers, consumers, and environmental actors in the sustainable agriculture community. For example, some sustainability advocates, particularly those in the environmental community (and some farm groups in that community), believe that the federal (and global) levels of action are most important or efficacious, whereas others believe that at this time the local (community or regional) arena is where advocates can most easily make a difference. Nonetheless, it is apparent that over the long term sustainable agriculture cannot advance far in a public policy environment that involves the strong disincentives to sustainability that currently prevail. There is a need for more active federal, state, and local regulation of both the on-site and the off-site impacts of agriculture; for ending the commodity-driven pattern of federal agricultural policy that shovels the lion’s share of subsidies in the direction of large, monocultural producers of overproduced commodities; and for redirection of the public

agricultural research agenda. Some of the most innovative public policy ideas in sustainable agriculture are being developed in Europe. Green payments, taxes on pesticides and fertilizers, and the embracement of a “multifunctionality” approach to government agricultural policy are particularly promising policy instruments.^[11] Each of these policy instruments would support sustainability and yield other benefits (reduced government outlays, rural development, reduced greenhouse gas emissions). Still, there are no technocratic shortcuts to sustainability. Sustainability is, and must remain, as much a social movement as it is a set of practices and measuring sticks of agro-food system performance.

Somaclonal Variation: Origins and Causes

Philip Larkin

CSIRO Plant Industry, Canberra, Australia

INTRODUCTION

Somaclonal variation is the genetic variation that is sometimes observed when plants are regenerated from cultured somatic cells, compared to the plant used as a source of the culture. Such variation represents both a problem and an opportunity. For those concerned with micropropagation of valuable elite clones, this variation can result in problematic off-types that diminish the commercial value of propagules. Likewise, genetically enhanced (transgenic) plants are carefully screened to avoid unwanted and unintended somaclonal variation, so that the commercially released clone has only the beneficial effects from the transgene. On the other hand, some somaclonal variants have proved to be of agronomic and commercial advantage and in a limited number of cases have been released as new cultivars. Various types of somaclonal mutation have been described, including point mutations, gene duplication, chromosomal rearrangements, and chromosome number changes. Transposable element movement and changes in DNA methylation have been implicated as mechanisms behind some, but not necessarily all, somaclonal variation. It may be that somatic cells, both in the plant and in culture, naturally accumulate these changes and that the tissue culture environment provides an opportunity for these mutations to be uncovered in tissue culture-derived plants.

BACKGROUND

Recognition that plants regenerated from cell culture could carry mutations began in the 1970s and was initially met with scepticism. The earliest systematic work on somaclonal variation was in sugarcane, tobacco, rice, ryegrass, lettuce and, potato.^[1–4] Potato variants were observed after regeneration from cultured protoplasts; this was named protoclonal variation.^[5] The more general designation “somaclonal variation” was coined when it had become evident that the phenomenon could occur following all forms of culture of somatic cells.^[6]

NATURE OF THE GENETIC CHANGES

Table 1 summarizes types and examples of somaclonal variation.^[1]

Experiments with multiple regenerated plants from isolated single-leaf protoplasts have demonstrated that somaclonal variation sometimes occurs during the period of culture and sometimes appears to preexist in the leaf. The frequencies of occurrence of these mutations vary widely. The maize ADH (alcohol dehydrogenase) point mutation was found only once among 645 regenerants. One β -amylase mutation in wheat was found among 149 regenerants in which four loci were screened. In some experiments^[7] the rate of mutation from somaclonal variation was about tenfold higher than from mutagen ethyl methanesulfonate (EMS) on seed or pollen.

ORIGINS OF THE GENETIC CHANGES

The causes (nature) of the genetic changes can be described more easily than the originating mechanisms. The trigger for somaclonal variation may not be unique to cell cultures but may occur naturally in plant somatic tissues. In other words, cell culture may simply be an effective means to uncover and reveal the genetic changes by giving opportunity for the mutated cells to become mutated plants.

It has been suggested that the causative condition for somaclonal variation is high auxin levels, rapid cell division, or return to a juvenile genomic state, but there is little persuasive evidence. Likewise, the trigger has been described as genomic shock or plasticity, which occurs after the plant has exhausted its ordinary physiological responses to environmental stress.^[8] These interpretations of the sometimes massive genetic changes observed with somaclonal variation seem reasonable but do not describe the actual mechanism of unleashing the genetic plasticity.

More recently it has been shown that cell culture can cause the activation of transposable elements.^[9] Excision of a transposable element leaves a double-stranded break at the donor site. The cell attempts to repair the breaks

Table 1 Types and examples of somaclonal variation

Type of genetic change	Examples	Comments
Point mutation	Alcohol dehydrogenase (ADH) gene	An altered electrophoretic mobility due to a single amino acid change
Simple genetic changes	Chlorsulfuron resistance in tobacco	These are simply inherited and may be due to one or more base changes
New isozymes	New β -amylase in wheat	A silent member of a multigene family may be activated
Gene amplification	Phosphinothricin resistance in alfalfa	Amplification of the number of copies of glutamine synthase gene
Gene deamplification	Reduction in rDNA spacer region in triticales	An 80% reduction in Nor locus of chromosome 1R
Chromosomal rearrangement	Deletions, telosomics, translocations, inversions	Breakage most often at or near heterochromatic blocks
Chromosome number	Monosomy, trisomy, extreme aneuploidy, gross ploidy changes	Such changes are not simply inherited, i.e., not according to Mendelian ratios

sometimes by strand-to-strand sister chromatid ligation. Subsequent rounds of replication initiate the so-called breakage-fusion-bridge cycle, which ceases only when new telomeres are added to the chromosome ends.

A number of researchers have observed both increases and decreases in C-methylation and A-methylation during cell culture.^[3] This phenomenon can result in altered gene expression, although the direct effects are likely to be less stable over time. However, others^[8] have described how short-term changes in methylation can result in stable point mutations. "Repeat-induced point mutation" (RIP) was first described in *Neurospora*, and may be a significant underlying cause of somaclonal variation in cultured plant cells; in the plant cell context "methylation-induced mutation" may be a more appropriate name. Newly methylated cytosines can be deaminated to form thymines, resulting in sequence mutation. It is also possible that transient changes in DNA methylation lead to bursts of transposable element movement, with consequent stable genetic changes and chromosome structural alterations, as explained above.

It is therefore difficult to envisage a single originating mechanism that can trigger all the various types of somaclonal variation. The current author therefore favours the view that there are a variety of mechanisms, most or all of which occur naturally in the somatic cells of plants and also in cultured plant cells, perhaps at a higher frequency. Plant regeneration from single somatic cells gives the opportunity to reveal these changes as solid mutant plants. In addition, cell culture itself may be sufficiently stressful to unleash the preprogrammed genomic shock, which is an adaptive mechanism that activates when ordinary physiological responses are insufficient. The occurrence of hot-spots of mutation and recurring menus of alternative alleles,

described by some investigators, is consistent with this preprogrammed response.

HOMOZYGOUS MUTATIONS

A number of researchers have observed somaclonal variation appearing as homozygous mutations (e.g., in rice, wheat, and maize). Homozygosity might be explained in a number of ways: The mutational mechanism is not random and occurs on both homologues; the mutation is rendered homozygous by a type of gene conversion; there are cycles of haploidy (or chromosomal monoploidy) and diploidy such that a mutation on one homologue is duplicated to achieve homozygosity. Some researchers^[10] describe a type of somatic meiosis in culture that might explain the ability for mutations to become homozygous. Somaclonal variation in soybean produces alleles already known in the soybean germplasm, suggesting a type of non-random mutation giving controlled formation of alternative alleles in response to stress.

PROBLEM FOR MICROPROPAGATION AND GENETIC MODIFICATION OF CROPS

Almost invariably micropropagation of horticultural species (and clonally propagated crops such as banana) is intended to produce chosen elite individuals in mass. Somaclonal variation is problematic under these circumstances, where even a low percentage of off-types is unacceptable for commercial use; a high percentage can

be very costly, as has been proven in both the banana and oil palm industries.

Likewise, somaclonal variation can be problematic in the genetic modification of crops. A number of studies indicated higher levels of somaclonal variation following transformation procedures than in control populations of regenerants. Here, however, hundreds of individual transgenics are exhaustively tested and only proven elite individuals are chosen to become commercial releases. Somaclonal variation is not a great problem in species where transformation is relatively easy or where the breeding system allows backcrossing to eliminate unwanted changes. The problem is very significant in species such as sugarcane.

EXAMPLES OF SOMACLONAL MUTANTS BEING BENEFICIAL

The literature records instances of somaclonal variation in a large range of plant species, including major food crop species wheat, barley, sugarcane, rice, maize, potato, tomato, soybean, and oilseed rape. The potential improvements reported include enhanced resistance to fungal, bacterial, and viral diseases, improved insect and nematode resistance, enhanced economic yield, improved drought, chilling, salinity, and aluminium tolerance. In a limited number of cases there have been new varieties and cultivars named and released commercially. Examples are listed in Table 2.

Table 2 Examples of commercially available cultivars

Species	Somaclonal trait	Commercial name
Barley	Improved yield and downey mildew resistance	AC Malone
Wheat	Improved yield and agronomy	HeZu 8
Potato	Reduced tuber browning	White Baron
Blackberry	Thornless	Lincoln Logan
Flax	Salt and heat tolerance	Andro
Celery	Fusarium resistance	UC-TC
Celery	Fusarium yellows resistance	MSU-SHK5
Tomato	Fusarium resistance	DNAP-17
Rice	Picularia resistance and improved cooking quality	Dama

SPECIFIC EXPLOITATION OF CHROMOSOMAL CHANGES

Somaclonal variation involving subchromosomal recombination has been exploited to achieve the introgression into wheat of a particular segment of an alien grass chromosome with Barley Yellow Dwarf Virus (BYDV) resistance.^[11] In this case it was possible to introduce the whole chromosome by backcrossing the wide hybrid between wheat and *Thinopyrum intermedium*. This alien chromosome neither pairs nor recombines with the wheat chromosomes. However, cells from the monosomic alien addition line (all 42 wheat chromosomes and one from the grass) were cultured, plants regenerated, and progeny families screened for recombination. Five of about 1000 families (0.5%) had a recombination in which a portion of the alien chromosome, carrying the BYDV resistance, had been translocated onto a wheat chromosome. Two new Australian wheat cultivars (cvs. Mackellar and Glover) have just been released with two of these translocations.

CONCLUSION

It was thought for some time that regeneration by somatic embryogenesis might render some protection from somaclonal variation, but this appears not to be the case. Reducing the length of time in culture does seem to reduce the likelihood of gross chromosomal variation but not necessarily the less obvious and fine structural changes. If it is true that cell culture merely enables the recovery of naturally occurring somatic mutations, then it seems unlikely that somaclonal variation can be entirely avoided whenever plants are regenerated from individual somatic cells. If, however, the underlying cause is a stress that triggers changes associated with genomic trauma, then some types of culture may be found to be less traumatic. A recent study in rice indicates that while no form of culture entirely eliminates somaclonal variation, protoplast culture nevertheless results in a much higher incidence. Some vigilance will therefore continue to be required in the selection of transgenic events for commercial release.

Somatic Cell Genetics of Banana

D. K. Becker

Queensland University of Technology, Brisbane, Queensland, Australia

M. K. Smith

Queensland Department of Primary Industries, Queensland, Australia

INTRODUCTION

Bananas and plantains (*Musa* spp.) are grown throughout the humid tropics and subtropics, where they are of great importance both as subsistence crops and as sources of domestic and international trade. They are monocotyledonous perennial herbs consisting of sympodial rhizomes and large pseudostems composed of tightly clasping leaf sheaths, slightly swollen at the base. Suckers are freely produced. Bracts and flowers are inserted independently on a peduncle and are usually deciduous by abscission, except for functional female ovaries in the basal hands. Basal flowers are generally female with male flowers on distal hands.

Edible, seedless banana, plantain cultivars are derived from intra- and interspecific hybridisation of the two seeded, wild diploid species, *Musa acuminata* (A genome) and *Musa balbisiana* (B genome). The haploid genome of both *M. acuminata* and *M. balbisiana* consist of 11 chromosomes, but the *acuminata* genome has been estimated as being slightly larger, 610 Mbp cf. 560 Mbp for *balbisiana*. Many edible hybrids are parthenocarpic, female sterile and triploid with the relative contribution of each species to the genome being annotated by either A or B. Dessert bananas are usually AAA, plantains AAB and cooking bananas ABB.

Banana breeding programs have largely focused on generating pest and disease resistant cultivars while at the same time retaining acceptable yield and fruit quality. The two major diseases of banana are Sigatoka leaf spots (*Mycosphaerella* spp.) and Fusarium wilt (*Fusarium oxysporum* f. sp. *cubense*). Due to infertility, triploidy and long generation time, very few conventionally bred cultivars have reached commercial release. As a result, a great amount of effort has been directed towards improving banana through the manipulation of somatic cells.

SOMACLONAL VARIATION AND MUTATION INDUCTION

Banana has benefited greatly from in vitro-induced mutation. This is largely due to the resources directed

towards this approach in view of difficulties associated with breeding triploid cultivars. Genetic variation can arise as a result of the tissue culture process or be intentionally induced by the use of physical and chemical mutagens. All three approaches have been applied to banana.^[1,2]

Banana plants regenerated from in vitro culture sometimes exhibit morphological and biochemical variation due to genetic changes, which is of serious concern for clonal micropropagation. These genetic changes, nonetheless, may be exploited as a source of genetic variation for banana improvement. Somaclonal variation in banana usually leads to undesirable characteristics. However, there are several examples of somaclonal variants with advantageous characteristics, some of which have been released commercially. Variants identified include Tai-Chiao No 1 (AAA), TC1-299 (AAA) and Mutiara (AAB) with Fusarium resistance, a variant of SH 3436 (AAAA) with greater resistance to Sigatoka diseases, JD Special (AAA) with larger fruit, and higher yielding variants of Agbagba (AAB).

Of the physical mutagens used in banana and plantain improvement, gamma rays have been most commonly used. Differences in radiosensitivity have been observed among different genotypes and ploidy levels. In one study,^[3] the LD₅₀ was 20–25 Gy for diploid (AA), 30–35 Gy for triploid (AAA), and 35–40 Gy for the tetraploid (AAAA). Plantain and cooking clones (AAB, ABB) had a radiosensitivity of 25–35 Gy. Among a population of plants that had regenerated from a 60 Gy irradiated explant of “Grande Naine” (AAA), an early-flowering plant was identified. The clone was extensively field tested, released as “Novaria,” and entered into commercial production in Malaysia in 1993.

Ethyl methanesulphonate (EMS) has been widely used as a chemical mutagen in banana and has resulted, at least at an experimental level, in the generation of clones with increased *Fusarium* tolerance.^[4] The concentration required is dependent on exposure time and whether a carrier is used. EMS has been shown to be effective at 8–16 mM with an exposure of 4–5 days and also at 200 mM with a much shorter exposure of 30 min. Dimethylsulphoxide (DMSO) has been used as a carrier agent as

it facilitates greater uptake of EMS. Other mutagens such as sodium azide and diethylsulphate have also been shown to be effective in inducing variation from banana shoot apices.

Chemical methods have also been used to manipulate ploidy in *Musa*, with a view to incorporating the material into conventional breeding programs. By breeding and selecting elite diploid clones, and using them to generate autotetraploids and to cross with diploids, triploid bananas could be resynthesised. Tetraploidy has been readily induced with colchicine in *M. acuminata* and *M. balbisiana* seedlings and also in vitro shoot tips. The in vitro technique has the advantage of rapid multiplication and ease of distribution of new clones for evaluation and breeding.^[5] Of importance is the number of in vitro multiplication cycles, usually more than three, following colchicine treatment in order to reduce chimerism. Treatment of shoot cultures with oryzalin has also been effective in producing high frequencies of tetraploids in banana.

SOMATIC EMBRYOGENESIS AND ORGANOGENESIS

Most reports of banana regeneration have been via embryogenic cell suspensions (ECSs). Potential uses of such cultures include micropropagation, as a source of regenerable protoplasts and for genetic transformation. There is also the potential for use as a source of cells for mutagenesis, although, to date, there have been no reports of this application. Banana somatic embryos are thought to be unicellular in origin and therefore offer the potential of generating nonchimeric plants from genetically altered cells.

ECSs have been generated using a range of explants including rhizome tissue, leaf bases, immature zygotic embryos, meristems, and immature male and female flowers. Currently, ECSs are most commonly derived from immature flowers or meristems.^[6,7] Both these techniques appear to be applicable to a wide range of genotypes including diploids (AA, AB), triploids (AAA, AAB, ABB) and tetraploids (AAAB). ECSs contain a heterogeneous mix of cell types and their regenerative capacity depends on the proportion of cell types. Single isolated cells and large cell clumps (200 μm to 2 mm) in general do not give rise to somatic embryos, whereas small cell aggregates (50 to 100 μm), consisting of small cells with dense cytoplasm readily form somatic embryos.^[8]

The ECSs from immature male flowers entail dissecting out clusters (hands) of immature flowers that are close to the apical meristem of the inflorescence and placing them on induction medium where they remain without subculture until embryogenic complexes appear. Embryogenic complexes are then transferred to liquid medium where a suspension of cells forms. Regeneration involves

plating suspension cells on embryo development/maturation medium. Very large numbers of somatic embryos can be generated from these cells with as many as 3.7×10^5 embryos formed per 1 mL Packed Cell Volume (PCV) being reported.^[6] When embryos are transferred to germination medium, the germination rate varies depending on their maturity. Leaving embryos on embryo formation/maturation medium for long periods (up to four months) results in a germination rate of over 80%.

To generate ECSs from meristems, highly proliferating clumps of meristems are induced by placing in vitro shoot cultures on multiplication medium that, depending on the cultivar, contains varying concentrations of BAP. Over a series of subcultures on this medium, primordia gradually stop forming leaves and meristems enlarge, resulting in large white meristematic nodules. Following the formation of meristematic clumps, the upper 4–6 mm of these structures (termed “scalps”) are used as explants for induction of embryogenesis followed by initiation of ECSs in a manner similar to that of flower-derived cultures.^[7] Recent work suggests that “scalps” are not required, but rather ECSs can be generated directly from longitudinal sections of conventional shoot tip cultures.^[9]

In the only reported field trial of plants derived from ECSs, measurements were taken for the growth characteristics of 500 “Grand Nain” (AAA) plants regenerated from flower-derived ECS.^[10] Overall, there were no significant differences in growth characteristics. The frequency of off-types for ECS-derived plants was nil, while the frequency for those derived from micropropagation was between 1.8% and 3.3% depending on the accession. This study suggests that plants regenerated from ECSs may not be any more prone to somaclonal variation than plants derived from shoot-tip culture.

PROTOPLAST ISOLATION AND CULTURE

Somatic hybridization of bananas is possible and has potential to assist the breeding of edible bananas. In a similar manner to manipulation of ploidy with chemicals, tetraploids could be generated via protoplast fusion and triploids resynthesised by crossing with diploids. Allotetraploids created by the somatic hybridization of two elite diploid clones would be very different from autotetraploids produced by chromosome doubling. As there are now a number of examples of plant regeneration from protoplasts, fusion is now a technique that can potentially contribute to banana-breeding programs. Genotypes for which plants have been regenerated from protoplasts include breeding diploids (AA), dessert bananas (AAA), plantains (AAB), and cooking banana (ABB).^[11] All reports of successful plant regeneration have two factors in common. Firstly, protoplasts were derived from ECSs and

secondly, feeder cells and/or protoplast culture at high densities was required.

GENETIC TRANSFORMATION

As this article is concerned with genetic manipulation of somatic cells, a brief mention should be made of genetic transformation. Both meristems and embryogenic cells have been targeted for transformation; however, due to greater efficiency and the greatly reduced risk of chimerism, embryogenic cells are the tissue of choice. Following the development of efficient regeneration systems for various cultivars, transformation systems using both microprojectile bombardment^[12] and *Agrobacterium*-mediated transformation^[9] of embryogenic cultures have been developed. Reports of transformation to date have focussed on the development of the technique itself and the examination of the strength and tissue specificity of various promoter elements. Work in this area has now moved on to conferring useful new traits including disease resistance and altered fruit characteristics. Indeed, potentially disease-resistant transgenic banana are currently undergoing glasshouse and field trials, and delayed fruit ripening using sense suppression of genes involved in ethylene biosynthesis has been reported.

CONCLUSION

The difficulties associated with conventional breeding of banana have been the driving force behind the genetic manipulation of somatic cells. In some cases, such as mutation breeding, new cultivars are already in commercial production. Other techniques, such as ploidy manipulation and protoplast fusion may provide assistance to conventional breeding or be utilised independently to generate new cultivars. Although at times some controversy is associated with genetic transformation, it does provide the potential to circumvent fertility problems and allow the transfer of genes within the banana gene pool or indeed introduce genes from completely unrelated organisms. The possibilities for banana improvement have entered a new and exciting phase based on our understanding of somatic cell genetics.

Somatic Embryogenesis in Plants

Ray J. Rose

The University of Newcastle, Callaghan, Australia

INTRODUCTION

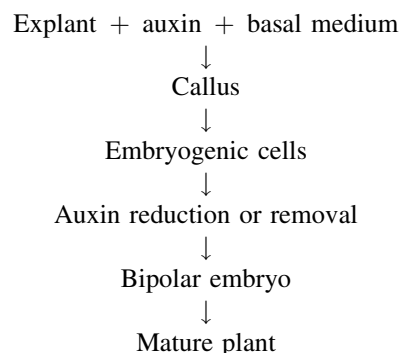

Somatic embryogenesis refers to the remarkable ability of nonzygotic plant cells (including haploid cells) to develop through characteristic embryological stages into an embryo capable of developing into a mature plant. Somatic embryogenesis is an expression of totipotency and the associated differential gene expression.

Somatic embryos may be produced in nature in certain plant species as a form of apomixis known as adventitious embryony. Somatic embryogenesis in plants usually refers to the induction of somatic embryos *in vitro*, first demonstrated by both Steward and Reinert in 1958. Research into somatic embryogenesis has intensified as plant regeneration *in vitro* has come to be widely utilized in transformation and somatic hybridization.

This article emphasizes basic procedures and key variables for inducing somatic embryos, their developmental biology, and their mechanism of induction. Somatic embryogenesis may be direct or indirect. Direct somatic embryogenesis does not require a callus phase to induce somatic embryos from the explant. Indirect somatic embryogenesis has been most extensively studied and is widely used in transformation and somatic hybridization.

PRODUCING SOMATIC EMBRYOS—THE BASIC PROCEDURE

Steward was able to produce embryos from phloem tissue explants from carrot storage roots; Halperin^[1] was able to show that auxin is essential for inducing embryos and that subsequent auxin withdrawal or lowering of auxin concentration is required for embryo maturation. Based on Dudits,^[2] the basic paradigm is:

In leguminous plants the first success was with *Medicago sativa* where calli (produced using an auxin + cytokinin) were induced to form embryos with a pulse of high 2,4-D;^[2] and in Poaceae, immature embryos cultured in the presence of 2,4-D led to the induction of embryogenic calli from which plants could be regenerated when levels of 2,4-D were greatly reduced.^[3,4] There are differences in these examples in the initial explant, the timing of auxin treatments, and the use of special cultivars. The auxin paradigm from carrots has had to evolve; a discussion of the parameters to consider in producing somatic embryos in a given species follows.

PRODUCING SOMATIC EMBRYOS—KEY VARIABLES

Cultivar Selection and Genotype

Within a species, certain cultivars are more amenable to plant regeneration via somatic embryogenesis, reflecting a strong genotypic component in the ability to form somatic embryos. In *M. sativa*, Bingham and co-workers produced Regen S using recurrent selection, and two genes have been invoked in breeding for somatic embryogenesis.^[5,6] In *Medicago truncatula*, highly embryogenic plants can be obtained after a single cycle of tissue culture followed by selection.^[6] Whether this has an epigenetic or genetic basis is unclear. Plant regeneration via somatic embryogenesis has been achieved in numerous species (Fig. 1)—dicotyledons and monocotyledons, woody and herbaceous species, annuals and perennials.^[3,7,8]

Explant Type

The type of explant is a key variable in successful somatic embryogenesis. Immature embryos have been an important source of explants in obtaining somatic embryogenesis in such difficult species as wheat and soybean.^[3,4] This is consistent with the idea that immature tissues are less likely to have suffered irreversible somatic genetic change. Explant type is less important in genotypes that are strongly embryogenic (e.g., in *M. sativa* Regen S and *M. truncatula*, 2HA explants from fully expanded leaves

Fig. 1 Somatic embryogenesis in calli of two legumes, (A) the annual *Medicago truncatula* and (B) the perennial *Medicago sativa*; in (C) *Nicotiana suaveolens* and (D) the monocotyledon *Zea mays*. (A), (B), and (C) show examples of globular through (B) late torpedo stage embryos. In (D) an embryonic coleoptile is visible. Bar is 1 mm. (Photographs from author's laboratory by (A) K.E. Nolan, (B) J.T. Fitter, and (C,D) M.R. Thomas.

are fine), whereas in more recalcitrant legumes, immature tissues from embryos are necessary.^[3,5,6]

Hormone Requirements

The hormonal regulation of any plant process is physiologically-, developmentally-, and species-dependent so it is not surprising that the auxin paradigm must be qualified. A cytokinin plus auxin may be essential for somatic embryogenesis,^[6] or cytokinin may augment the auxin response.^[2] In the case of alfalfa, an auxin plus cytokinin induces callus formation, and then a high 2,4-D pulse induces somatic embryos.^[2]

Abscisic acid (ABA) also plays a role in somatic embryogenesis. Initially it appeared that the role of ABA was to mimic the *in vivo* effect where it is part of controlled desiccation during seed formation; it was thought to lead to improvement in embryo quality. ABA studies overall indicate that it stimulates auxin-induced somatic embryogenesis. In some cases, exogenous ABA

alone can stimulate direct somatic embryogenesis.^[9] This recent work suggests that the role of ABA may reflect its involvement in stress responses, which are known to be capable of inducing somatic embryogenesis.^[9]

Nutrition

Nutrition plays an important role in optimizing somatic embryogenesis; a few widely used standardized basal media have been developed.^[7] The form of nitrogen is an important variable—reduced nitrogen in addition to nitrate enhances embryo initiation and maturation.^[7]

DEVELOPMENTAL BIOLOGY OF SOMATIC EMBRYOGENESIS

Histological studies suggest that the precursors of somatic embryos are frequently provascular cells. In these cells

near the vascular tissue, endogenous substances in the phloem may be significant. Epidermal cells may also be sites of somatic embryo precursor cells in direct somatic embryogenesis.^[9] In direct somatic embryogenesis, the precursor cells are already embryogenically determined, whereas in indirect somatic embryogenesis, determination has to be induced. In direct somatic embryogenesis a single cell serves as the embryo precursor, whereas in indirect somatic embryogenesis, single cells can be precursors,^[10] although this is not unequivocal^[8] and must be established by cell tracking studies.

Once somatic embryos are formed by direct or indirect somatic embryogenesis, it is common for secondary cycles of somatic embryogenesis to be initiated, suggesting that embryogenicity has been selected for in some way, similar to the increased embryogenicity of regenerated plants in *Medicago truncatula*.^[6] The development of the mature somatic embryo proceeds through stages similar to their zygotic counterparts (Ref. 3, Fig. 1).

THE MECHANISM OF INDUCTION OF SOMATIC EMBRYOGENESIS

An understanding of the induction of somatic embryogenesis requires a number of fundamental effects to be considered, including the consequences of the wounding effect when tissue is excised, hormonal influences, and how the genetic program is reset or redetermined to induce the sequential expression of embryogenic genes (see accompanying flow diagram). Broadly speaking, we can assume that most of the somatic embryo development genes will be similar to *in vivo* embryogenesis, and that it is the induction of somatic embryogenesis that is special.

Hormone Action and Stress Influences

Hormones are the key regulators in inducing embryogenic cells. Although progress has been made in understanding basic hormone action, understanding is required in the context of somatic embryogenesis and in relation to genes such as somatic embryo receptor kinase (*SERK*). In *Daucus carota*, it has clearly been illustrated that stress can both induce and stimulate somatic embryogenesis, and in some studies stress has been related to the production of ABA.^[9]

Redetermining the Genetic Program

There is clearly a complex of signalling pathways to be unravelled to link the earliest hormone- and stress-induced changes to chromosome remodelling and transcriptional activation. Chromatin remodelling involving changes in methylation may be one of the earliest changes.^[3]

Early Embryo Development Genes

An understanding of somatic embryogenesis induction requires that the earliest genes in the embryo pathway be identified. The most substantive work has been carried out on the *SERK* gene, which has been shown to be a marker of embryogenic cells in *Daucus carota*, *Dactylis*, and *Arabidopsis*.^[10] An important result has been the demonstration that transformation of the *SERK* gene into *Arabidopsis* can increase somatic embryogenesis.^[10] The ligand for this receptor and the substrate for serine-threonine kinase activity is as yet unknown. *SERK* expression initiated in cells destined to become embryos continues until the globular stage, and is also part of normal sexual embryogenesis.

CONCLUSION

Somatic embryogenesis is a characteristic of flowering plants that can be unlocked in most species by defined *in vitro* culture of a suitable genotype, explant, and appropriate hormone regulatory signals. Although auxin is a key variable, there are repertoires of strategies that require testing in order to obtain a suitable protocol for somatic embryogenesis in a given species. Understanding the mechanism requires more fundamental knowledge of the genetic regulation of cellular dedifferentiation and differentiation.

Soy Wood Adhesives for Agro-Based Composites

Monlin Kuo

Deland J. Myers, Sr.

Iowa State University, Ames, Iowa, U.S.A.

INTRODUCTION

Before the advent of synthetic thermosetting adhesives in the 1950s, soybean, blood, and casein glues were the major adhesives for production of plywood and other glued wood products. Uncertainty regarding future supplies of petroleum-derived chemicals and stringent regulations on toxic emissions from building materials bonded with certain synthetic resins has compelled the industry to reevaluate wood adhesives from renewable resources. Rapid progress during the past 10 years in the development of soybean-based wood adhesives will be emphasized. The use of agricultural residues for panel products also will be discussed.

HISTORICAL PERSPECTIVES

Soybean-based adhesives were developed in 1928 for Douglas fir plywood production in the U.S. Pacific Northwest.^[1] In the original formulation, partially defatted (extruded and expended) soy meal or flour was mixed with water and dispersed (denatured) with sodium hydroxide. Later formulations also included the use of defatted (solvent-extracted) soy flour and chemicals such as carbon disulfide, hydrated lime, and sodium silicate to impart a better water resistance to the adhesive bonds, and a small amount of preservatives to prevent mold growth.^[2] Soy protein, about 50 to 55% in soy flour, is the active bonding agent. Carbohydrates (over 30%) in soy flour provide useful consistency properties for the glue but contribute little adhesion. Soy protein isolates also were used to formulate wood adhesives, but they did not offer enough advantages over soy flour to offset the cost. Annual consumption of soy meal or flour for plywood in North America was about 60 million pounds in 1940 and reached a peak of 100 million pounds in 1950.^[2]

Soybean plywood adhesives typically contained 20% soy flour and 10% chemical solids in water and had high pH and viscosity. The plywood's assemblies were either cold- or hot-pressed for up to 9 minutes, but it would take several hours to set the adhesive bonds completely. The plywoods adhesive bond strength was adequate, but the adhesive bond had very poor moisture resistance. Petro-

leum-based thermosetting adhesives, mainly urea-formaldehyde (UF) and phenol-formaldehyde (PF) resins, because of their low costs, short hot-press time for a high production rate, and water-resistant adhesive bonds, quickly replaced soybean and other protein glues after World War II. In 1999 North America consumed 4.2 billion pounds of UF for interior plywood, particleboard, and fiberboard and 2.99 billion pounds of PF for exterior plywood and oriented strand board (OSB), as well as 195 million pounds of isocyanate resins for OSB and agro-based particleboard.^[3] Very little proteinaceous wood adhesive is being used today by the wood industry.

CURRENT RESEARCH AND CHALLENGES

Soy-Based Adhesives

Carbohydrates and proteins are the most abundant renewable substances suitable for use as wood adhesives. It is a significant challenge to develop adhesives from these natural substances at reasonable costs to compete with synthetic thermosetting adhesives and to meet stringent performance requirements. The current concept to achieve this goal is to use these natural substances as copolymers with synthetic polymers to reduce the dependency on petroleum-derived chemicals. In this respect, proteins are more suitable than carbohydrates because amino, carboxyl, aliphatic and aromatic hydroxyl, and other functional groups in proteins provide abundant functionality for chemical cross-linking. Research of protein-based adhesives during the past 10 years has been made mainly with soy protein, primarily because of its availability and low cost.

Roland Kreibich (Weyerhaeuser scientist, retired) invented a cold-setting adhesive for finger-jointed lumber containing equal parts of soy protein isolate and phenol-resorcinol-formaldehyde (PRF) resin. In this lumber finger-jointing system, a soy isolate hydrolyzate and a PRF resin are separately applied onto different lumber fingers. Upon joining the two fingers a gel is formed immediately from the cross-linking between soy protein and PRF, and the adhesive bond is cured at the ambient temperature without further application of pressure. This

invention has not been published, but the adhesive is being produced and sold by a chemical company in Oregon. A U.S. patent^[4] describes methods of preparing a soybean-based molding compound for rigid biocomposite materials. This soybean-based powder resin was formulated by cross-linking soy flour with 12% methyl diphenyl isocyanate (MDI). The powder resin was mixed with recycled paper fiber in a ratio of 4 parts resin to 6 parts fiber to produce molded composite products. More recently, a PF-cross-linked soy resin composed of 70% defatted soy flour and 30% of a PF cross-linking agent was developed at Iowa State University.^[5] This light-colored soy resin can be used as a liquid resin for exterior grade plywood or as a powder resin for molded products, but it is not adequate as a spray resin for OSB and fiberboard. Subsequent research at Iowa State University resulted in an adhesive resin containing 70% soy flour hydrolyzate and 30% PF that could be used as a spray resin for OSB and fiberboard production.^[6] A similar PF-cross-linked soy resin composed of 30% soy flour hydrolyzate and 70 % PF has been developed for OSB production.^[7] About 3.5% spray-dried animal blood is used as a forming agent in plywood glues for foam extrusion application. Research at the USDA's National Center for Agricultural Utilization Research has shown that soy protein has desirable mixing and foaming properties for plywood glue foam extrusion.^[8] The potential to replace blood with soy protein in plywood glue formulation would significantly reduce plywood production cost because soy flour is cheaper than spray-dried animal blood (\$0.22/lb vs. \$0.40/lb).

Research on the use of soybean for wood adhesives during the past decade has resulted in the commercialization of the soy isolate/PRF lumber finger jointing system and the MDI-cross-linked soy flour as a compression-molding compound. Development of the PF-cross-linked soy resins and the use of soy flour as a foaming agent in the plywood glues discussed above also are at a stage very close to being commercialized.

Agricultural Fibers

Growing concerns in the United States over the environment have led to changes of forest management practices, resulting in a significant reduction in wood harvest in the midst of a growing demand for wood fiber. The use of agrofibers for pulp and composite materials is commonplace in many parts of the world where there is a lack of forest resources. There is clearly potential in North America to use underutilized agrofibers for industrial purposes, and since 1995 there has been a proliferation of new manufacturing facilities in North America to produce particleboard from wheat straw.^[9] The surfaces of crop plant parts are lined with an inert cuticle layer that is very difficult to bond with UF and PF resins, but it can be

effectively bonded with more expensive isocyanate resins. However, the straw particleboard industry is experiencing difficulties in the use of isocyanate resins, including high resin cost, lack of tack for mat integrity, and the difficulty of releasing boards from hot presses.

Research at Iowa State University favors the use of agrofibers for the production of fiberboard instead of particleboard. The basic assumption is that the specific cuticle surface area can be very much reduced by refining crop residue (e.g., thermomechanical pulping) into pulp so that the resulting fiber furnish can be bonded with UF, PF, or soybean-based resins to produce fiberboard. It has been shown that cornstalk and switchgrass fibers are inferior to wood fiber for fiberboard, but satisfactory medium-density fiberboard (MDF) and high-density fiberboard (hardboard) bonded with UF, PF, and soybean-based resins could be made by mixing equal parts of either cornstalk or switchgrass fiber with wood fiber.^[10]

FUTURE PROSPECTS

The wood products industry in the past 50 years has almost totally depended on petrochemicals for manufacturing wood-based composite products. Since the oil embargo of the mid-1970s, there has been a constant threat of worldwide oil shortage. Therefore, the wood products industry strongly favors research into renewable materials for wood adhesives, and the agricultural industry also is eager to invest in researching such industrial uses to expand their markets. The prices of wood adhesive raw materials fluctuate, but the order of their costs has not changed much in the past 20 years. It ranges from less than \$0.10/lb for urea, followed by soy flour, phenol, blood, melamine, and isocyanates (e.g., MDI), to more than \$1.5/lb for resorcinol. The current price of soy flour is about \$0.15/lb, compared to just under \$0.30/lb for petroleum-derived phenol. Soybean clearly has an advantage over phenol, not only in price but also for its stable future supply. Recently developed soybean-based adhesives may not be fully competitive in performance with synthetic adhesives, but they can be implemented if circumstances require.

Agricultural residue has been an important raw material for pulp and composite panel production in China. Agrofibers also are becoming important raw materials for the same purposes in other regions of the world that are poor in forest resources. The agro-based panel industry in North America has just begun. Based on available volumes of agricultural residues, the North American agro-based panel industry could potentially grow to a size about two-thirds as large as the present wood-based panel industry.^[9]

INTRODUCTION

Crop productivity is regulated by complex interactions among multiple factors that affect plant growth and development. Historically, research has overcome limitations to inherent plant productivity by altering a crop through breeding and genetics, by direct alteration of a crop during its life cycle (bioregulation, pruning), or by altering the growing environment through managed inputs. Scientific advances in these pathways have produced large increases in plant productivity during the 20th century, although there remain considerable differences in crop performance from place to place and from year to year. Variability in crop productivity commonly exists because many of the factors regulating plant performance—soils, weather, pests, and diseases—vary continuously in space and time.

DISCUSSION

Scientists and farmers have made attempts to account for and control the effects of spatio-temporal variation in crop production; however, the tools to effectively deal with this source of variability have lagged behind other advances in plant and crop science. With a suite of technologies and principles composing what is commonly termed precision agriculture,^[1] quantifying and managing for spatial variability in crop production is possible at increasingly smaller scales of resolution. The combination of technologies including global position systems (GPS), sensors, controllers, radios, and high-speed computers makes the acquisition, storage, and use of spatial data possible at extraordinary levels of spatial and temporal detail. However, the value of spatial data would be limited without equally impressive tools to manage and analyze these data and subsequently communicate their meaning to users in a variety of formats.

Two tools of great significance in this regard have evolved over the last few decades. These are geographic information systems (GIS), whose roots date back to the 1960s when cartographers first began to adopt computer techniques in mapmaking,^[2] and geostatistics, first developed for the mining industry, also in the 1960s.^[3] Briefly, a GIS provides a set of tools for collecting, storing, retrieving, transforming, and displaying spatial data for a particular set of purposes,^[2] while geostatistics provides a set of tools aimed at understanding and modeling spatial variability.^[4] Currently, geostatistics is to some extent offered as an integral part of a GIS but commonly, geostatistical analyses are often performed in an external software application dedicated to geostatistics and the resultant data or functions imported into a GIS.

GEOGRAPHIC INFORMATION SYSTEMS

A GIS allows you to visualize agricultural data. Nearly all agricultural data have some form of spatial component, and a GIS allows you to visualize spatially referenced tabular data in meaningful maps—data that otherwise are very difficult to interpret. The GIS represents agricultural data using geographic coordinates, which serve as the foundation for GIS software. GIS software platforms range from field GIS to desktop GIS, to Internet-enabled GIS, to the popular RDBMS (relational database management system) extended with GIS. These scalable GIS platforms operate independently or integrate together for the enterprise. The common geographical coordinate space of agricultural data is a powerful feature of the GIS that lets users from multiple disciplines manage a project and collaboratively share their work. A farmer, an agronomist, and an agricultural economist can all assess a crop condition and evaluate it using their own professional practices, which are applied through the GIS. Specialized features in the GIS serve to document each sequential

spatial operator and process used. This allows different users to compare and share their spatial analyses and results for optimum decision making.

An agricultural landscape is made up of many interconnected spatial components; a GIS is used to model and analyze this complexity. Georeferenced map layers can include hydrological features, soil characteristics, slope and its derivatives, yield, pests, and anything relevant to a particular investigation. The functionality to extract and highlight certain data features from one layer of information by defining a data feature from a second layer is a powerful analytic tool. Spatial operations are available, like distance buffers that allow the determination of boundaries around a location such as a creek. Some features—an irrigation well, for example—have many associated attributes that cannot be defined as a simple location. Knowledge about a well's depth, the salinity of its water, and the time required for an aquifer to recharge it are some of the data attributes that can be evaluated with a GIS.

A field GIS provides the ability to look at images and maps of fields while actually standing in them. Editing capabilities provide the functionality to map a measurement or observation such as those encountered in crop-scouting activities. Users are able to collect in the field whatever information is relevant to them and record it directly using the map to provide the geographic location. The data highlighted and recorded in the field GIS map can be transferred to other GIS platforms, such as an Internet GIS server, or to a desktop GIS.

Desktop GIS software provides tools to carry out more intensive computational procedures such as those made using satellite images or aerial photographs. Images are generally raster based, being made of discrete cells with numeric values. Data layers that are made up of points, lines, and polygons are referred to as vector data. Raster data can be combined with vector data, but require different tools for management and interpretation. Remote sensing/GIS applications include estimating crop vigor, the remote estimation of areas in a field that are under physiological stress, and the documentation of natural resource conditions, such as soil erosion extent.

A GIS is well suited to address significant social and economic issues related to agriculture, although the mechanics of engineering a GIS solution from the farm field to the grocery store shelf can be complex. For example, the geodatabase underlying a GIS can be engineered for the application development of intelligent polygonal objects that can spatially account for transactions in the food supply chain for identity preserve (IP) requirements. This type of GIS implementation is able to record every transaction on every parcel, warehousing metadata and other critical data required for future certification of genetically modified organism (GMO) compliance regulations.

GEOSTATISTICS

Although spatial data are essential to GIS, they are sometimes too expensive or difficult to obtain. Fortunately, techniques are available to model spatial variability based on limited sampling from which estimates of spatial data can be obtained. These so-called geostatistical techniques rely on the concept of spatial continuity (i.e., the notion that two attributes close to each other are more likely to have similar values than are two that are far apart).

The scientific methods used to collect, summarize, analyze, and interpret empirical data that are referenced geographically are assembled under the heading of spatial statistics. The three main components of spatial statistics are distinguished through the data structures as methods applicable to lattice, point pattern, and geostatistical data. A geostatistical data set consists of measurements or classifications of one or more attributes of interest, along with the geographic coordinates at which the observations were obtained throughout a continuous domain.

Statistical methods appeal to a random mechanism in order to separate sources of variation. Consider, for example, the sampling of crop yield on a field at 50 randomly chosen locations. The geostatistical method appeals to a random mechanism that generates the entire (continuous) crop yield surface (a random field). The 50 samples represent an incomplete observation of a randomly generated, continuous surface. It is of interest to reconstruct the surface by predicting the yield values at unsampled locations (i.e., to produce a continuous map of crop yields). Worth noting is that a second realization—in the statistical sense—of the random process would lead to a different crop yield surface.

The prediction task is accomplished by methods of kriging. The term ‘kriging’ was coined by Matheron^[3] in recognition of mining engineer D.G. Krige. Although kriging is often considered an optimal method of spatial prediction, the classical kriging predictors are best only in the sense of minimizing the mean square prediction error in the class of predictors that are unbiased and linear functions of the observed data.

Computation of the kriging predictor requires: 1) knowledge (simple kriging) or a model of the large-scale trend (constant mean: ordinary kriging; linear mean function: universal kriging), and 2) the ability to evaluate the autocovariance between attributes at spatial locations. In practice, the large-scale trend and the spatial covariance structure are usually subject to estimation. Because estimating the autocovariance or semivariance (one-half the variance of the difference between two attributes) is usually not possible without some form of stationarity assumption (the expected value is constant and does not depend on position), it is important to remove large-scale trends in the data prior to estimating covariances or the semivariogram to

prevent these representations of the second-order structure from depicting spurious spatial dependencies. Alternatively, methods that estimate large-scale trend and spatial correlation structure simultaneously can be employed. Likelihood methods belong to this latter class and have recently gained much momentum. Even for stationary processes, the fact that process parameters are estimated is typically not reflected in measures of prediction error. Estimates of the prediction error that consider estimates of semivariogram (covariogram) parameters as fixed quantities tend to overestimate the precision of kriged maps.

Through the years, a large number of kriging variants were developed to cope with the varied situations in which predictions of random attributes are needed. We mention by name only a few: block-kriging, indicator kriging, probability kriging, trans-Gaussian kriging, log-normal kriging, cokriging, and disjunctive kriging. For details on the various kriging methods and their implementation consult, for example, Journel and Huijbregts,^[5] Cressie,^[6] Chilès and Delfiner,^[7] and Schabenberger and Pierce.^[8] The basic premise of these variations is the same: to obtain predictions that are best based on the second-order properties of the process under study.

It has been questioned whether the rapid increase in the complexity of scientific questions can be met by current or new geostatistical concepts based on these classical ideas.^[9] In particular, as the temporal component in spatial data is becoming increasingly important, new approaches for modeling and analyzing spatio-temporal data structures may be called for that make allowances for nonstationarity in time and/or space. Hierarchical spatial models that incorporate spatial correlation structures implicitly by considering parameters of a spatial model not as fixed quantities but as random variables at different temporal and/or spatial scales offer great promise in this regard.

CONCLUSION

Projected advances in computer processing and storage capacity suggest that in the near future, such massive

amounts of data will be collected and stored that very little data will ever see the human eye; rather, data will be automatically processed and relevant information graphically displayed. Thus, spatial data will become increasingly available and the ability of plant and crop scientists to understand the spatio-temporal dimensions of agriculture will become increasingly important in the production and marketing of food. Both GIS and geostatistics will be tools of choice for plant and crop scientists as they strive to manage and understand the spatial nature of agricultural data.

Spatial Distribution of Weeds

J. A. “Anita” Dille

Kansas State University, Manhattan, Kansas, U.S.A.

INTRODUCTION

Individual weed species do not occur randomly or uniformly but as part of aggregated or patchy populations in agricultural fields. Furthermore, population densities vary greatly across individual fields such that there are areas of no weeds mixed with areas containing weeds that range from low- to high-density populations. If we can characterize the spatial distribution of weeds and understand the causes that generate this distribution, site-specific weed management systems can be developed.

CHARACTERIZING THE SPATIAL DISTRIBUTION OF WEEDS

The spatial distribution of weeds can be described by conducting surveys to collect specific location information across multiple sampling points. Two main types of weed survey methods include grid-based and remote-sensing approaches.

In a grid-based approach, weed species are identified and counted with a quadrat-sampling frame, typically 1 m², located at specific grid-intersection points in a given area (Fig. 1). These intersection points can be regularly or randomly distributed throughout the area. The grid spacing used in various research studies has varied from 7- to 24-m intervals.^[1–3] The appropriate scale to assess the spatial distribution of weed populations, and subsequent choice of sample grid spacing, will depend on the desired end use of the spatial information. For regional management of noxious weeds, general geographic regions where the species occurs can be identified.^[4] At the individual field level, a grower may indicate that a certain weed species is a problem in the entire northwest corner of the field, but once surveyed, individual patches can be identified within that corner^[1,2] (Fig. 2). For weed population dynamics modeling, small grid spacing is appropriate to obtain detailed weed information.^[5] From a site-specific weed management perspective, information on the equipment to be used for weed control, such as the width of the spray boom or tillage equipment, will likely mandate larger grid spacing.^[6]

Data from individual field surveys typically have frequency distributions with 60–90% of the sample sites

having no weed seedlings, whereas a small number of sample sites have densities ranging from 60–200 seedlings/m².^[3] Spatial statistics (geostatistics) can be used to further describe and map spatial distributions of weeds where standard statistical approaches are confounded by spatial autocorrelation; that is, data collected from sites closer in space are more closely related than data from sites further away in space.^[3,7–10]

In a remote-sensing approach, aerial images of color or spectral reflectance are obtained from ground-, airplane- or satellite-based equipment and provide pixilated data (contiguous 1-m² pixels, for example) of agricultural fields. Weed populations must then be discriminated from crop, soil, and other residues in the image based on unique spectral signatures^[11,12] or image analysis.^[13] Remote-sensing approaches automate the procedure of surveying fields. Two challenges include obtaining aerial images in a timely fashion, such as when in-season weed control decisions must be made, and ensuring that weed populations are being captured in the image by on-the-ground sampling.

Data obtained from these two approaches are used to generate maps of the spatial distribution of weeds, providing population estimates at unsampled locations across the field if using the grid-based approach^[5] or estimates of weedy ground cover using the remote-sensing approach.^[12] Maps of the spatial distribution of weeds are used to develop maps that direct application of weed control practices. A weed control practice, such as herbicide or tillage applications, is applied if the weed population density at a given location is above a treatment threshold.^[14–16] This is the basis of a site-specific weed management system.

CAUSES FOR SPATIAL DISTRIBUTION OF WEEDS

In an agricultural row crop environment, abiotic, biotic, and human factors contribute to the spatial distribution pattern of weeds. Understanding the extent to which each factor contributes to the pattern could lead to improvements in site-specific weed management. Abiotic factors include topography, soil texture, soil pH, organic carbon, and soil fertility, which vary spatially in fields. Spatial

Fig. 1 Regular (a) and random (b) distribution of sampling points across a field.

correlation exists between certain abiotic factors and weeds, and causes have been hypothesized.^[2,17] For example, certain weed species may emerge through a soil-applied herbicide that has interacted with soil texture and organic matter making it less active for weed control.^[18,19] Another is that variation in soil fertility or available soil moisture will influence crop and weed growth, competitive interactions, and potential weed seed productivity.^[2]

Biological characteristics of weeds and additional biotic factors in the environment can influence their spatial distribution. Often, weed seedlings are clustered around the parent plant because of localized seed dispersal, enhancing patchiness.^[20,21] Alternatively, the extent of clustering depends on activity of dispersal agents (wind, animals), weight and shape of weed seed, distribution of parental plants in the field, and potential

Fig. 2 Representation of a field with individual oval patches located within a general infestation in the northwest corner of the field.

longevity of seed in soil. Seedling emergence patterns are influenced by spatially variable soil temperature and moisture in the field and by higher survival of seedlings in response to soil- and foliar-applied herbicides in high- rather than low-density populations.^[22] Individual shoots of perennial weeds, such as Canada thistle,^[9] hemp dogbane,^[23] and johnsongrass,^[24] show spatial aggregation caused by clonal growth.

Human factors include all agricultural practices employed such as soil tillage, crop choice, weed control methods, and harvesting procedures. Patchiness may be reduced because of soil tillage practices or harvesting equipment spreading weed seed or perennial shoots away from the location of the parent plant. Patchiness is enhanced through weed control application errors such as sprayer skips or poor crop establishment resulting in less competitive crop environment against weeds.

Seed and seedlings of most weed species generate a patchy spatial distribution. However, numerous studies and observations have indicated that these patterns are highly irregular. The spatial distribution of weed species is a result of complex interactions of abiotic, biotic, and human factors.^[2,8,20,21]

FUTURE PROSPECTS

The fact that individual weed species are neither randomly nor uniformly distributed has implications in 1) developing efficient scouting protocols to accurately estimate weed population densities, 2) predicting yield losses caused by those densities, and 3) managing weed populations using site-specific weed management systems. Research continues in the areas of scouting for weed populations so that it will be less labor intensive while still providing detail. For example, real-time reflectance or image analysis sensors are being developed that can detect weeds and activate herbicide “patch” sprayers as equipment is driven through the field.^[25]

Understanding the spatial distribution of weeds, where they occur and why, has the potential to more accurately apply weed control practices where and when needed, change crop and soil management practices to discourage weeds, and reduce economic and environmental costs associated with weed control.

Starch

Wolfgang Eisenreich
Alfons Gierl
Adelbert Bacher

Technische Universität München, Garching, Germany

INTRODUCTION

The seeds of cereals are an important metabolic sink and an essential source of human and animal nutrition. Information on the biosynthetic pathways of carbohydrates, amino acids, and vitamins in crops provide the basis for the metabolic engineering of plants with improved nutritional profiles. In plants, pathways leading to starch, amino acids, and vitamins have been investigated in some detail at the level of enzymes and their cognate genes, but quantitative aspects of carbon flux including transport processes under *in vivo* conditions have been investigated less comprehensively.

Although it is clear that isotope incorporation studies can contribute important metabolite flux information, most isotope incorporation studies in the literature are limited to simple concepts that assume metabolism proceeds in a linear and unidirectional fashion. Based on this implicit assumption, the diversion of isotope from a given precursor to a given target compound is accepted as evidence for direct metabolic relatedness between the respective molecular species. In reality, however, metabolism is a complex and nonlinear network, and metabolic flux can occur from any node in the network to virtually any other node. As a consequence, isotope incorporation studies have been repeatedly plagued by remarkable errors of interpretation.

Recently, relatively fail-safe alternatives using general ^{13}C -labeled precursors (such as glucose or acetate) have been developed for the quantitative assessment of carbon fluxes in microorganisms and plants. As an example, this article describes studies on the formation of starch in kernel cultures of maize.

ISOTOPOMER EQUILIBRIA

Terrestrial carbon is an isotopic mixture of 98.9% ^{12}C , 1.1% ^{13}C , and traces of ^{14}C . Consequently, all organic compounds are complex isotopomer mixtures. For any 6-carbon compound (e.g., glucose), the number of non-radioactive carbon isotopomers is $2^6 = 64$. The isotopomer composition of glucose with natural ^{13}C abundance is

close to the state of chemical equilibrium; minor deviations caused by isotope selectivity of enzymatic reactions are below the level of sensitivity of the method used in disturbance studies and thus can be disregarded. The approximate abundances of different isotopomers in naturally occurring glucose are summarized in Fig. 1(A). Isotopomers that are labeled with ^{13}C at multiple positions do not occur in significant amounts. Notably, the sum of the concentrations of all naturally occurring isotopomers with two or more ^{13}C atoms in glucose with natural isotope abundance is less than 0.07 mol%.

The quasi-equilibrium isotopomer distribution of biomass can be perturbed by the introduction of any singly or multiply ^{13}C -labeled metabolite. Cellular metabolism is then conducive to a complex relaxation process in which virtually all chemical reactions occurring in the experimental system are involved. Whereas catabolic processes direct the system to a new equilibrium state (characterized by an increased ^{13}C abundance in the case of closed systems), anabolic processes are conducive to metastable states that can be gleaned from the assimilated biomass (i.e., proteins, polymeric carbohydrates, lipids). It is obvious that enzyme reactions involving the breaking or formation of carbon/carbon bonds play a central role in these relaxation processes.

A detailed analysis of the isotopomer populations formed by the enzyme-catalyzed relaxation processes in the wake of a perturbation (by introduction of a multiply-labeled metabolite) is possible by nuclear magnetic resonance (NMR) analysis^[1] and affords an abundance of information that can not be obtained by traditional experimental setups that monitor global isotope enrichment or enrichment at selected positions but fail to document the quantitative composition of the entire isotopomer population.

ANALYSIS OF STARCH BIOSYNTHESIS IN KERNELS OF MAIZE

Using this methodology, the biosynthesis of starch was studied with immature maize kernels that were grown in sterile cultures and then supplied with a mixture of

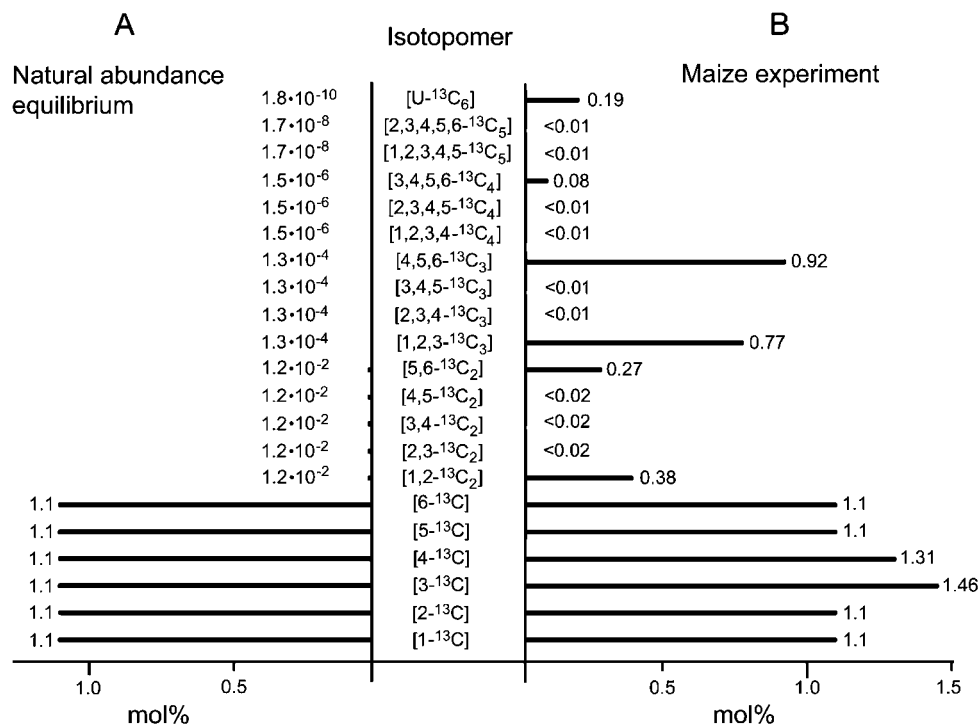

Fig. 1 Molar abundance of ¹³C isotopomers of glucose. A. In natural abundance material; B. In starch hydrolysate from maize kernels supplied with [U-¹³C₆]glucose and unlabeled glucose at a ratio of 1:40 (w/w).

[U-¹³C₆]glucose and unlabelled glucose at a ratio of 1:40 (w/w).^[2] After growth, starch was hydrolyzed and the resulting glucose was isolated and analyzed by quantitative NMR spectroscopy. The detailed description of the NMR analysis has been published,^[2] and will not be repeated here.

Of the 57 ¹³C-isotopomers of glucose that were labeled at more than one position, six occurred with an abundance above 0.08 mol% (Fig. 1(B)), i.e., well above their stochastic occurrence in natural abundance glucose (Fig. 1(A)). Notably, the abundance of [U-¹³C₆]glucose in the sample is nine orders of magnitude above the level of that isotopomer in natural abundance glucose. Two isotopomers carrying single ¹³C atoms ([3-¹³C₁]- and [4-¹³C₁]glucose) also occurred with increased abundances of 1.46 and 1.31%, respectively, due to the metabolic processes.

The relative paucity of the [U-¹³C₆]-isotopomer (0.19 mol%) shows that the carbon skeleton of the vast majority of the proffered carbohydrate precursors had been broken and reassembled at least once. Glycolysis followed by glucogenesis results in breaking of the C3/C4 bond of glucose. Passage of glucose through the pentose phosphate pathway during regeneration of a hexose is conducive to breaking the C2/C3 bond (transketolase activity, Fig. 2) and/or the C3/C4 bond (transaldolase activity) of hexoses. Evidence for both processes is

immediately obvious from the relatively high abundance of [1,2-¹³C₂]-, [1,2,3-¹³C₃]-, [4,5,6-¹³C₃]-, [3,4,5,6-¹³C₄]-, and [3-¹³C₁]-isotopomers (Fig. 1).

The [5,6-¹³C₂]- and [4-¹³C₁]- isotopomers can be explained by the cooperative action of the pentose phosphate pathway and the glycolysis/glucogenesis pathways (Fig. 3). Thus, the transfer of a [¹³C₂]-fragment from [U-¹³C₆]fructose 6-phosphate to unlabeled erythrose 4-phosphate derived from unlabeled glucose generates [1,2-¹³C₂]pentulose 5-phosphate and, subsequently, [1,2-¹³C₆]hexoses (via transketolase catalysis) (Fig. 2). Glycolysis can produce [2,3-¹³C₂]dihydroxyacetone phosphate from the double-labeled hexose, which yields [2,3-¹³C₂]glyceraldehyde 3-phosphate by the catalytic action of triose phosphate isomerase. Regeneration of a hexose from [2,3-¹³C₂]glyceraldehyde phosphate, either by glucogenesis or via the pentose phosphate pathway could afford the [5,6-¹³C₂]glucose isotopomer observed in our experiment (0.27 mol%) (Fig. 3). The abundance of the [5,6-¹³C₂]-isotopomer is only slightly lower (about 30%) than that of the [1,2-¹³C₂]-isotopomer from which it is proposed to be formed by the sequence of events described earlier. This suggests that the interconnection of the pentose phosphate pathway and the glycolysis/glucogenesis pathways is operating quite efficaciously. More specifically, the data indicate that 87% of the glucose moieties of this

Fig. 2 Formation of [1,2- $^{13}\text{C}_2$]- and [3,4,5,6- $^{13}\text{C}_4$]hexose phosphate by the catalytic action of transketolase in the pentose phosphate cycle. Bonds in bold type connect ^{13}C atoms in multiply ^{13}C -labeled isotopomers derived from [U- $^{13}\text{C}_6$]glucose in the precursor mixture.

precursor are not directly derived from external glucose; the hexose is recycled with high efficiency by the pentose phosphate pathway and glycolysis/glycogenesis, prior to their fixation in starch via the well known intermediate ADP-glucose^[3] (Fig. 4).

Plant metabolism is a very complex network, even when only carbohydrate metabolism in a maize endosperm cell is under investigation. Metabolic reactions

involving hexoses take place in the cytosol and in the amyloplast of these cells. In fact, with the exception of the nonoxidative branch of the pentose phosphate pathway—which is localized in the maize plastid^[4]—both compartments harbor redundant sets of enzymes catalyzing both anabolic and catabolic reactions. The metabolite pools of the cytosol and the amyloplast are efficiently connected by transporters for triose phosphate,

Fig. 3 Pathways for the formation of [1,2,3- $^{13}\text{C}_3$]-, [4,5,6- $^{13}\text{C}_3$]-, [1,2- $^{13}\text{C}_2$]-, [5,6- $^{13}\text{C}_2$]-, [3- $^{13}\text{C}_1$]-, and [4- $^{13}\text{C}_1$]-isotopomers of hexose phosphate in the perturbation experiment with [U- $^{13}\text{C}_6$]glucose.

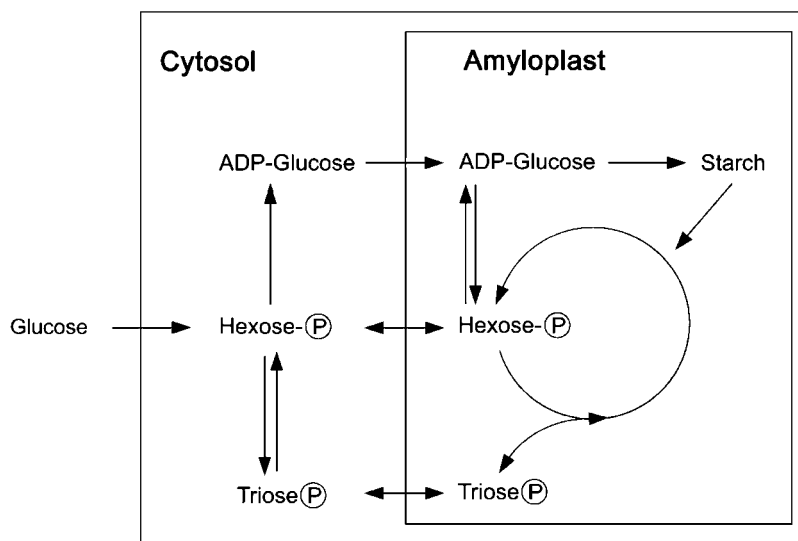

Fig. 4 Metabolic networks involved in starch biosynthesis in growing kernels of maize. The pentose phosphate pathway is shown as a circle in the amyloplast.

hexose phosphate, pentose phosphates, and ADP-glucose that enable metabolite flux and maintain the phosphorus balance in the different compartments of the cell^[5] (Fig. 4). In this context, the extensive cycling processes inferred from the glucose labeling pattern describes a flexible metabolic network that serves the physiological needs of the cell.

CONCLUSION

The perturbation of ¹³C-isotopomer equilibria by general ¹³C-labeled precursors (e.g., glucose) can serve to analyze carbon fluxes in complex metabolic networks with high resolving power. Many biosynthetic isotopomers of glucose can be assessed quantitatively by NMR analysis and provide detailed information about carbon-carbon connectivities that had been either retained or broken and regenerated during the metabolic conversion of glucose into starch. The technique can now be exploited to investigate and compare glucose flux under different physiological conditions.

Striga: A Subterranean Parasitic Angiosperm (Witchweed)

John I. Yoder

Department of Plant Sciences, University of California-Davis, Davis, California, U.S.A.

Lytton John Musselman

Department of Biological Sciences, Old Dominion University, Norfolk, Virginia, U.S.A.

INTRODUCTION

Striga is a parasitic angiosperm that invades the roots of other plants to rob them of water and essential nutrients. The effects on the host plant can be debilitating, and *Striga* is among the world's most destructive agricultural pests. The success of *Striga* as an agricultural weed is owing in large part to its intimate and obligatory association with its host plant. At several stages in its life cycle, *Striga* uses chemicals that are released by the host to trigger developmental events critical for the parasitic lifestyle. The host–parasite communication system provides genetic targets for the development of resistant crop varieties.

STRIGA TAXONOMY

Striga is the genus of root parasites in the plant family Orobanchaceae. All of the 30 or so genera of Orobanchaceae are root parasites that realize at least some nutritional value by parasitizing other plants.^[1] The effects on the host plants can be debilitating, and some of the world's most destructive agricultural weeds are parasitic Orobanchaceae, the most important of which is *Striga*.^[2] Of primary agricultural concern are two species that parasitize cereal crops, *Striga hermonthica* and *S. asiatica*, and one that parasitizes broadleaf dicots, *S. gesnerioides* (Fig. 1).

Striga is found in Africa, Arabia, East Asia, India, China, Indonesia, and Australia. Despite quarantine restrictions against *Striga* in U.S.A., there have been sporadic infestations, the most notable being an infestation of the Carolinas in the 1950s, which was the target of an extensive control and eradication program.^[3]

AGRICULTURAL SIGNIFICANCE OF STRIGA

Striga is colloquially known as witchweed, because it “bewitches” the growth of crops before it appears above the ground. Parasitism by *Striga* results in stunted growth and yellow- or brown-wilted leaves (Fig. 1C and E). The degree of host damage is in part

dependent on the host–parasite ratio. However, the reduction in host biomass exceeds the corresponding increase in the parasite; so clearly *Striga* causes pathogenesis beyond nutrient deprivation.

Because *Striga*'s host range includes food crops of many poor farmers in lesser-developed countries, it has an enormous impact on food security. Approximately two-thirds of agricultural land in sub-Saharan Africa is infested with *Striga*, and complete losses to maize, sorghum, and millet crops may occur. *Striga* is a primary biotic constraint to agricultural production throughout much of the semiarid world.^[4]

STRIGA BIOLOGY

As a parasitic plant, *Striga* straddles the boundary between autotrophy and heterotrophy with about half its life taking place underground (Fig. 2). Without sunlight, achlorophyllous seedlings gain nutritional needs by invading the roots of nearby host plants through invasive structures called haustoria. *Striga* lives about six weeks as an obligate, subterranean parasite before emerging from the soil to flower. While *Striga* species perform limited photosynthesis after emergence, the bulk of fixed carbon in the parasite is obtained from the host.^[6]

Key to *Striga*'s success is a remarkable host plant recognition system based on the perception of infochemicals released by host roots. *Striga* and other Orobanchaceae use host molecules to induce developmental events associated with plant parasitism.^[7] The developmental stages in *Striga* that depend on host factors are targets for developing genetic resistances in crops.

Germination

A single *Striga* plant produces hundreds of thousands of tiny seeds (0.3–0.5 mm) that are dispersed by wind and water in nature but spread more widely through contaminated seed. Because *Striga* must attach to a host root within a few days of germination, seed germination is carefully regulated to ensure parasitism. *Striga* seeds

must first be imbibed with water at particular temperatures and then exposed to factors exuded from host roots that stimulate *Striga* germination.

The potential to use germination factors to precociously germinate *Striga* in the absence of host crops motivated early biochemical efforts to identify the active molecules. Parts of Fig. 2, i.e., 2 and 3, diagram strigol, the first of several natural and synthetic germination factors identified.^[5] Most are sesquiterpene lactones that are active at picomolar concentrations. Unfortunately the biosynthesis of these molecules is complex and their use as control agents in subsistence farms field settings has not been possible.

Haustrorium Development

A germinated *Striga* seed will produce a radicle superficially resembling other plants. However, the radicle will not develop beyond about 5 mm, unless a host root is contacted. Upon contact with the host, the *Striga* tip

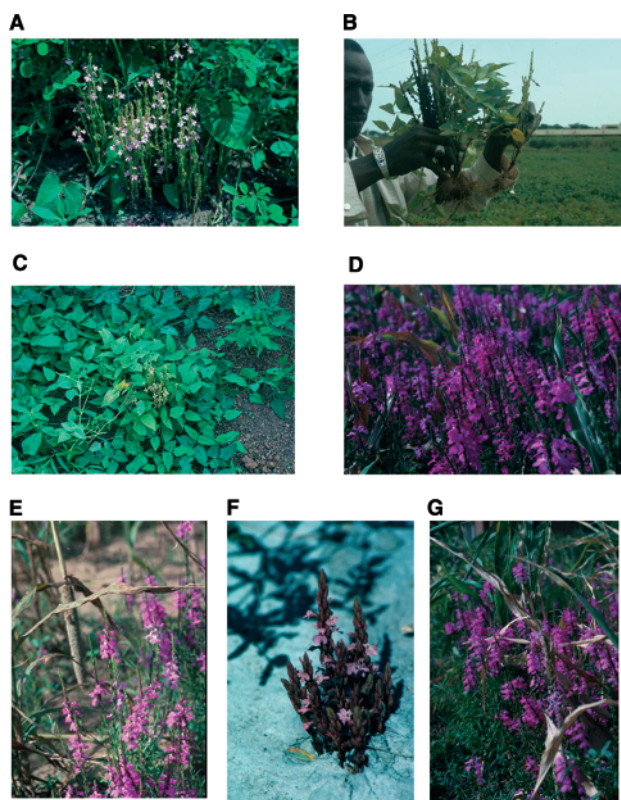

Fig. 1 *Striga* plants in natural settings. (A) *S. gesnerioides*, Florida, U.S.A. (B) *S. gesnerioides* on cowpea (*Vigna unguiculata*), Mali. (C) *S. gesnerioides* on cowpea, Benin. Fig. 2 *Striga* life cycle parasitizing maize. 1. Although parasitic, *Striga* resembles any other dicot with perfect flowers that can be either self pollinating or out-crossing. 2. A single plant produces 50,000–200,000 tiny seeds. Prolific seed production together with tight regulation of germination results in the buildup of large *Striga* seed banks that persist in the soil for many years. 3. Strigol was the first *Striga* germination factor identified and is typical of a group of strigolactones that induce germination. 4. *Striga* germination occurs after a period of environmental preconditioning followed by exposure to a host encoded germination factor. 5. The haustorial inducing factor 2,6 dimethoxybenzoquinone (DMBQ) is a secondary metabolite broadly represented in angiosperms as a component of lignin. 6. Early haustorium development is observed in vitro as an almost immediate cessation in radicle elongation, an isodiametric swelling of cortical cells at or near the tip, and the transformation of epidermal cells into haustorial hairs. Diagram represents about 24 hr after treatment. 7. The *Striga* seedling attaches to a host root via adhesive molecules produced at the tips of the haustorial hairs and an intrusive peg penetrates host tissues. The haustorium develops vascular connections between the host and parasite, which are represented by dashed lines. 8. A shoot emerges from the haustorium and secondary roots produce lateral haustoria that infect additional host roots. The subterranean heterotrophic life phase of *Striga* lasts about four to five weeks. (From Ref.^[8], redrawn from Kuijt, 1969.)

differentiates into a primary haustorium, a bulb-shaped structure covered by long epidermally derived hairs.^[8] These haustorial hairs exude factors that bind the haustorium to the host root. An infection peg

then penetrates the host through a combination of enzymatic and intrusive growth.

Early haustorium development can be induced in vitro by applying host root exudates or purified root factors to the parasite root. This has allowed the identification of certain phenolics and quinones, collectively termed “xenognosins,” with haustorium-inducing activity.^[9]

Postinvasion Events

Once the haustorium penetrates the host, another set of host infochemicals influence *Striga* maturation. An obvious manifestation of host-affected haustorium maturation is the development of xylem elements that connect host and parasite vasculature. These can be observed within two days of host–parasite contact. Typical phloem elements are not observed, and the transport of water, sugars, and inorganic minerals is through transfer cells and xylem.

The *Striga* stem continues to grow toward the surface and extends secondary roots into the soil. Secondary roots can develop haustoria on their lateral surfaces, which further invade host roots. A mature *Striga* plant can have an extensively branched root system with numerous haustoria invading a single or multiple host roots. The *Striga* life span from germination to seed set is about three months, the entire period of which it continues to feed off the host.

CONCLUSIONS

Striga is the representative of a small group of organisms at the juncture between autotrophy and heterotrophy. The study of parasitic plants such as *Striga* provides the unique opportunity to investigate molecular events associated with the evolution of

heterotrophy. *Striga* is also a devastating parasitic weed that affects some of the poorest farmers on earth, and novel control strategies are needed. Multiple stages in *Striga*'s life cycle require chemical signals that are made by the host plant, and these developmental stages provide genetic targets for weed-control interdiction.

Sucrose

Ed Etxeberria

University of Florida, Lake Alfred, Florida, U.S.A.

INTRODUCTION

Sucrose plays a unique role in the plant kingdom. Aside from being the primary product of photosynthesis and the main form of carbon transport in plants, sucrose constitutes the most abundant form of soluble storage carbohydrate and also serves as a signaling molecule that triggers essential metabolic events. Furthermore, sucrose plays a key role in plant reproduction and propagation. In nectars, sucrose concentration can determine the type and frequency of visiting pollinators, which may change with the sexual state of the flower, and its presence in fruits serves as an attractant to animals for seed dispersal. A readily available source of energy, sucrose sustains the initial stages of growth after dormant periods in temperate plants. From photosynthetic cells in leaves to heterotrophic root cells, sucrose is found in virtually every living plant cell. There are other soluble saccharides present in plants, and in all cases they are accompanied by high levels of sucrose. In effect, sucrose is the ultimate building block for all other organic compounds in plants and most other carbohydrates in nature, given the position of plants as the cornerstone of the energy food chain.

WHY SUCROSE?

The reason for the ubiquitous position of sucrose in the plant kingdom is not evident. In comparison with trehalose, the other prominent disaccharide found in nature with equivalent functions in insects and fungi, and with raffinose-based saccharides, which are commonly found in various plant species, several conjectures have been made.^[1] Based on the process of natural selection to perform equivalent functions, the general premise is that these molecules must share important properties that impart physiological advantages. A common characteristic to all aforementioned saccharides is their nonreducing nature. Nonreducing molecules are less reactive and less susceptible to breakdown by the cellular enzymatic milieu. Their high energy of hydrolysis conserved in their glycosidic linkage makes these molecules more valuable

as energy currency and as a readily available carbon source. Two other disaccharides found in living systems, maltose and lactose, have glycosidic linkages with less than half the energy of hydrolysis of sucrose. Finally, both of these molecules have been shown to protect membrane lipids during dehydration and freezing, and to help stabilize organelles and proteins.

FROM PHOTOSYNTHETIC PRODUCT TO THE PHLOEM STREAM

In green cells, glucose 1-phosphate and fructose 6-phosphate are synthesized in the cytosol from triose-phosphates that are produced in the Calvin cycle and exported from the chloroplast. Sucrose is synthesized from UDP-glucose and fructose-6-phosphate in a sequence of two reactions catalyzed by sucrose-phosphate synthase (SPS) and sucrose-phosphate phosphatase (SPP). Both enzymes are localized in the cytosol and appear to form a metabolic unit during synthesis.^[2] Regulation of sucrose synthesis is a complex system that involves fine and coarse control.^[3] Although some controlling elements have been described, it is likely that other factors yet to be discovered may contribute to the overall regulation and may modify prevailing opinions about sucrose synthesis. In photosynthetic cells, newly synthesized sucrose has two potential fates depending on cellular, physiological, and environmental factors. Sucrose is either stored in the vacuole and/or exported to supply carbon to heterotrophic cells. Temporary storage of excess sucrose in the vacuole usually takes place at times of high photosynthetic activity and limited phloem loading capacity. The mechanisms of sucrose transport into the vacuole of green cells are not fully understood, but the process is believed to be mediated through a passive transport mechanism.^[4]

The movement of sucrose from mesophyll cells to the phloem elements can take various routes depending on the plant species, and it involves different cell types (Fig. 1). One route consists of intracellular symplastic movement of sucrose across the plasmodesmata of leaf cells and eventual release into the sieve element/companion cell

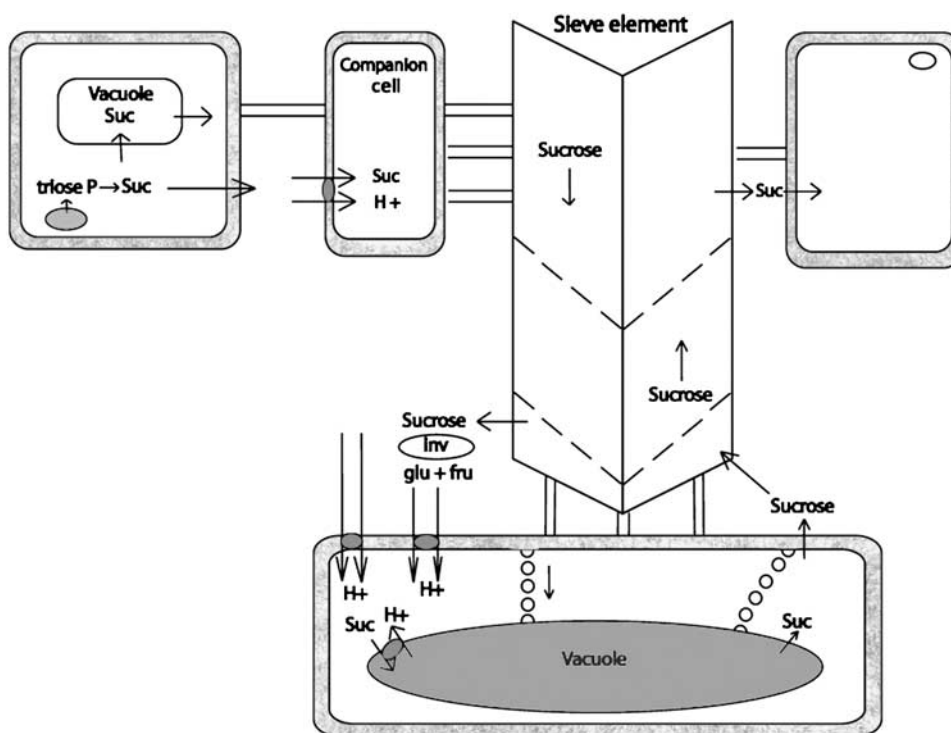

Fig. 1 The cycle of sucrose in a plant, from its synthesis to its storage and utilization. Synthesized in the leaves from photosynthetic products, sucrose is exported to support heterotrophic cells and/or stored temporarily. Along the transport route, the involvement of several carriers is required, either for retrieval of leaked sucrose or as part of the apoplastic route. Once stored, the direction of sucrose transport is reversed to sustain developing plant parts. Loss of sucrose to herbivore consumption can occur at many points along the route. (View this art in color at www.dekker.com.)

(SE/CC). In the second route, sucrose is released into the extracellular apoplast at some point, where it diffuses through the cell wall milieu. After reaching the SE/CC complex, sucrose is retrieved by the well characterized plasmalemma-bound sucrose/ H^+ symport.^[5] Accumulation of sucrose in the SE/CC increases the hydrostatic pressure, which drives mass flow transport to other plant parts via the phloem.

FROM THE PHLOEM TO HETEROTROPHIC CELLS

It is not known whether release of sucrose along the phloem pathway or at the sink end of the phloem route is also proton coupled, occurs by diffusion, or involves transport through the symplast along heterotrophic cells. Sieve element unloading invariably includes an apoplastic component, but its contribution to the overall unloading process depends on many factors and seems to be restricted to specialized circumstances and tissues.

Symplastic unloading and transport apparently constitute the principal unloading route. In most cases, there is evidence indicating that sucrose exits the phloem cells and is transported to heterotrophic cells through plasmodesmata connections. Although plasmodesmata connections are present along the entire length of the transport path, efflux seems to occur only at specific regions (Fig. 1).^[5]

That sucrose and other photoassimilates are transported into heterotrophic cells through the symplast has been largely inferred from the existence of plasmodesmata connections, the observed transport of large protein or fluorescent probes to the storage cells, and the use of transport inhibitors and transgenic plants. However the presence of plasmodesmata is not a universal characteristic within heterotrophic cells, and transport through the apoplast is undoubtedly required in some instances.^[6] The apoplastic route is necessary in cases where there is symplastic discontinuity between two tissues, as is the case for filial and maternal tissue in developing seeds. Once released into the apoplast, sucrose may be hydrolyzed into glucose and fructose

by cell wall-bound invertases to maintain a concentration gradient. The situation is quite complicated, given that in some organs (such as potato) both types of postphloem transport take place, depending on developmental stage.

STORAGE OF EXCESS SUCROSE

Whereas some of the sucrose entering the cell is utilized to satisfy immediate metabolic demands, excess sucrose is stored in the vacuole for future needs. The mechanism of sucrose transport into the vacuole of heterotrophic cells depends on its entrance pathway into the cell. Symplastically loaded sucrose needs to traverse only one membrane barrier into the vacuole: the tonoplast, which is believed to possess a sucrose/H⁺ antiport. Such an antiport system has been identified at the tonoplast of a few storage cells such as red beet (*Beta vulgaris*) and Japanese artichoke (*Stachys sieboldii*), but this system is conspicuously absent from the high-sucrose-storing cells of sugarcane (*Saccharum officinarum*) and sweet lime (*Citrus limettioides*).

Where sucrose unloading takes the apoplastic route, the plasmalemma offers an additional barrier to accumulation. A sucrose symporter similar to that located at the plasmalemma of SE/CC is presumed to carry sucrose into the cytosol. However, a plasmalemma-bound sucrose symport in storage cells has been inferred from gene expression studies, but its activity has never been demonstrated directly. More recently, an endocytotic system of transport has been proposed to carry sucrose (and other dissolved solutes) from the apoplast to the vacuole of storage cells. Endocytotic vesicles would transport solutes to be stored directly into the vacuole, whereas the plasmalemma-bound sucrose symporter allows the passage of sucrose required by cytosolic activities. In this way, the cytosolic homeostasis is not disrupted by the constant fluctuations of the phloem contents (Fig. 1).

UTILIZATION AND MOBILIZATION OF RESERVE SUCROSE

Metabolic demands for long-term stored vacuolar sucrose occur in vital processes such as resumption of growth in dormant or reproductive tissues, seed germination, and the maintenance of cell viability in stored commodities.^[7] Depending on metabolic demand, stored sucrose can be mobilized by storage cells to supply their own physio-

logical requirements and those of remote cells, such as developing shoots, roots, and reproductive organs. Therefore, the mechanisms of sucrose export depend on the ultimate fate of the disaccharide. For internal metabolic use, sucrose can be exported from the vacuole to the cytosol by an ATP-dependent sucrose pump.^[7] The exported sucrose can be either released as a disaccharide or catabolized after export by sucrose synthase, which forms a metabolic unit with the ATP-dependent sucrose pump to release UDP-glucose and fructose.

For external transport, a reverse vesicle-mediated system (exocytosis) carries sucrose and other vacuolar substances to the apoplast^[8] (Fig. 1). Once released into the apoplast, sucrose is transported to growing points throughout the plant to maintain growth, and in a large number of biennial plants, to sustain the entire second year reproductive activities. In many ways, sucrose secretion as part of flower nectar follows a similar exocytotic route. However, it is believed that some solutes in the nectar originate in other cellular organelles and that a more complex network of vesicle transport is involved.^[8]

COMPLETING THE CYCLE

Whether originating from the storage organs or from neighboring exporting photosynthetic leaves, sucrose provides the energy for the development of new leaves until they become fully autotrophic. A series of soluble and wall-bound invertases, in addition to sucrose synthase, channel sucrose to different metabolic pathways. Once the leaf becomes an autotrophic organ, the direction of sucrose flow reverses and export of sucrose renews the cycle. Therefore, as the primary product of photosynthesis, sucrose powers life on earth by virtue of being the basic fuel for life.

Sustainable Agriculture and Food Security

Jules Pretty

University of Essex, Colchester, U.K.

INTRODUCTION

Despite several decades of remarkable agricultural progress, the world still faces a massive food security challenge, with an estimated 790 million people lacking adequate access to food. Most agree that food production will have to increase in the coming years, and that this will have to come from existing farmland. But solving the persistent hunger problem is not simply a matter of developing new agricultural technologies. Most hungry consumers are poor, and so simply do not have the money to buy the food they need. Equally, poor producers cannot afford expensive technologies. They will have to find solutions largely based on locally available natural, social and human resources. The key questions are, therefore, to what extent can agricultural systems become more productive while not causing harm to the environment, and do such system offer any new hope for the hungry?

SUSTAINABLE AGRICULTURE

Something is wrong with our agricultural and food systems. Despite great progress in increasing productivity in the last century, hundreds of millions of people remain hungry and malnourished. More hundreds of millions eat too much, or the wrong sorts of food, and it is making them ill. The health of the environment suffers too, as costly degradation seems to accompany many of the agricultural systems we have evolved in recent years.^[1,2] Can nothing be done, or is it time for the expansion of another sort of agriculture, founded more on ecological principles and in harmony with people, their societies and cultures?

In the earliest surviving texts on European farming, agriculture was interpreted as two connected things, *agri* and *cultura*, and food was seen as a vital part of the cultures and communities that produced it. Today, however, our experience with industrial farming dominates, with food now seen simply as a commodity and farming often organized along factory lines. To what extent can we put the culture back into agri-culture with-

out compromising the need to produce enough food? And can we create sustainable systems of farming that are efficient and fair, and founded on a detailed understanding of the benefits of agroecology and people's capacity to cooperate?

As we advance into the early years of the 21st century, we have some critical choices.^[3,4] Humans have been farming for some 600 generations, and for most of that time the production and consumption of food has been intimately connected to cultural and social systems. Foods have a special significance and meaning, as do the fields, grasslands, forests, rivers, and seas. Yet in just the last two or three generations, we have developed hugely successful agricultural systems based on industrial principles. In most cases they produce more food per hectare and per worker than ever before, but they look so efficient only if we ignore the harmful side effects—the loss of soils, the damage to biodiversity, the pollution of water, and the harm to human health.

Over these 12,000 years of agriculture, there have been long periods of stability, punctuated by short bursts of rapid change. These changes resulted in fundamental shifts in the way people thought and acted. We are at another such junction. A sustainable agriculture making the best of nature and of people's knowledge and collective capacities has been showing increasingly good promise. But it has been a quiet revolution, because many accord it little credence. It is also silent because those in the vanguard are often the poorest and the marginalized, whose voices are rarely heard in the grand scheme of things. No one can exactly say where this revolution could lead us. Neither do we know whether models of sustainable production would be appropriate for all farmers worldwide, but the principles do apply widely. Once these come to be accepted, then it will be the ingenuity of local people that shapes these new methods of producing food to their own particular circumstances.

We know that most transitions involve trade-offs. A gain in one area is accompanied by a loss elsewhere. A road built to increase access to markets helps remote communities, but it also allows illegal loggers to remove valuable trees more easily. A farm that eschews the use of pesticides benefits biodiversity, but may produce less food. New agroecological methods may mean more labor

is required, putting an additional burden on women. But these trade-offs need not always be serious. If we listen carefully and observe the improvements already being made by communities across the world, we find that it is possible to produce more food while protecting and improving nature. It is possible to have diversity in both human and natural systems without undermining economic efficiency.

RECENT DEVELOPMENTS

In recent research, we examined the extent to which farmers have improved food production in recent years with low-cost, locally available, and environmentally sensitive practices and technologies.^[5-7] During 1999–2000 we analyzed by survey 208 projects in 52 developing countries, in which 8.98 million farmers have adopted these practices and technologies on 28.92 million hectares, representing 3% of the 960 million hectares of arable and permanent crops in Africa, Asia, and Latin America.^[8,9]

We found improvements in food production occurring through one or more of four mechanisms: 1) intensification of a single component of a farm system; 2) addition of a new productive element to a farm system; 3) better use of water and land, thereby increasing cropping intensity);

4) improvements in per-hectare yields of staples through introduction into farm system of new regenerative elements, locally appropriate crop varieties, and animal breeds. The 89 projects with reliable yield data show an average per-project increase in per-hectare food production of 93% (Fig. 1).

There are several key practices and technologies that have led to these increases: increased water use efficiency, improvements to soil health and fertility, pest control using biodiversity services with minimal or zero-pesticide use, and social organization for collective action.^[6,10-13] This research reveals promising advances in the adoption of practices and technologies that are likely to be more sustainable, with substantial benefits for the rural poor. With explicit support through national policy reforms, better markets, and more integrated and cross-disciplinary approaches to science, these improvements in food security could spread to much larger numbers of farmers and rural people in the coming decades.

Social learning is a vital part of the process of adjustment in sustainable agriculture projects.^[5,10] The conventional model of understanding technology adoption as a simple matter of diffusion, as if by osmosis, no longer holds. But the alternative is neither simple nor mechanistic. It involves building the capacity of farmers and their communities to learn about the complex ecological and biophysical complexity in their fields and farms, and then to act in different ways. The process of

Fig. 1 Sustainable agriculture project/initiatives: relative crop yield changes for 89 projects, where 1.0 represents no change and relative yields above 1.0 represents multiples. (From. Ref. 9.)

learning, if it is socially embedded, provokes wider changes in behavior.

Farmers require timely information on pest–predator relationships, moisture and plants, soil health, and the chemical and physical relationships between plants and animals. These are subject to manipulation—and farmers who understand this, and who are confident about experimentation, are better innovators. The empirical evidence tells us two important things. Social learning leads to greater innovation, and there is increased likelihood that social processes producing these technologies are likely to persist.

CONCLUSION

Several things are now clear with respect to sustainable agriculture:^[3]

- The technologies and social processes for local-level agroecological improvements are well-tested and established.
- The social and institutional conditions for spread are less well-known, but have been established in several contexts (in particular social groups at the local level and novel partnerships between external agencies).
- The political conditions for the emergence of supportive policies are the least established, with only a very few examples of real progress.

Most of the sustainable agriculture improvements seen in the past decade have arisen despite existing national policies, which will need major reform. Policies framed to deliver increased food production will have to be changed if they also are to help deliver environmental and social benefits. Food policies framed to help deliver cheap and abundant food, regardless of quality, will have to change as well. And rural development policies and institutions focusing on “exogenous” solutions to the economic and social problems of rural communities are ill-suited to the needs of community-based and participatory development.^[6,11]

Nevertheless, there has been increasing global recognition of the need for policies to support sustainable agriculture.^[3,8] Although almost every country would now say it supports sustainable agriculture, the evidence points toward only patchy reforms. Only three countries—Cuba, Switzerland, and Bhutan—have given explicit national support for sustainable agriculture, putting it at the center of agricultural development policy and integrating policies accordingly. Cuba has a national policy for alternative agriculture, Switzerland has three tiers of support to

encourage environmental services from agriculture and rural development, and Bhutan has a national environmental policy coordinated across all sectors.

Some countries, such as in India, Brazil and Sri Lanka, have seen subregional support at the state level for zero-tillage, watershed and soil management, and participatory irrigation management. A much larger number of countries have reformed elements of agricultural policies through new regulations, incentives and/or environmental taxes, and administrative mechanisms, and these are having considerable—though partial—effect. These changes include catchment approaches for soil conservation and bans on selected pesticides, combined with a national program for farmer field schools and integrated pest management (IPM) in rice, support for soybean processing and marketing, and regional integration of agricultural and rural policies. But most countries have not yet explicitly put sustainable agriculture at the center of their policy frameworks.

Sustainable Agriculture: Definition and Goals

Glen C. Rains

University of Georgia, Tifton, Georgia, U.S.A.

W. Joe Lewis

Dawn M. Olson

USDA—Agricultural Research Service, Tifton, Georgia, U.S.A.

INTRODUCTION

Agricultural technology has increased farm production to unprecedented levels. However, returns on investments are diminishing and environmental concerns are in conflict with current chemically intensive farm practices. Emerging technologies—such as precision farming and genetically modified crops—can potentially improve farm management through reduced chemical use and better distribution of those chemicals. However, using these farm management strategies to redirect or change the types of chemicals needed continues the reliance on external chemical inputs that are reducing farm profit. To change this trend, management strategies must be redirected to promote sustainable and holistic management that encourages interdependent and diverse properties. With this redirection, use of chemicals can be relegated to a backup role, giving way to a management strategy that enhances and promotes the inherent strengths and processes of the agroecosystem.

NEED FOR CHANGE

Agricultural production in the United States has increased dramatically during the past 75 years. Corn production has nearly quadrupled from 1920 to 1995, while the crop acreage has been reduced by one-third.^[1,2] Such impressive crop yields stem primarily from the development and application of agricultural chemicals (pesticides and fertilizers), new and improved agricultural machinery, educational and extension programs, and improved plant cultivars resistant to pests and designed for higher yield.

But these yield gains are showing diminishing returns even with increased inputs (Fig. 1), and have come at the expense of impaired natural resources and diminished soil and water quality.^[3] The two farm management practices most devastating to soil and water ecologies are intensive chemical use (pesticides and fertilizers) and tillage practices.^[4] High chemical use destroys soil microorganisms that decompose residue and aid in nutrient recycling; kills beneficial insects; and can, with water runoff and

leaching, poison water resources. Agriculture is the leading source of wetland water quality impairment.^[5] Pesticide use causes destruction of natural enemies and increased pest resistance, thereby resulting in secondary pests, pest resurgence, and a treadmill of pesticide dependency. This dependency on chemical inputs creates an unstable farming enterprise that continues to spiral toward higher and higher chemical inputs to make up for the depletion of inherent resources on the farm. In the United States, crop losses due to pathogens, animal pests, and weeds have increased from 34.9% in 1965 to 42.1% in 1988–1990,^[6] despite a 170% increase in pesticide use over roughly the same period (1964–1985).^[3] Heavy tillage is an energy-intensive management practice that increases pollution and energy costs and removes soil cover, exposing it to erosion by wind and water. Compounding the issue for farmers is the rising per unit cost of inputs and the recent drop in commodity value. Recent commodity prices have combined with inclement weather patterns to force many farmers out of business. New sustainable management strategies must be developed to reverse the escalating economic and environmental consequences of conventional management practices. As argued by Lewis et al.,^[7] these new strategies must go beyond the mere ongoing replacement of therapeutics with alternative newer, more sophisticated intervention materials. Rather, truly satisfactory solutions require a shift to a systems approach to understanding and renewing the inherent strengths and balances of agricultural ecosystems, with therapeutic interventions serving strictly as backups to the natural components. This article defines and discusses the goals of sustainable agriculture as compared to conventional agriculture, and generally outlines the shift in operating philosophy required to achieve the new goals.

SUSTAINABLE VERSUS CONVENTIONAL AGRICULTURE PRACTICES

Sustainable agriculture is a management strategy that seeks to meet current production and profitability needs while protecting the long-term ecological health and

Fig. 1 Price indexes for fertilizers and lime, pesticides, and farm output, 1940–2000. (View this art in color at www.dekker.com.)

production capacity of a system through fostering and utilizing inherent and renewable strengths. Sustainable systems are noted for six key attributes: diversity, self-renewal, self-sufficiency, self-regulation, efficiency, and interdependence.^[8] Diversity and interdependence develop self-regulating mechanisms such as multitrophic interactions, self-renewing properties through nutrient recycling, and self-sufficiency through reliance on inherent resources. A sustainable system is thereby driven not by chemical and energy-intensive inputs, but by the development of renewable resources and inherent strengths within the agroecosystem. For example, by nurturing soil microbial and earthworm activity and nitrogen-fixing and cover crops, nutrients are replenished within the system, reducing the need for applied fertilizers. This requires an understanding and management of the interactions among vertebrates, invertebrates, plants, water, and soils to build on the inherent renewable strengths and resources of the agroecosystem.

In contrast, current farming practices are generally highly input-dependent and have eroded the inherent strengths of the agroecosystem. Monocultural practices, single-tactic strategies, and reliance on chemical pesticides and fertilizers as well as heavy soil tillage have created a system of farming that requires constant therapeutic inputs. This input-driven farming system is extremely inefficient, costly, and unstable as pest resistance and resurgence require continued heavy pesticide use (Fig. 2, current farming system). Subsequently, inherent strengths of the agroecosystem—such as the self-regulation of pests with beneficial insects—are eroded. As it becomes more difficult to farm for profitability, farmers look to new tools such as better chemical pesticides,

precision agriculture, and genetically engineered crops to maintain production. However, these new technologies are still just therapeutic inputs that are not sustainable. Therefore, while efficiency and stability improve initially, the intrinsic ability of agroecosystems to neutralize external interventions causes the new inputs to lose their effectiveness, and instability returns, as the treadmill of input dependency continues (Fig. 2, upper arrow). This is very evident in the reaction of pests to new pesticides. Their efficacy is very high initially, but continually diminishes as pest resistance increases. A redirection in technology development toward sustainable agriculture

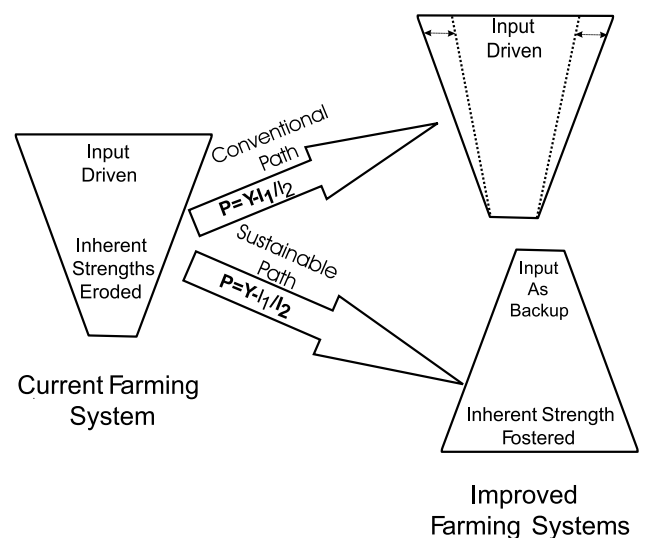

Fig. 2 Conventional versus sustainable paths of farming systems.

will increase farming stability by fostering the natural ecological mechanisms that regulate pests and nutrient recycling. This is accomplished by fostering the inherent strengths of the farming enterprise and reducing therapeutic inputs to a backup role (Fig. 2, lower arrow).

DECIPHERING ISSUES OF PROFITABILITY, YIELD, AND SUSTAINABILITY

As yield increases have begun to plateau, input costs have continued to rise. Consequently, the cost of farming has increased and the price index has begun to flatten (Fig. 1). One factor that is important in determining profitability but that has not been accounted for since the advent of chemical fertilizers and pesticides is the utilization of the built-in, on-farm inherent strengths already described. Farming profit (P) is a function of the commodity yield (Y) and the money spent to produce that commodity (I). Inputs can further be divided into a numerator—therapeutic inputs (I_1)—and a denominator—inputs developed by utilizing the inherent resources on the farm (I_2). I_1 is in the numerator because, as therapeutic input costs increase, profit is reduced. I_2 is placed in the denominator because, as the inherent strengths of the system are utilized, they reduce I_1 and increase the profit margin. The farming profit can then be represented by Eq. 1:

$$P = Y - I_1/I_2 \quad (1)$$

where P = profit (\$); Y = yield (\$); I_1 = input costs for seed, chemical fertilizer, pesticides, equipment, land, and fuel (\$); I_2 = agroecosystem (on-farm) resources and inherent strengths that are normally ignored (\$)

The benefits of inherent strengths and on-farm resources (I_2) have not been utilized in a holistic manner and are practically invisible to the equation as long as therapeutic inputs are the driving force behind agricultural production. The resulting system is inefficient and unsustainable, as inputs continue to eat away at the farming base (Fig. 2, current farming system). New technologies are being developed in an attempt to reduce this dependency and improve the profitability of farming, but are only met with an ever growing dependence on therapeutic and costly inputs (Fig. 2, upper arrow). For example, precision agriculture has helped redistribute chemicals across a field, but has to date not addressed the underlying causes of field variability and has not addressed potentially less intrusive solutions that utilize the inherent strengths of the agroecosystem. The inherent strengths and resources, when properly utilized and fostered in a sustainable manner as defined previously, act to reduce input costs (I_1) as sustainable strategies are put in place. Therapeutic inputs such as chemical pesticides are then reduced to a backup

role in the development of inherent strengths and multiple interactions within the agroecosystem as a whole, improving the profitability and sustainability of the agroecosystem (Fig. 2, lower arrow). Eq. 1 becomes

$$P = Y - I_1/I_2 \quad (2)$$

where I_1 (therapeutic) inputs are reduced to a backup role in developing and utilizing inherent strengths (I_2).

It may be difficult to move from a conventional farm management system to a sustainable managed agroecosystem due to cultural biases, economic trends, and technological or knowledge limitations. Economic hardship usually has a negative impact on implementing sustainable practices. Paradoxically, there is a tendency to add more inputs in hopes of increasing production. Unfortunately, profits are typically reduced through increased production costs without a subsequent increase in production. There is also a reluctance to attempt practices that do not yet have a proven track record. Farmers who are successfully managing sustainable agroecosystems are few, making it difficult to demonstrate to farmers real-world, long-term benefits. Finally, developing and maintaining a sustainable agroecosystem and making systematic improvements year to year to improve sustainability requires knowledge of the mechanisms of self-regulating systems and tools for monitoring the factors that affect these mechanisms.

Each of these issues must be addressed if there is to be widespread acceptance of such practices. Cultural biases can be reduced by supporting farmers who develop these practices of sustainable and precision management, so they can become mentors for other farmers in the community. As successful practices emanate out, more widespread adoption will become possible. Farmers will also need the support of local community leaders who also practice these ecologically-based principles. Research and educational programs at federal, state, and local levels must be directed to ward developing and understanding agroecosystems so that management practices are well-understood and adopted. Technological tools to monitor and assess the health of agroecosystems can provide databases that provide knowledge of sustainable practices. With increased knowledge, farmers can make informed decisions to manage sustainable agroecosystems more confidently.

CONCLUSION

Current farm production practices are not environmentally friendly and require high levels of chemical and mechanical inputs to maintain and manage. Besides the environmental consequences, the financial burden is high,

as chemical inputs are the driving force behind maintaining an acceptable level of production. To reduce the environmental and financial burden of current farm production practices, a fundamental shift in farm management strategies is needed to create a more sustainable farming system that preserves the long-term productivity of existing farmland with less reliance on chemical inputs and more reliance on developing farm resources and inherent strengths. These agroecosystems must be managed in a holistic manner, fostering biodiversity and multiple interactions at several scales. By developing farming systems that are sustainable, with therapeutic inputs reduced to a backup role, farmers can increase profitability and be less susceptible to adverse outside influences.

Sustainable Agriculture: Economic Indicators

David Pimentel

Cornell University, Ithaca, New York, U.S.A.

INTRODUCTION

Food production suffers from overpopulation and environmental degradation at a time when food shortages are critical. The World Health Organization recently reported that more than 3 billion people are malnourished in the world.^[1] This is the largest number and proportion of malnourished people ever in history. In the United States and throughout the world, agriculture suffers from many serious environmental problems that reduce the sustainability of crop and livestock production. The environmental resources most notably affected are soil, water, nutrients, energy, and biodiversity—all vital resources for food production.

Degraded agricultural lands require more fertilizers and more irrigation in order to maintain production. This is costly in terms of energy and the economics of agricultural production. In addition, the abandonment of some agricultural technologies (such as crop rotations) has resulted in loss of biodiversity and increased insect pests, plant pathogens, and weeds. These changes in turn require the intensive use of pesticides and other types of pest controls.

In addition to the direct effects of poor environmental resource management on agricultural production are the indirect effects off-site, such as pesticides and nitrogen fertilizer leaching and washing into rivers and groundwater. All of these negative effects reduce the sustainability of agriculture and the natural environment.

SOIL

World and U.S. food supplies depend on the availability of productive soils. Currently, more than 99.7% of world and U.S. food supply comes from the land, whereas less than 0.3% comes from the oceans and other aquatic ecosystems.^[2] Therefore, the dimensions of soil and land destruction in the United States and the world are of increasing concern. At present, the rate of soil erosion on U.S. cropland averages about 13 times greater than soil reformation. In Africa, Asia, and South America, the rate of soil erosion is 30 to 40 times greater than soil reformation. Soil erosion and land degradation result in the

loss and abandonment of about 10 million hectares (ha) of cropland each year worldwide.^[3]

The abandonment of productive cropland coupled with the removal of forests is having negative impacts on world forests. Approximately 60% of world forest removal is associated with agricultural spread into forests.^[2]

Soil erosion is intensifying, especially in developing countries where poor people depend on biomass energy for cooking and heat.^[4] Wood fuel in most developing countries is in short supply, forcing the rural poor to turn to burning crop residues for cooking and heating their homes. The removal of crop residues leaves the soil unprotected from wind and water erosion. Without crop residues, soil erosion rates often increase tenfold. In addition, the crop residues contain nitrogen, phosphorus, and potassium—all essential nutrients for crop production. These vital nutrients are an integral part of the crop residues.

Erosion adversely affects crop productivity by reducing the availability of water, soil nutrients, soil biota, soil organic matter, and soil depth. The reduction in the amount of water available to the crop is considered the most harmful effect of erosion. After water, shortages of soil nutrients are the most important factors in limiting crop production.^[3]

Severe soil erosion and associated rapid water runoff problems now seriously diminish the food economy as well as the health of the environment in the United States and world. In total in the United States, soil erosion effects both on the farm and off-site on the environment are estimated to cause more than \$45 billion dollars in damages yearly.^[3]

WATER

All crops require and transpire massive amounts of water. For example, a corn crop that produces about 8000 kg/ha takes up and transpires about 5 million liters of water during the growing season of a little over three months.^[5] If the corn crop requires irrigation, close to twice this much water (about 10 million liters) must be applied because not all the water is picked up by the corn plants.

Irrigation is highly energy intensive and costly. Approximately three times as much energy is required for crop production if the crop must be irrigated,

Table 1 Energy and economic inputs per hectare for conventional and alternative corn production systems

	Conventional			Ridge planting and rotations		
	Quantity	10 ³ kcal	Economics (\$)	Quantity	10 ³ kcal	Economics (\$)
Labor (hrs)	10	7	50	12	9	60
Machinery (kg)	55	1485	91	45	1215	75
Fuel (litres)	115	1255	38	70	764	23
N (kg)	152	2280	81	27	5591	17
P (kg)	75	450	53	34	214	17
K (kg)	96	240	26	15	38	4

Corn seeds (kg)	21	520	45	21	520	45
Cover crop seeds (kg)	–	–	–	10	120	10
Insecticide (kg)	1.5	150	15	0	0	0
Herbicide (kg)	2	200	20	0	0	0
Electricity (10 ³ kcal)	100	100	8	100	100	8
Transport (kg)	322	89	32	140	39	14
TOTAL		6910	532		3712	337
Yield (kg)	7500	26,514		8100	29,160	
Output/Input ratio		3.84			7.86	

compared with requirements for a rain-fed crop. Between \$1000 and \$1500 is required to irrigate a hectare of land. Approximately 1000 liters of water are required to produce 1 kg of grain. In the United States and world, about 70% of all water used is applied to crops for irrigation.^[5]

Producing meat requires more water than crop production. For example, the production of 1 kilogram of beef requires about 43,000 liters of water. (This is not the water that a cow drinks; rather, it is the water required to produce the grain and forage that the cow consumes.)

Water and fossil energy are the two critical resources now limiting world food production.

PESTICIDES

Each year approximately 3 million metric tons of pesticides (insecticide, herbicides, and fungicides) are applied worldwide; approximately 500,000 tons are applied in the United States.^[6] Despite the heavy application of pesticides worldwide, pest insects, weeds, and plant pathogens destroy more than 40% of all potential crop production. Losses of crops to pests in the United States are similar to world losses, or about 37% of potential production.^[6] It should be pointed out, however, that food losses in each nation are related to cosmetic standards established in each nation. For example, fruits and vegetables sold in markets in India and Guatemala would generally not be salable in markets in the United States.

One concern over the use of pesticides is that less than 0.1% of the pesticide applied actually reaches the target pest. Thus, more than 99.9% disperses widely to

contaminate the environment, including water and soil resources.^[7]

Although each dollar invested in pesticide control returns about \$4 in protected crops, this benefit overlooks the environmental and public health costs of pesticide application. In the United States, pesticide use causes approximately \$9 billion in damages to the environment and public health each year.^[6]

Related to the public health problems in the United States are about 110,000 nonfatal human pesticide poisonings each year. In addition, between 10,000 and 12,000 cases of cancer are annually associated with the use of pesticides. Worldwide, about 26 million nonfatal pesticide poisonings occur, resulting in approximately 220,000 deaths each year. During the past 15 years, Sweden has been able to reduce pesticide use by 68%, while at the same time reducing public health problems associated with pesticides by 77%. Several nations (including Norway, Denmark, the Netherlands, and Indonesia) and the Canadian province of Ontario have programs to reduce pesticide use by 50% or more.^[6]

FOSSIL ENERGY

The spectacular increases in grain and other crop yields during the past 40 years have been due to fossil energy inputs for fertilizers, irrigation, and pesticides. Thus, the green revolution was in reality due to the use of fossil energy. Grain crops such as rice and wheat were bred to be of short stature so they could produce increased yield in response to higher inputs of nitrogen fertilizer. The old

varieties of these crops with large inputs of nitrogen would grow tall and then fall over and rot. Therefore, short varieties were essential to allow large amounts of fertilizers to be applied.

SOUND ENVIRONMENTAL AND ECONOMIC AGRICULTURAL MANAGEMENT

The major difficulties associated with conventional high-input agriculture are 1) high costs of production; 2) serious environmental resource degradation; and 3) instability of crop yields. Numerous agricultural technologies can be implemented to make agriculture environmentally and economically sustainable. These technologies can reduce chemical inputs (including fertilizers and pesticides), reduce soil erosion and rapid water runoff, and make better use of livestock manure.

The economical and environmentally sound agricultural practice of ridge planting and the rotation system are compared with the conventional corn production system in Table 1. Note the high level of inputs in the conventional corn system. The total costs of these inputs average \$844 per ha in the United States. The total energy input is 7.0 million kcal/ha. The yields in both systems are the same, 8000 kg/ha.^[8]

In the ridge-planting system, employing a cover crop and crop rotation reduced soil erosion from about 20 t/ha/yr to about 1 t/ha/yr. No insecticides or herbicides were employed in this system, demonstrating that corn can be produced without these chemicals.

Environmentally and economically sound corn production required only 4.0 million kcal and cost only about \$700 per ha (Table 1). These values were 44% lower for energy and 17% lower for economic inputs than conventional corn production.^[9]

Sustainable Agriculture: Ecological Indicators

Stephen S. Jones

Washington State University, Pullman, Washington, U.S.A.

INTRODUCTION

Agricultural sustainability is a process rather than an end point. From a purely ecological view, the process leads to a system of food and fiber production that is in such a state of environmental health that it can continue at the given rate of extraction into the measurable future. To evaluate the progress or the status of sustainable systems requires measurable units. Following the precedence of economic models, the term used to describe such units is indicators. To monitor the biological robustness of a system then requires that these units be indicators that reflect on the entire ecology of the system, hence the term ecological indicators.

Ecological indicators go beyond the canary-in-the-coal mine analogy, in that the best indicators do not merely take an immediate assessment of the health of the system but should be able to be monitored over time. They should also be easily measurable, applicable to a wide range of systems, responsive to change, inexpensive, relevant, and easy to interpret. These indicators should also measure ecological health rather than the productivity of a system. Farm productivity, in many cases, may result in the reduced long-term health of a system.

Some very powerful indicators can also be very simple. For example, it is impossible for a system that loses soil more rapidly than it is replaced to be sustainable. As an indicator, then, soil erosion is a very obvious and relevant measurable unit. Other indicators may be far more subtle, however. Shifts in microorganism populations, soil tilth, and above- or below-ground flora and fauna may all have value in assessing the level of sustainability for a particular system. However, each is quite complicated to measure and monitor over time, and no single indicator can monitor an entire system. Thus, the use of indicators based on more holistic approaches is also being considered.

TYPES OF ECOLOGICAL INDICATORS

Indicators can be either biotic or abiotic. Abiotic indicators deal primarily with the general health of the soil relative to sustaining life, while biotic indicators involve the monitoring of various life forms. Holistic approaches to identifying biological indicators can in-

volve such issues as farmer choice of cultural practices and indicators that can be used on a landscape level, as opposed to a single-field level. Holistic approaches are an attempt to move away from reductionist measurements of ecological systems.

Abiotic Indicators

Some abiotic indicators are obvious and require no measurement whatsoever. One such indicator is illustrated in Fig. 1. Here we see massive amounts of soil being lost due to the combined erosive forces of slope and water. This is an excellent example of the stresses, and the results of these stresses, placed on systems. Soil loss at this rate is dramatic, but losses at levels much lower than this can render a practice unsustainable. It is a rare agricultural system that is not losing soil at some rate, and any loss of soil is enough to render agriculture unsustainable.

The loss of soil can be easily seen and measured. By contrast, determining the health of the soil as an indicator is much more complex.^[1,2] Changes in pH, organic matter, nitrate leaching, salinization, heavy metals and pesticide accumulation, compaction, and general fertility are just some of the indicators used to determine soil health. Many of these indicators also have confounding effects on the others. For example, as soils become more acid certain metals, such as aluminum, are released.

The interaction of these items with biotic soil factors then complicates the equation even further. As complex as it is, the measure of soil health should be considered the main indicator of sustainability. All nonaquatic agricultural systems rely on this slow-to-build, rapid-to-degrade resource. In fact, nearly all agricultural soils can be viewed as degraded. Indicators then must measure improvements, rather than stability, if a system is to be deemed sustainable.

Biotic Indicators

Species diversity and the relative frequencies of butterflies,^[3] spiders,^[4] true bugs,^[5] and earthworms^[6,7] have all been used as indicators of sustainability. Earthworms (Fig. 2) are especially well suited to a role as indicators. More than 3500 species of earthworms exist, they are easy to capture and sort, and they are slow to recolonize. Slow

Fig. 1 Erosion of winter wheat field near Pullman, Washington. Photo by Stephen Jones, Original Data. (View this art in color at www.dekker.com.)

Fig. 2 Many species of earthworms are usually found in individual fields. Each may have different tolerances and susceptibilities to biotic and abiotic pressures. Photo courtesy of Mary Fauci, Washington State University. (View this art in color at www.dekker.com.)

recolonization is beneficial in an indicator because the shifts in populations can be more easily studied as they rise and fall over time. Species that recolonize rapidly may cause sampling problems, because rapid shifts may be missed if sampling is infrequent.

As early as the 1600s, earthworms were used as a measure of soil fertility.^[7] Today, they are a simple and economic measure of soil life. Individual species vary in their sensitivity to pesticides, tillage, moisture, soil structure, salt, heavy metals, predation, and many other relevant aspects of soil ecology. Paoletti^[7] lists 16 unique situations in which earthworms have been used to measure sustainability. The uses range from detecting archeological pesticide residues to comparing soil health at a landscape level in rural and urban interfaces.

Buckerfield et al.,^[6] using four species of earthworms in southern Australia, showed a significant inverse relationship between intensity of tillage operation and earthworm abundance. They also recorded a significant correlation between crop productivity and earthworm abundance. They warned, however, that diverse crop management practices and cropping histories over time and space might make simple relationships between earthworms and productivity tenuous. With this in mind, they concluded that on an appropriate scale earthworm communities are useful as indicators of crop sustainability.

Crop and livestock diversity can also be used as indicators of sustainability.^[8,9] Ratios of annuals to perennials, permanent pasture to annual crop, and pest plants and animals to useful species may also indicate sustainability.

Aboveground diversity can be highly changeable, however. An individual farmer can go from a total monoculture system to intercropped multilines with perennial borders in a single season. The most important question of crop and animal diversity, therefore, is not if it is here today, but rather, if it will be available tomorrow. The use and availability of plant and animal varieties bred for long-term sustainability is an important indicator of the long-term health of sustainable systems. Where will farmers get seed and livestock that will be appropriate for sustainable agriculture in the future? Will the biodiversity be available? Will improved varieties be available to the farmers for a reasonable cost?

A MORE HOLISTIC APPROACH TO INDICATORS

Ecological indicators must be combined with economic and other factors when evaluating sustainability. Some also think that they should be viewed over an entire landscape rather than used as a single-field or farm measure. Di Pietro^[10] points out that traditional agriculture leads to simplification and that, in general, systems

that use simplification as a style are poorly adaptable, and thus not sustainable. Working in the central Pyrenees of France, Di Pietro studied two holistic indicators: 1) the contributions of a field's environmental features to land use choices (i.e., is sloping ground used for pasture or for crops), and 2) the diversity of environmental resources used by farms. The study was performed in two separate valleys. One was organized as a single unit of many farms, and the other as many units of individual farms and fields. Di Pietro showed that decisions at a landscape level are needed for sustainable measures to be effective.

Kemp et al.,^[9] however, state that indicators at a farm level should be emphasized, because it is only at this level that environmental management can be applied effectively. This may be true today, but sustainability must eventually get past the single-farm level as the basic unit and move up to landscape levels and beyond. Nonpoint sources of influence, usually detrimental, are all too real in today's agriculture.

CONCLUSION

Ecological indicators can be as simple as soil erosion or as complex as the availability of biologically diverse domestic crops and animals. To be effective, indicators should be used in concert with other relevant measures of sustainability. And as with the components of all models, indicators should be used with the caution that they are only as good as the inferences on which they're based. For example, it is common to find biological indicators of sustainability based on yield and other measures of productivity. Short-term levels of high productivity can be based on unrealistically high amounts of imported inputs. To sustain these levels of production in most cases requires a highly extractive system. The result is anything but sustainable. Once systems have been deemed sustainable, then production would be a valid choice of indicator. Prior to that, though, the choice is ill-timed.

Sustainable Agriculture: Philosophical Framework

Paul B. Thompson

Michigan State University, East Lansing, Michigan, U.S.A.

INTRODUCTION

Several different philosophical frameworks are currently being deployed in developing programs and research projects for sustainable agriculture. Although the choice of a framework may depend on the aims and interests of those who develop these projects, it is important to be clear about the various ways in which sustainable agriculture is conceptualized. Successful programs and projects depend upon agreement about the basic meaning of sustainability in agricultural food systems.

APPROACHES TO SUSTAINABLE AGRICULTURE

The adjective ‘sustainable’ implies that the activity it modifies can continue, if not indefinitely, then for some foreseeable and generally accepted period of time. Hence ‘sustainable agriculture’ should simply indicate ways of producing standard agricultural food and fiber goods that can continue to be practiced for the foreseeable future. But this formulation is both vague and ambiguous. Underlying assumptions, methods, and values for sustainable farming practices and for research undertaken under the rubric of sustainable agriculture have been debated ever since the term came into wide usage in the 1980s.

The primary source of disagreement can be traced to an ambiguity in the basic idea of a sustainable practice that has led to two conflicting fundamental philosophical orientations. To say that an activity can be continued indefinitely is, on the one hand, to predict or estimate the feasibility of undertaking the activity over a future period of time. On the other hand, it may also be understood to mean that the activity should be allowed to continue in the future. This ambiguity has led to two incompatible schools of thought about sustainable agriculture.

In emphasizing prediction and measurement the first approach allows one to draw upon principles and methods developed in the agricultural sciences, as well as for such diverse areas as sustainable development, sustainable structural design, and sustainable urban planning. In this approach articulation of these principles and methods becomes critical to the conceptualization of sustainable agriculture. The alternative view is to understand sustain-

able agriculture in terms of pluralistic values and social interests that derive coherence from their mutual opposition to a perceived status quo. Advocates of this approach do not typically seek to clarify or unify their understanding of sustainable agriculture in terms of scientific principles. However, they might support the creation of research that would support and further the values and social interests to which they are committed.

SUSTAINABILITY AS A RESEARCH PROBLEM

There is disagreement even among those who have attempted to articulate scientific criteria for sustainability. In one of the first systematic attempts to specify the guiding principles of sustainable agriculture, Gordon Douglass^[1] identified three distinct schools of thought: resource sufficiency, or the view that the resources needed to carry out a farming practice are on hand or foreseeably available; ecological, or the view that practices must not disrupt natural biological processes integral to the renewal of organic materials; and social, or the view that farming must be compatible with principles of justice and economic opportunity. Advocates of accounting principles to audit available resources understand sustainable agriculture in terms of resource sufficiency, in much the way that Douglass originally proposed. Other approaches can be categorized as stressing the functional integrity of systems. These can include both ecological and social dimensions of the food system; hence these approaches encompass elements of both ecological and social sustainability.^[2]

Resource sufficiency has the advantage of suggesting specific quantitative and auditable measurements. The current stock of available resources can often be measured or estimated, and the rate at which resources such as soil, water, fossil fuel energy, and other inputs are being both consumed and resupplied can be calculated. These basic measures can be made more dynamic with models that estimate fluctuations in climate and the evolution of pathogens, or that predict the rate at which insects become resistant to given control strategies. In principle, it is even possible to incorporate changing economic incentives for producers into such models as the relative costs of various

inputs shift due to increasing scarcity and policy changes. A full integration of such modeling techniques would produce a comparative measure of the relative sustainability of alternative production systems, and an indication of where strategic vulnerabilities may be thought to lie.

However, one weakness of the resource sufficiency approach is that its measure of sustainability is only as good as the data and the accuracy and completeness of the models used to assess the availability and rate of use for critical resources. Furthermore, some of the greatest strategic vulnerabilities of a given farming system may in fact be associated with the most difficult modeling and auditing challenges. What is more, social factors ranging from farm bankruptcy to policy changes and shifting consumer tastes clearly have great influence on producers' ability to continue utilizing any given farming practice over time, yet the underlying processes governing such social changes are so complex that most have never been modeled.

This weakness in the resource sufficiency approach is, in part, why more qualitative conceptualizations that stress the way that various elements of a food and farming system are integrated have proliferated. The theme of functional integrity is that a set of practices or a farming system is sustainable when it is comparatively invulnerable to internal threats. Many of the accounting approaches utilized in measuring the sufficiency of resources reveal threats to the integrity of an agricultural or food system, but stressing functional integrity provides a philosophical framework that points toward a more holistic system and subsystem analysis. Two kinds of qualitative or philosophical value judgment are critical to the formulation of functional integrity. First, one must define system boundaries. Second, one must identify key strategic vulnerabilities.

System boundaries are critical to any conceptualization of sustainability, though boundary judgments are often implicit. The example of climate change illustrates why. Consider a case in which a local farming area suffers from dramatic climate change induced by industrial emissions of greenhouse gases. Drought conditions become commonplace, perhaps, or rising sea levels flood arable lands. Does this imply that the agriculture formerly being practiced there was unsustainable? Most would say not, and the reason is that they have implicitly accepted a boundary condition: Adverse affects on an agricultural system owing to industrial pollution do not count against the sustainability of the system. The industrial emissions certainly threaten the agricultural practice, but this is seen as an external threat—a threat coming from a source outside the system.

Incompatible boundary judgments give rise to disagreements about the sustainability of a given agricultural

practice. This may occur especially when biologically trained individuals implicitly assume that all types of social causality are outside the system of interest. This kind of assumption may reflect the classical biologically oriented training of many agricultural researchers, who conduct laboratory research and field trials under conditions in which socioeconomic variables are controlled. Yet for any number of real-world applications, it is clearly the interaction of socioeconomic and ecological factors that will determine whether a system can continue to function under existing conditions.

Sometimes a single social criterion (such as profitability) is taken to determine sustainability irrespective of ecological factors. Here the problem may not be a disagreement about system boundaries, but may reflect implicit linkages between social and ecological system components that are simply being taken for granted. For example, some may assume that increasing scarcity of resources will be reflected in input costs, making profitability an adequate proxy for many ecological system elements. However, this assumption is itself based upon characteristics of policy and market structure that may or may not be reflected in the system of interest. In such instances, it is critical to articulate key vulnerabilities in qualitative terms, and to develop agreement among all participating parties about them.^[3]

The need for agreement among those who participate in a sustainable agriculture has led some to argue that sustainability always implies a commitment to democracy. This may simply reflect the assumption that sustainable agriculture is a social movement rather than a researchable topic, but as a component of the feasibility of continuing any agricultural practice, democracy is a situation-specific element of sustainability, at best. In complex systems with many participants, the functional integrity of the system may depend upon including all relevant actors in decision making, and upon conducting decision-making processes in a democratic way. However, if the system of reference is a farmer's field, and the key threats are ecological in nature, democracy may not figure importantly in the operational criteria for sustainability. In general, the specific criteria for functional integrity will vary widely depending upon the system of reference and its boundaries.^[3]

SUSTAINABILITY AS A SOCIAL MOVEMENT

An alternative approach has been to see sustainable agriculture purely as a social movement. Deriving in some respects from Douglass's idea of social sustainability, Patricia Allen and Carolyn Sachs^[4] have argued that sustainable agriculture should be understood as a banner for interest groups seeking political change. In this view,

one should not seek the principles that make agriculture sustainable, but should see the term as a convenient label for politically aligned interests. The interest groups associated with the term often include farm labor, women, consumer groups, small-farm groups, and advocates of animal welfare.

Although this approach to sustainable agriculture is clearly normative, the norms advocated are broad and not necessarily compatible. Sociologists Curtis Beus and Riley Dunlop^[5] offer a complex portrait of competing agricultural paradigms. Sustainable agriculture is portrayed as an alternative to the conventional status quo on each of 27 points, summarized in 6 categories: decentralization, independence, community, diversity, restraint, and harmony with nature. To the extent that these points reflect a normative commitment to opposing conventional or industrial agricultural methods, they can be said to reflect a philosophical framework for sustainable agriculture.

CONCLUSION

The choice of a philosophical framework for approaching sustainable agriculture may reflect the specific interests and capabilities of the individuals undertaking a sustainable agriculture project. However, the opportunities for

disagreement and misunderstanding are great, and it is always wise to be as explicit in articulating this framework as one possibly can be.

Sweet Sorghum: Applications in Ethanol Production

Glen C. Rains

University of Georgia, Tifton, Georgia, U.S.A.

John W. Worley

University of Georgia, Athens, Georgia, U.S.A.

INTRODUCTION

Ethanol demand is currently over 1.8 billion gallons per year and estimated demand is expected to grow at an annual rate of 1.7 percent through the year 2020.^[1] Although corn will continue to be the primary feedstock for ethanol, several biomass crops have been investigated for their merits as an ethanol feedstock. Sweet sorghum is an annual crop that has an excellent yield of fermentable sugars, is resistant to drought and adaptable to poor soils, and can thrive in a wide range of climates. It has been found that in certain geographical regions, such as the U.S. Piedmont (a geographical region spanning 170 counties from Virginia to Alabama), sweet sorghum produces more carbohydrates per hectare than corn, and would not directly compete in the food market. However, a system that economically produces and processes sweet sorghum for ethanol production has yet to be developed. This article discusses three systems of sweet sorghum for ethanol production in the U.S. Piedmont, and future developments that could make sweet sorghum an economically viable ethanol feedstock.

CONVERSION OF SWEET SORGHUM TO ETHANOL

The sweet sorghum stalk contains approximately 94% of the total soluble sugars (TSS) in the plant; about 85% of the TSS are located in the stalk pith fraction inside the stalk. Consequently, ethanol production has been examined in terms of both juice expression from whole stalks and pith fraction after separation from the rind and leaf fraction (rind-leaf). Crandell et al.^[2] compared juice and sugar expression efficiencies from chopped whole stalks with those from the pith fraction after processing to remove most of the stalk rind and leaves. They found that juice expression as a percentage of whole stalk mass increased from 36 to 45% when the pith was first separated from the rind-leaf fraction. In the same experiment, sugar expression increased from 44 to 61% of whole stalk sugars from the separated material.

POTENTIAL SYSTEMS FOR PROCESSING SWEET SORGHUM FOR ETHANOL

Three systems for sweet sorghum harvesting and processing to produce ethanol have been analyzed.^[3] The three systems are referred to as the forage chopper system, pith combine system, and Piedmont system (Fig. 1). The forage chopper system is characterized by harvesting sweet sorghum with a commercially available forage chopper and transporting the chopped stalks to a screw press parked next to or inside a bunk silo. The stalks are fed to the screw press for juice extraction and the residue (presscake) is conveyed into the silo. The ensiled presscake can be utilized for cattle feed, or taken to the fermentation plant for fiber breakdown and conversion to sugars for ethanol.

The pith combine system uses a modified forage chopper that chops the forage and then separates the pith (sugar fraction) from the rind-leaf (fiber fraction) using a straw-walker mechanism.^[2] The rind-leaf is left on the field and the pith fraction is transported to the silo. The pith fraction is then fed into the screw press and the presscake conveyed into the bunk silo. By separating the rind-leaf fraction from the pith, screw-press efficiency and capacity are increased. The presscake is then ensiled for cattle feed or for further cellulose breakdown into sugars as in the forage chopper system. The rind-leaf can also be baled for hay and fed to cattle, stored and processed later to break down the cellulose into sugars, or left on the field to increase soil organic matter. The third system is the piedmont system. This system requires the highest capital investment because the harvesting and processing of the sweet sorghum is conducted with a dedicated machine that must be purchased or rented from a contractor who harvests and processes sweet sorghum on a custom basis. The piedmont system operates as follows: A whole-stalk harvester cuts stalks at the base and lays them in continuous windrows around the field. A field loader then loads stalks onto a trailer for transport to a storage facility near a bunk silo. Because the stalks are kept whole and intact, they can be stored 30 to 60 days without substantial loss in fermentables.^[4] Stalks are loaded into a

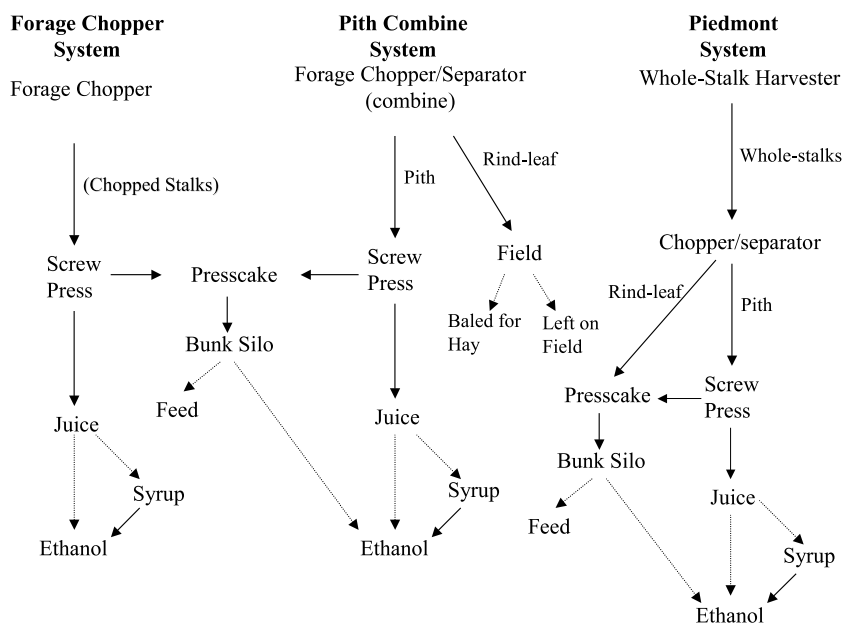

Fig. 1 Three systems for harvesting and processing sweet sorghum for ethanol production.

mobile processor that consists of a feeder, chopper, and pith separator (straw-walker). The pith separator separates the pith from the rind-leaf. The pith is entered into the screw press to express the juice, and the pith presscake is then recombined with the rind-leaf fraction and conveyed into the bunk silo. The presscake and rind-leaf can be handled as cattle feed or as future feedstock for ethanol.

In each system, juice from the screw press can be directly delivered to the fermentation/distillation plant for production of ethanol, or to an evaporation plant where the juice is concentrated into syrup for storage and later carried to the fermentation plant for ethanol production.

ECONOMIC CONSIDERATIONS

Limited data indicate that the expression ratios (mass of juice as a fraction of whole stalk mass) for the screw press using the three systems are 0.35 (forage chopper), 0.45 (pith combine), and 0.55 (piedmont system). An increased expression ratio increases screw press performance and decreases the cost of operation. The piedmont system requires the greatest capital investment and the forage chopper system the least. An important economic consideration is the ability of the piedmont system to store the fermentable sugars in the whole stalk, extending the processing window beyond the harvest season. (Equipment breakdowns do not immediately endanger the processing because stalks can be processed whenever the equipment is ready.) The forage chopper and pith

combine systems must either ferment or distill the juice before it begins to sour. A systems model^[5] examined the cost of production of each system of sorghum harvesting and processing, and indicates that transportation contributes significantly to the cost of production, especially when moving the by-products for further ethanol production. The model shows that the pith combine system is the cheapest per Mg whole stalk, whereas the piedmont system is the most expensive. All three systems are too expensive to make a profit without government subsidies.

Each system has options for processing the sweet sorghum once it is separated into juice, presscake from the screw press, or rind-leaf fractions (Fig. 1). Juice can be sent to a fermentation/distillation plant for direct conversion to ethanol. In this case, sweet sorghum by-product (materials placed in the bunk silo) can be transported to the plant later, after harvest season peak demand, and be converted to sugars for further ethanol production. A recent study indicates that one or more microorganisms can carry out simultaneous hydrolysis and fermentation of cellulose to ethanol in the same bioreactor.^[6] If the by-product is useful as a cattle feed, part of the juice can be sent to an evaporation plant to be concentrated into syrup and stored for processing until peak demand for the fermentation/distillation plant concludes.

Other by-product uses such as source of heat energy, pulp for fiberboard manufacture, hay for animal feed, and organic matter for field amendments are important in determining the economic viability of sweet sorghum for ethanol production. By-product value is difficult to estimate. Based on a model by Worley et al.,^[7] the by-product

values depend less on the system chosen to produce ethanol than on the intended use of the by-product. The highest value is assigned to by-product silage used as cattle feed on the grower's own farm. Fiber conversion to obtain further ethanol production yields the lowest value. However, this study did not consider some of the newer techniques for bioconversion of presscake that show a yield of 5.1 g ethanol per 100 g of fresh stalks.^[6]

CONCLUSION

Sweet sorghum research is in its infancy relative to research on other biomass crops such as corn and sugarcane. As such, it is highly likely that increases in biomass production can be achieved through development of improved genotypes. Studies continue on the use of sweet sorghum as an energy source through conversion to ethanol or electricity.^[8,9] Developing more uses for by-products and improved production practices seem to hold promise for improving the economic viability of sweet sorghum.

Sweetgrass and Its Use in African-American Folk Art

Robert J. Dufault

Clemson University, Charleston, South Carolina, U.S.A.

INTRODUCTION

Sweetgrass (*Muhlenbergia filipes*) is the main structural material used in African-coiled basketry. The plant is a native, perennial, warm-season grass found growing sparsely along the ocean in narrow bands between coastal sand dunes from North Carolina to Texas. Much of the native sweetgrass groves have been lost in the region due to oceanfront development. The continuance of this old African-American folk art is jeopardized by the loss of sweetgrass. Since the late 1980s, horticultural research has determined that sweetgrass can be grown successfully as a row crop, but the plant is a short-lived perennial, needing replanting every four years to maintain supply. With knowledge of how to propagate and cultivate sweetgrass, sweetgrass “gardens” could be planted in the backyards of individual basketmakers to finally solve the supply problem.

SWEETGRASS BASKETS

The city of Charleston, South Carolina, was founded in 1670 and is bedazzled with lovely old homes and gardens throughout its old and winding streets. However, even older than most homes in Charleston is the ancient tradition of sweetgrass basketmaking. The significance and legacy of producing these historic baskets has been a treasured, beloved birthright held dear by generations of basket makers, the direct descendants of enslaved Africans of plantation days. About 30 years ago, approximately 1200 families were involved in basketmaking, but now only about 300 families are involved in the tradition (personal communication with Mary Jackson, past president of Mt. Pleasant Basketmaking Association). The most insidious factor contributing to the demise of this folk art is the gradual loss of natural sweetgrass habitats in the region. Sweetgrass once was readily available and abundant in the Charleston area, but today sweetgrass is very scarce and difficult to find.

Sweetgrass (*M. filipes*), the main structural material used in African-coiled basketry, is a native, perennial, warm-season grass found growing sparsely along the ocean in narrow bands between coastal sand dunes from North Carolina to Texas. The narrow leaf blades are

harvested green and dried before use in sweetgrass baskets. Successive coils of sweetgrass are sewn together in rows, not woven, with strips of leaf material from the palmetto tree (*Sabal palmetto*), the state tree of South Carolina. The explosion of growth in the Charleston area by new residents and industries has caused a boom in urban and beachfront development to support the demand by the growing population. Urbanization has destroyed much of the natural habitats of sweetgrass, as has development of beachfront communities on the barrier islands off the coast of Charleston. Basketmakers now have to travel hundreds of miles to Georgia and Florida to find adequate supplies. Many basketmakers are old and these long, expensive, arduous trips are impossible and frustrating, which has fueled the loss of basketmakers (Fig. 1).

The roots of the sweetgrass basket craft were borne out of slavery. Colonial Charleston was a very prosperous city built on many agricultural industries beginning with rice in the late 1600s and early 1700s, then indigo, and lastly cotton. With Charleston’s warm climate, a long growing season, and extensive marshy wetlands, the area was a natural for growing the lucrative rice crop. Rice was a staple crop in Africa, and Africans had cultivated rice for centuries and perfected its production. Slavers identified these people, the ancestors of today’s Low Country basketmakers, and abducted them into the slave trade for use on rice plantations in the New World.

The enslaved Africans brought the expertise to produce rice from the planting, harvesting, and processing. African-coiled basketry was critical in the processing of the rice. With flat fanner sweetgrass baskets, the seed was thrown into the air to separate the rice seed from chaff. Slavers were paid premium price for Africans from the West African Rice Kingdoms of the Windward Coast (Senegal to the Ivory Coast) to the mouth of the Congo River (Gabon, Zaire, and Angola).^[1] A man or woman who made baskets was worth more than one who did not, with age, strength, and other skills being equal.^[2] History has not fully credited the enslaved African for the success of the rice kingdom in the South, but without their knowledge of the crop cultivation and processing, rice would have never flourished.^[3] Besides fanner baskets, enslaved Africans sewed all sorts of utilitarian vessels to hold and store agricultural commodities and to use in

Fig. 1 A fanner basket (left) and tote baskets (center and right) showing consecutive rows of sweetgrass (light coils) and pine needles (dark coils) woven together with strips of palmetto palm fronds.

plantation houses for domestic purposes. The barter of baskets among plantations was also a very lucrative trade in colonial days.

Sweetgrass basketry is one of the earliest traditional crafts with a rich documented history from “carryover” from African enslavement and colonial plantation days to the present. These African skills remained unchanged and have been passed down from generation to generation for over 300 years from parents to siblings. Though the raw materials are different in American and African baskets, amazingly the construction techniques of sweetgrass baskets are unchanged from their African counterparts to this day. Some American basketmakers have journeyed to Senegal, Africa, and have reported very similar baskets and techniques still produced by today’s African basketmaker. Modern basketmakers in the Low Country of South Carolina have introduced a multitude of new basket forms and functions, which are still very useful in the home, but these baskets are now considered “objects of art” more than just utilitarian baskets of old.

To basketmakers, sweetgrass basketry symbolizes 1) their heritage and connection to their African ancestry and 2) a remembrance of people who survived centuries of oppression. They have made a reaffirmation of these goals with each new generation with sweetgrass basketry representing the heart and keepsake of their devotion.

Basketmakers have always wondered if they could cultivate sweetgrass inland similarly to vegetables, but individual attempts to transplant the plant were not successful. By 1988, the plight of the basketmakers was common knowledge due to timely newspaper articles. In 1989, I became intrigued with the idea of domesticating sweetgrass and became involved in attempts to learn how to grow it in a cultivated state. After four years of part-

time trial and error using many different horticultural approaches and techniques, in 1993 I felt confident to plant a large experimental planting somewhere in the Low Country. The Historic Charleston Foundation offered land at the old McLeod Plantation for our field trials. Established in 1947, the Historic Charleston Foundation is a nonprofit educational organization dedicated to historic preservation. McLeod Plantation, now owned by the Historic Charleston Foundation, is the last intact plantation on James Island and a historic landmark. So, with enthusiasm, members of the Mt. Pleasant Basketmakers Association and I toiled to prepare and plant 2000 sweetgrass plants in an effort to eventually eliminate the shortage. A second acre was planted at McLeod, and in May 1995 two more acres were planted. Many other important benefactors joined us to help support our goal of ending the sweetgrass shortage problem, such as the City of Charleston, the Agricultural Society of South Carolina, the SC Seagrant Consortium, and the Trident Community Foundation. We enlisted the assistance of the National Civilian Community Corps to help prepare and plant the expansion acreage in 1995. By summer 1995, we had four acres of sweetgrass maturing for harvest within two years.

The year of 1995 was a historic year for the basketmakers, as the first acre of sweetgrass at McLeod was finally mature enough for extensive harvesting. In past years, the plants were rather succulent and brittle, which rendered the cultivated grass unsuitable for basketry. However, in 1995, the plants matured and grew into very large clumps. Plant competition caused the leaves to lengthen and become very strong and fibrous, which are critically important characteristics of high-quality sweetgrass for basketry. By midsummer, we finally knew that our grand experiment of cultivating sweetgrass at McLeod was a rousing success. Basketmakers judged the quality of the cultivated sweetgrass excellent for basketry. The downside of this grand experiment was twofold: 1) Sweetgrass in cultivation was found to be a short-lived perennial, and earlier plantings only lived for about four years and then declined by 1998; and 2) maintenance of such large acreage by basketmakers was too difficult for the community to handle. It appeared that large plantings were not the best approach to solve the supply issue.

CONCLUSION

During the years I worked with this crop, I learned many secrets about the plant’s growth and development. Although the supply problem still plagues the basketmakers, we now know the horticulture of this plant. I feel that the supply problem can be solved easily by individual basketmakers establishing sweetgrass plantings in their own backyard. A 25’ by 25’ plot would probably

sustain the needs of a basketmaker or two. The plant thrives on benign neglect and doesn't require any fertilizer or much water during the growing season. This scheme would provide a free product to supply individuals who would take responsibility and pride in not only producing a beautiful art object but also growing the "basket" from seed.

Switchgrass As a Bioenergy Crop

Samuel B. McLaughlin

Lynn A. Kszos

Oak Ridge National Laboratory, Oak Ridge, Tennessee, U.S.A.

INTRODUCTION

The production of renewable bioenergy from crops grown on American farms to supplement fossil-derived energy sources could provide the United States with many desirable ecological and economic benefits. These include reduced dependency on imported oil and its associated geopolitical and economic risks; reduced damage to sensitive ecosystems associated with the high ecological costs of fossil fuel mining/recovery; reduced emissions of both greenhouse gases and toxic air pollutants associated with combustion of fossil fuels; and increased economic benefits to American farmers who would produce and harvest the renewable energy embodied in crops or crop residues.

Among the many types and sources of renewable energy—which include solar, wind, water, municipal waste, and agricultural residues—perhaps the greatest potential for ecological and economic gains to the agricultural industry is from dedicated energy crops. Dedicated energy crops include short-rotation woody crops as well as annual or perennial herbaceous crops grown specifically for energy industries. These are potentially very attractive to industry because they can be selected to provide desirable feedstock chemical and physical attributes, and can be planted in close proximity to industrial sites to assure adequate supply of feedstock of acceptable quality with reduced transportation costs. Among the potential dedicated energy crops, switchgrass (*Panicum virgatum*) was selected by the U.S. Department of Energy-sponsored Bioenergy Feedstock Development Program (BFDP) in 1991 as a model herbaceous species for further development. Characteristics of switchgrass that reflect its potential to serve as a national source of renewable energy are the focus of this article.

ECOLOGICAL AND AGRONOMIC ATTRIBUTES OF SWITCHGRASS

Switchgrass is a perennial bunch grass native to the United States. It has the highly efficient C4 carbon metabolism typical of warm season grasses and a deep

rooting pattern that equips it to thrive in a wide variety of habitats and soils that are unsuitable for many types of row crops.^[1] Switchgrass formed an important component of the original tall-grass prairie in the central United States. Much of the original prairie habitat has been converted to cropland, and switchgrass can currently be found in more thinly dispersed and smaller stands in diverse habitats. These include both grasslands and open forests in North America east of the Rocky Mountains. Two main ecotypes occur naturally in this genetically diverse, open-pollinated species: 1) lowland ecotype, that is thicker-stemmed and adapted to warmer, moister sites in the South; and 2) an upland ecotype that has thinner stems and is adapted to somewhat drier soils and cooler climatic conditions. Switchgrass was chosen as a model herbaceous bioenergy crop for research and development based on the relatively low energy and resource requirements associated with high-yield capacity, its ecological value in protecting and improving soil quality and wildlife habitat, and its compatibility with conventional farming equipment and management practices.^[2,3]

Switchgrass has been planted as a forage grass in the great plains for over 50 years and is one of the principal grasses planted to restore soil quality in the U.S. Conservation Reserve Program. As a species for bioenergy production, the criteria for successful development shifted toward maximum production of biomass and associated cell wall constituents (such as cellulose that could be converted to fuels such as ethanol, or combusted to produce heat and electricity). In addition, achieving low mineral content in harvested biomass is important in reducing mineral buildup during combustion or conversion processes. Thus, high yields and low mineral nutrient content became relatively more important in selecting, improving, and managing switchgrass as a bioenergy species. This represents a shift in focus from the criteria for traditional forage production for animal consumption, where high mineral nutrient content and low stem:leaf ratios are more desirable attributes.

The past 10 years of BFDP research have focused on strategies for efficiently establishing and managing switchgrass for maximum biomass production; defining and improving breeding techniques to maximize biomass

production potential; and basic studies to better understand the underlying genetics, physiology, and soil-carbon cycles of switchgrass grown as an energy crop. More recently, integrative assessments have evaluated the potential of switchgrass to contribute ecological and economic gains as a component of a national energy strategy.

ESTABLISHING AND MANAGING SWITCHGRASS

One of the principal challenges of producing switchgrass lies in successful establishment of this light-seeded perennial species, which typically attains less than a third of its full production potential during the first year. Because of slow growth in the establishment year, switchgrass typically takes 2–3 years to attain full production capacity. Planting seed of known viability in a firm seedbed, controlling weeds during the initial year, and restricting cutting practices to 1–2 cuts per year are important considerations in maximizing switchgrass production.^[4] There are several pre- and post-emergence herbicides available for use on nongrazed grasses, including Platteau[®], Paramount[®], Roundup[®], and atrazine. However, the success of these herbicides and appropriate dosage rates can vary regionally, and latitude should be considered in designing an optimum weed control plan. Higher temperatures in Texas, for example, can increase the toxicity of some herbicides to switchgrass.^[5]

Growing within its zone of natural adaptation, switchgrass has very high resistance to foliar diseases, although there has been increasing evidence of leaf diseases on some varieties in larger plantings in the Midwest in recent years. Recently initiated research also suggests that nematodes play some role in inhibiting growth of switchgrass during the establishment year. More research is needed in this area, as important gains in early establishment might be realized from improved understanding of the role of belowground diseases.

Production management research within BFDP has focused on identifying the most productive existing cultivars, their regions of optimum adaptation, and the management practices that optimize production efficiency within the regions. The best commercial varieties determined by 10 years of production in field research plots are the lowland variety Alamo, in the deep South; the lowland varieties Alamo and Kanlow at mid-latitudes; and the upland variety Cave-in-Rock for northern latitudes.^[6,7] Yield of the best adapted varieties averages 15–22 Mg ha⁻¹ y⁻¹ in regional field trials. Yields of currently available varieties in production-scale fields are expected to be 30% lower, around 10–15 Mg ha⁻¹ (4.5–7 tons ac⁻¹).

Lowland varieties produce highest yields in the deep South, with either a single harvest in late August to mid-September, or two harvests with early July and November target dates. Upland varieties such as Cave-in-Rock may, under the best growing conditions, achieve yields comparable to lowland varieties in the South, but clearly require two harvests annually to attain those yields. In Alabama, row spacings may be increased to as much as 80 cm without yield loss.^[6] The combination of flexible harvest frequency and timing is attractive to landowners who are managing multiple crops, whereas the row spacing flexibility improves potential attractiveness of switchgrass stands for game bird cover. From the perspective of resource utilization efficiency, the single-cut system offers higher returns based on reduced energy inputs associated with a single harvest and substantially lower nutrient removal. Nitrogen is the only nutrient that consistently stimulated switchgrass yields, and nitrogen removal has been reduced by approximately 60%, to 30–50 kg N ha⁻¹, with single-harvest systems.^[7] Recommended N application rates are 50–100 kg N ha⁻¹ y⁻¹ in most areas; however, there is some evidence that switchgrass stands may become less dependent on external nitrogen as internal sources in roots, crowns and soil organic matter accumulate.^[6,7]

DESIRABLE PRODUCTION CHARACTERISTICS

Production characteristics of primary interest in selecting a bioenergy crop are high yield potential, low yield variability over time in the face of variable environmental conditions, the persistence of the stand over time, and the quality of the feedstock produced. The longest continuous yield plots in the BFDP system were planted to Alamo switchgrass in 1988 and have shown high yields (13 yr avg = 23 Mg ha⁻¹) and an apparent increase in resistance to drought (Fig. 1) over time.^[7] Whereas irrigation has not been considered a desirable management option for energy crops, experience in Texas^[5] suggests that a single midseason irrigation event may double switchgrass yields in dry years. The potential sharing of irrigation equipment among multiple fields for which only one or two irrigation events are required during the season increases the probability that irrigation would be an economically viable option for switchgrass. The capacity of switchgrass (as well as other warm season grasses) to maintain such high yields even during periods of infrequent rainfall can be attributed to its deep, well developed root system. In the mid-Atlantic states standing root mass has been found to be comparable to annual aboveground production.^[6]

Fig. 1 Long-term yields of Alamo switchgrass from Auburn, Alabama compared to annual rainfall. Note the relative insensitivity of annual yields to the very low rainfall occurring in 2000. This stand was planted in 1988 and was harvested twice each year in early July and September. (Data from Ref. 7.)

High switchgrass root production and turnover are important not only in nutrient and water acquisition from soils but also in increasing soil organic matter (SOM). Studies across diverse soil types in both the mid-Atlantic region and in Texas have documented significant increases in SOM in soils under switchgrass.^[5-7] In the mid-Atlantic region, SOM increases ranged from 20% to

125%, and averaged 43% across eight study sites over a 10-year period.^[6] The accumulation of SOM with root production and turnover has important implications for improving water and nutrient retention and availability in associated soils. Such increases are also important in the net reduction of carbon dioxide emissions derived from the utilization of switchgrass as a renewable energy

Fig. 2 Through production and turnover of fine roots, switchgrass can contribute significant amounts of soil organic carbon to the farm lands on which it is grown (POM-C = particulate organic matter, MOM-C = mineral-associated organic matter). Modeling studies indicate that these gains are influenced by soil temperature and prior accumulation of soil carbon ((a) cropland; (b) pasture) (MAT = mean annual temperature). (Prediction and analyses from Ref. 8.)

source.^[8] An empirically based model of soil carbon accumulation under switchgrass has been developed to estimate relative contributions of both labile and recalcitrant carbon to accumulated soil carbon under switchgrass over time (Fig. 2). The model projects annual accumulation rates that ranged up to 1.4 Mg C ha⁻¹ y⁻¹ over 10 years on degraded soils in warmer climates and averaged 0.78 Mg C ha⁻¹ y⁻¹ over 30 years across diverse regions in the U.S. East. Thus, carbon storage in soils under switchgrass can represent a significant contribution to total reduction in carbon emission achieved in utilizing switchgrass for bioenergy.

BREEDING

Breeding research with switchgrass over the past 10 years has contributed significant new knowledge to the basic breeding biology of switchgrass.^[9] Switchgrass has been found to typically occur in either tetraploid (4x = 36n) or octoploid (8x = 72n) multiples of the nine basic chromosome pairs. It is an open-pollinated, self-incompatible species, within which crossing across ecotypes does occur, although crosses between ploidy levels are rare. At present, germplasm derived from accessions from nine clusters that were delineated within a larger population of 115 accessions of switchgrass examined in the BFDP has been submitted to the U.S. Department of Agriculture's National Plant Germplasm System.^[9] Early in the breeding effort with switchgrass, fast-track breeding approaches such as Recurrent Restricted Phenotypic Selection based

primarily on first-year growth of switchgrass were replaced with a slower but more predictable genotypic selection process based on performance of test plants over at least 2 years, and quantitative evidence of high heritability of desirable agronomic traits from candidate parent plants. In addition, heterosis has now been demonstrated in switchgrass allowing a narrowly restricted breeding base to be used to target specific desirable traits. More than 15 experimental synthetics have been developed, at least three of which are undergoing performance verification for commercial release by seed companies. Expected genetic gains estimated from among half-sib families have been 5–26% above the best commercially available varieties; however, yield gains have also been shown to be strongly influenced by the test environment.^[9]

EVALUATING SWITCHGRASS AS A BIOFUEL

To be successful as a biofuel crop, a species like switchgrass must be physically and chemically acceptable as a fuel for industrial use as well as economically competitive in both agricultural and industrial markets. The chemical and physical attributes of switchgrass shown in Table 1 include a relatively high energy content combined with a relatively low ash content.^[10] These traits make switchgrass a desirable fuel, both for combustion to produce heat and electricity, and for conversion to ethanol as a transportation fuel. Estimates of the competitive potential of switchgrass as a crop in agricultural markets

Table 1 Chemical and physical properties of switchgrass as a biofuel relative to selected alternate fuels

Fuel property	Units	Switchgrass	Alternate fuel	
		Value	Value	Fuel type
Energy content (dry)	Gj.Mg ⁻¹	18.4	19.6 27.4	Wood Coal
Moisture content (harvest)	%	15	45	Poplar
Energy density (harvest)	Gj.Mg ⁻¹	15.6	10.8	Poplar
Net energy recovery	Gj.Mg ⁻¹	18	17.3	Poplar
Storage density				
(6 × 5) round bale	kg.m ⁻³	133	150	Poplar chips
(4 × 5) round bale	(dry weight)	105		
Chopped		108		
Holocellulose	%	54–67	49–66	Poplar

Sulfur content	%	0.12	0.03 1.8	Wood Coal

(From Ref. 10.)

using an agricultural sector model indicate that at a price of \$44 Mg⁻¹, switchgrass would be more profitable than crops currently grown on approximately 16.9 million ha of American farmland.^[8] As reliance on energy from biofuels increases in the future, switchgrass should thus provide an economically attractive alternative cash crop for American farmers when priced at these levels. At present, switchgrass is not being utilized on a large scale for bioenergy production. However, pilot testing of switchgrass combustion characteristics and performance by research teams that have included two commercial power producers has been completed successfully. In addition, a large-scale power production system involving switchgrass produced on 8000 ha by a farmers' cooperative is currently being developed and tested for full-scale operational feasibility in Chariton Valley, Iowa.

The value of a fuel for national energy supply should theoretically include not only its value as a source of energy, but also its impacts on society as a whole. Currently, research in the bioenergy industry is increasingly being directed toward producing not only energy and fuels from biomass, but also a wide variety of industrial chemicals that can add value to the bioenergy cycle. The development of capabilities to transform crops like switchgrass to improve production potential^[11] may lead to increased recovery of specific chemicals of industrial interest as well as improved production potential of switchgrass. The true value of bioenergy crops also encompasses ecological and agronomic values that are not traditionally considered in fuel prices. For this reason, life cycle analyses of switchgrass production have been conducted to consider some of these secondary values relative to current fossil fuel scenarios. Included among the effects of production of 16.9 million ha of switchgrass at \$44 Mg⁻¹ in the previous example were estimated annual increases of \$6 billion in net farm revenues, \$1.86 billion reduction in government subsidies due to improved farm income, and displacement of 44–150 Tg (1 Tg = 10¹² g of carbon) emissions to the atmosphere.^[9] Benefits of this magnitude substantially reduce the societal costs of renewable biofuels relative to fossil fuels, and should provide economic incentives to expedite the commercialization of switchgrass as a bioenergy crop.

CONCLUSION

Production of dedicated energy crops on American farms represents a potentially important way to decrease America's dependency on imported energy while providing significant economic and ecological benefits to the national economy. Research on management, breeding, and both ecological and economic benefits of a perennial native grass species, switchgrass, as a source of renewable

energy suggests that this species could play an important role in the search for greater national energy self-sufficiency. Switchgrass can be used to produce electric power, transportation fuels, and biobased products. Benefits of developing a biobased economy with participation of America's farmers as energy suppliers are substantial and include improved farm income, improved soil productivity and stability, reduced greenhouse gas emissions, and reduced need for government subsidies of crop prices.

Symbioses with Rhizobia and Mycorrhizal Fungi: Microbe/Plant Interactions and Signal Exchange

James E. Cooper

Queen's University, Belfast, United Kingdom

INTRODUCTION

By virtue of their ability to capture (fix) atmospheric nitrogen, legumes assume a special significance among agricultural plants. Their productivity is theoretically independent of soil nitrogen status and they provide important grain and forage crops in both temperate and tropical zones. Nitrogen fixation can occur only when these plants are in the symbiotic state and the agents of fixation are soil bacteria, the rhizobia, which invade limited regions of the root cortex via infection threads in root hairs. Successful infections result in the development of root nodules, into which gaseous nitrogen diffuses to be reduced to ammonium by the nitrogenase enzyme of rhizobial bacteroids. An overwhelming majority of land plants, including most legumes, also form root symbioses with fungi, known collectively as mycorrhizae, which improve the supply of phosphate and other nutrients from soil to plant roots and confer increased resistance to plant pathogens. Most mycorrhizal associations can be allocated to one of two broad categories: the ectomycorrhizae, characterised by a fungal sheath and limited intercellular penetration of the root cortex of gymnosperms and woody angiosperms, or the endomycorrhizae, which possess hyphal structures that develop inside cortical cells of woody and herbaceous angiosperms. Arbuscules are examples of such structures; they are highly branched extensions of fungal hyphae that are common, though not ubiquitous, among the endomycorrhizae. Arbuscular mycorrhizal (AM) and rhizobial symbioses are similar in the sense that both are intracellular, but the former, involving the fungal order Glomales, is by far the more ancient of the two systems. In each case the progression to the symbiotic state is governed by reciprocal signal generation and perception, which may be viewed in terms of a "molecular dialogue" between the partners. While the early interactions between legumes and rhizobia are now largely understood at the biochemical and molecular genetic levels, details of events leading to the formation of mycorrhizal symbioses have not yet been elucidated.

PRIMARY SIGNALS FROM LEGUMES TO RHIZOBIA

In most examples studied to date, the first identified signals are flavonoids or isoflavonoids in legume root or seed exudates. These compounds are secondary metabolites of the plant phenylpropanoid biosynthetic pathway. (For examples of structural features, see Fig. 1.) Their main role in the initiation of a rhizobial symbiosis is an interaction with the constitutively expressed *nodD* gene product(s) of the microsymbiont to form a protein-phenolic complex: a transcriptional regulator of other rhizobial nodulation (*nod*) genes that are responsible for synthesis of reciprocal signals to the plant root. Different legumes release different compounds that act either as *nod* gene inducers or inhibitors for their specific rhizobia. The first symbiotically active flavonoid to be discovered was a flavone, luteolin, which is a *nod* gene inducer in the *Medicago sativa/Sinorhizobium meliloti* symbiosis.^[1] Daidzein, an isoflavone, is an inducer in the *Phaseolus vulgaris/Rhizobium leguminosarum* biovar *phaseoli* symbiosis, whereas kaempferol, a flavonol, is an inhibitor in the *Trifolium/R. leguminosarum* biovar *trifolii* symbiosis. It is the relative proportion of inducing and inhibiting compounds in seed or root exudates that is thought to determine the overall level of *nod* gene induction in compatible rhizobia.

Certain non-flavonoid compounds in legume root exudates also act as *nod* gene inducers: the betaines stachydrine and trigonelline from *Medicago* and the aldonic acids erythronic and tetric acid from *Lupinus*. However, unlike flavonoids, whose biological activity is expressed at nanomolar concentrations, these compounds elicit *nod* gene induction only at concentrations greater than c. 10 mM. The varying responsiveness to flavonoids of NodD proteins from different rhizobial species and biovars accounts for one of the elements determining the host specificity of these bacteria. For example, *Sinorhizobium meliloti* will form root nodules on alfalfa (*Medicago*) but not on clovers or soybean. Other responses of rhizobia to legume flavonoids that may be significant for

infection of the host plant include removal of glycosidic residues from flavonoid-sugar conjugates, degradation to yield new flavonoids and other, monocyclic phenolics, positive chemotaxis to some *nod* gene inducers, and increased growth rates in nutrient-limited media supplemented with low micromolar concentrations of inducing or non-inducing compounds.

REVERSE SIGNALS FROM RHIZOBIA TO LEGUME ROOTS—THE CHITOLIPOOLIGOSACCHARIDE NOD FACTORS

The combination of NodD proteins with appropriate plant flavonoids triggers the production of highly specific reverse signal molecules by rhizobia—the chitolipooligosaccharide (CLOS) Nod factors—by means of the transcriptional activation of common and host specific *nod* genes. The common *nodABC* genes are required for the synthesis of a chitinlike template, comprising several β 1,4-linked, *N*-acetyl glucosamine residues, which forms the basis of Nod factor structures found in all rhizobia studied to date. NodC is a β -glycosyl transferase that forms chitin oligomers and can influence host specificity of the Nod factor to some extent, depending on final chain length (2- to 6-mer). NodB deacetylates the terminal (non-reducing) glucosamine residue while NodA is involved in the transfer of a fatty acid moiety to this position. Fatty acids may be of the type common to bacterial phospholipids (e.g., C18:1), and chain length may vary even in Nod factors produced by a single bacterial species or biovar. In some rhizobia, *nodFEG* genes (which are usually classified as host-specific *nod* genes) are required for the formation of highly unsaturated fatty acids. An example of a typical Nod factor precursor template is shown in Fig. 2.

The major determinants of host specificity lie in the so-called “decorations” on the common CLOS template described above. Depending on the producing organism, acetyl, arabinosyl, carbamoyl, fucosyl, glycerol, mannosyl, methyl, or sulphate groups have been reported at various positions. In *S. meliloti*, whose Nod factor structure was the first to be discovered in 1990,^[2] an acetyl group is introduced at the 6-C position of the nonreducing end of the CLOS molecule by an *O*-acetyl transferase encoded by the *nodL* gene, while the *nodHPQ* genes control the synthesis of a sulphated residue positioned at the reducing end. Mutations in either *nodQ* or *nodH* result in the production of unsulphated molecules that fail to elicit the responses associated with wild type Nod factor on alfalfa, the normal host legume of *S. meliloti*. An overview of reciprocal flavonoid and Nod factor signaling in the alfalfa/*S. meliloti* symbiosis is presented in Fig. 3.

LEGUME ROOT RESPONSES TO RHIZOBIAL NOD FACTORS

Nod factors are essential signals for rhizobial entry into legume roots, through infection threads in root hairs, and for the development of root nodules. Rhizobial mutant strains that have lost the ability to produce Nod factor (for example, by deletion of common *nod* genes) cannot nodulate their normal host plant, but this property is restored in the presence of purified Nod factor isolated from the parent strain with its full complement of *nod*

Fig. 2 A typical Nod factor core template synthesised by enzymes encoded by the common *nodABC* genes of rhizobia.

genes.^[3] Application of femtomolar concentrations of purified Nod factor to the roots of a host legume elicits several responses that can be detected by biochemical or microscopical analysis: distortion of root hairs accompanied by membrane depolarization and deformation, calcium ion influx and chloride and potassium ion

efflux, preinfection thread formation in curled root hairs, and localized cortical cell division at the sites of root nodule primordia. Gene expression studies have shown that Nod factors, even in the absence of their producing rhizobia, can induce some of the plant genes (nodulins) that are involved in the preinfection, infection, nodule

Fig. 3 Overview of reciprocal flavonoid and Nod factor signaling in the alfalfa/*Sinorhizobium meliloti* symbiosis. Flavonoids released from the plant's roots (1) are received by the constitutively expressed NodD proteins of the bacterium (2). The resulting NodD/flavonoid complex activates transcription of common (3) and host-specific (4) *nod* genes whose enzymes act collectively to synthesize a chitolipooligosaccharide Nod factor (5) that is transmitted back to the plant root (6). (From Zance, C.P. Root-bacteria interactions: symbiotic N₂ fixation. In *Plant Roots, the Hidden Half*; Waisel, Y., Eshel, A., Kafkafi, U., Eds.; Marcel Dekker, Inc.: New York, 2002; 839–867.)

development, and nodule function stages of symbiotic interaction. Auxin flow in roots at the earliest stages of nodule formation is perturbed by Nod factors, in conjunction with certain endogenous root flavonoids acting as auxin transport inhibitors.^[4] Nod factors also control the number of nodules formed on a root system by inducing an autoregulation signal in the host plant. The nature of signal transduction pathways leading from the perception of Nod factors to symbiosis-related gene activation is currently the subject of intensive research. While a breakthrough was recently achieved with the discovery of a receptor kinase gene in *Lotus*^[5] and *Medicago*^[6] that is required for early signal transduction subsequent to Nod factor perception, the identity of the direct receptor for the Nod factor itself is yet to be established. Interestingly, this receptor kinase is essential for the formation of both rhizobial and AM symbioses with legumes, and it also shares structural features (leucine-rich-repeats) with animal proteins that function in the innate immune system.

While flavonoids and Nod factors are undoubtedly of prime significance as signal molecules in symbiotic development, they are not the only determinants of early recognition between host plant and bacterium. In addition to the chitolipooligosaccharide Nod factors, rhizobia produce an array of compounds with recognition functions, including extracellular polysaccharides, lipopolysaccharides, K-antigens, and cyclic glucans.^[7] In the legume partner carbohydrate-binding proteins on root surfaces, the lectins, appear to mediate host specificity through selective interactions with Nod factors and/or rhizobial extracellular polysaccharides^[8] but despite almost 30 years of research on this facet of symbiosis, the details of lectin function remain unresolved.

CROSSTALK IN MYCORRHIZAL SYMBIOSES

It is widely recognised that partially overlapping genetic programmes characterise the development of AM and rhizobial symbioses with terrestrial plants; the latter are thought to have recruited genes from the former during their (more recent) evolution, and the previously cited receptor kinase gene in *Lotus* and *Medicago* is one example. Such shared features notwithstanding, little is known about the mechanisms of reciprocal signaling and perception/response in AM symbioses.^[9,10] The obligate biotrophy of AM fungi, which does not allow them to be cultured in the absence of a plant host, and the small quantities of fungal tissue even in highly colonized roots (c. 1% of extracted mRNA is fungal), present obstacles to research into these systems.

AM fungal spore germination, as well as subsequent hyphal growth and branching, are stimulated by root exudates from host plants and CO₂ may act as a volatile

signal from the host to direct hyphal growth toward the root surface. Flavonoids are candidates for primary signals from plant root to fungus, mainly on the grounds that they enhance spore germination, but there is no evidence to indicate that they are obligatory compounds or that their mode of action is in any way similar to the one they exhibit in legume-rhizobia symbioses. Contact between fungal hyphae and root epidermal cells is required for the formation of appressoria (fungal structures formed on adhesion to the root surface in advance of host cell penetration) and the plant signal for this stage of infection, though not yet defined, is probably not found in root exudates. The identity of signal molecules from AM fungus to host plant (the equivalent of rhizobial Nod factors) is also unknown, but chitinaceous fragments from fungal cell walls may serve such a purpose. Some pathogen response proteins have been detected in plant roots during the early stages of AM colonization, but the sustained defense response associated with a pathogen attack is either not elicited or is suppressed, as is also the case in legume-rhizobia interactions. Symbiosis-specific gene expression has been detected in both partners and some legume early nodulin genes (e.g., *ENOD2*, *ENOD11*, and *ENOD40* in *Medicago*) are expressed during both rhizobial and AM fungal infections.

As with AM symbioses, the nature of interactive signaling processes in ectomycorrhizae is currently unknown or, at most, ill-defined. Rutin (a flavonoid) and zeatin (a cytokinin) in plant root exudates may stimulate fungal growth in the rhizosphere, while hypaphorine (a fungal alkaloid found in the ectomycorrhizal fungus *Pisolithus*) induces decreased rates and perhaps complete inhibition of root hair elongation in the region of fungal colonization behind the root apex.^[11]

Interestingly, the host specificity of mycorrhizal fungi appears to be low, while that of rhizobia, as intimated above, is normally high; six genera from the order Glomales form AM symbioses with 80% of angiosperms, whereas, apart from one known exception (*Parasponia*), rhizobial infections are limited to legumes. Among rhizobial species and biovars, particular specificity is further displayed towards individual or small groups of legume genera. Rhizobia with very broad legume host ranges do exist but they may be the exception.

Symbiotic Nitrogen Fixation

Timothy R. McDermott

Montana State University, Bozeman, Montana, U.S.A.

INTRODUCTION

The legume–*Rhizobium* association is an example of mutualism: Both the plant and the bacterium benefit from their interaction. Microbes have a long history of being somewhat selfish and nonfriendly to plants. Indeed, the initiation of this symbiosis (i.e., infection) has many features that are similar to those that initiate pathogenic relationships. When this symbiosis is viewed from the background of the very large number of pathogenic plant-microbe interactions, it is easy to ask questions about how evolution allowed plants to develop divergent relationships with some microbes. In most instances plants appear to go to a lot of trouble to avoid invasion by microbes, whereas in others (i.e., legumes) they will invest significant resources to closely interact with them. This article provides a very general description of the formation and function of the legume–*Rhizobium* symbiosis.

DISTRIBUTION, ECOLOGY, AND IMPORTANCE

Many aspects of the symbiosis are described in great detail in recent comprehensive overviews.^[1,2] Indeed, these major contributions are often cited in this article as source material to intentionally guide readers to more intensive treatment of any of the topics briefly touched upon in the following.

The literature documents over 3000 legume–rhizobia root–nodule symbioses (Table 1), ranging from relatively simple plants such as clover to larger organisms such as shrubs and trees.^[3] The nodules formed on the roots of legumes are often categorized into two different groups based on nodule shape, nodule meristem activity, and type of fixed nitrogen products transported from the nodule to the shoot (Fig. 1). Continuing research into the ecology of this symbiosis has shown that it can be found in virtually any climate, ranging from the arctic to the tropics, having evolved essentially the same basic phenotype. In each case, these organisms partner to build a specialized structure known as a root nodule. The nodule houses the rhizobia bacteria, serving as a protective environment where an exchange of metabolites occurs. The host legume provides the rhizobia with photosynthetic sugars for carbon

and energy; in return the rhizobia utilize some of these energy-yielding substrates to support nitrogen fixation via the enzyme nitrogenase. The ammonia thus generated is released to the plant.

The ecological advantage afforded to the plant is easily imagined. By taking the risk of allowing the bacteria to infect its roots, the plant stands to benefit by acquiring a limiting nutrient from a pool that it does not have to share with other plants. This symbiotically acquired nitrogen (N) also serves as an important N input to the local ecosystem. The value of legumes in this regard has long been recognized in agriculture, where about 80% of the biologically fixed N is obtained from this symbiosis.^[4] Legumes have been used in crop rotations to reduce N fertilizer inputs into a variety of cropping systems, where on a worldwide basis legumes account for roughly 30% of the world's dietary protein.^[5] This is of greatest proportional importance in Third World countries.

ROOT INFECTION AND NODULE ORGANOGENESIS

The legume–*Rhizobium* symbiosis is species-specific. Some legumes will only nodulate with specific species of rhizobia, and the rhizobia vary, displaying narrow- to broad-host range nodulation capabilities.^[6] Nodule formation involves two separate stages—infection and nodule organogenesis. Infection is initiated in the rhizosphere when the bacteria find themselves in close contact with newly emerging root hairs in the rhizosphere. The initial interactions occur as a result of a biochemical dialogue that first involves a class of plant root exudates, known as flavonoids, that act as an inducer of nodulation genes in the rhizobia. The flavonoids bind to key regulatory proteins (e.g., NodD in *Sinorhizobium meliloti*), which then function together to positively regulate the transcription of numerous genes required for infection. Often the nodulation genes are found clustered in a focused location on the chromosome or on large Sym plasmids.^[7] These nodulation genes encode proteins that are involved in the synthesis and secretion of lipo-chitgo-oligosaccharide Nod factors, and in protein secretion. Both of these activities are essential for numerous different aspects of infection initiation.^[8] Secretion and release of Nod factors represent

Table 1 Examples of *rhizobium*–legume symbioses^a

Legume	Rhizobia partner
<i>Grain/Food</i>

<i>Acacia</i>	<i>Mesorhizobium plurifarium</i>
<i>Prosopis</i>	<i>Sinorhizobium kostiense</i>

^aThis list is not exhaustive, either in terms of legume genera or with respect to nodulation range of some of the rhizobia listed. Some legumes are referred to by their common names, when well-known and available. (For further examples, the reader can refer to www.honeybee.helsinki.fi/users/lindstro/Rhizobium/Names.html).

the first response of the rhizobia in the aforementioned biochemical dialogue. These Nod factors elicit various plant responses, one of the most visible of which is root hair deformation and curling (Fig. 2A), although the curling phenotype apparently requires the presence of live rhizobia.^[9] The rhizobia become entrapped within the crook of the curled root hair and in this pocket begin the process of infection thread formation (Fig. 2A).

In addition to root hair curling, the Nod factors also induce plant responses in the root cortex cells. The reestablishment of mitotic activity in highly localized regions of the root cortex marks the initiation of nodule primordia, which is the beginning of organogenesis. In temperate legumes such as pea and alfalfa, nodule primordia become evident in the inner cortex cells, whereas in roots of subtropical legumes like soybean and bean they are apparent in outer cortex cells.^[10] Specialized gene transcription also occurs in the primordia cells, leading to the production of host plant nodulins^[11] that participate in nodule/nodulation functions such as oxygen binding (hemoglobin)^[12] or plant defense-like reactions.^[13] Many nodulins have been identified and their expression has been correlated to specific parts of the nodule or to specific times during nodule formation; however, exact functions of many have yet to be determined.^[14]

The infection thread (Fig. 1), which is continuous with the root hair cell wall, acts as a pipeline to transfer the rhizobia from the root surface into the root cortex cells

that compose the nodule primordia. After the infection thread penetrates a nodule primordia cell, the rhizobia are released from the infection thread in an endocytotic process that involves the encapsulation of the rhizobial cells within host plasma membrane derived from the infected cell.^[15] Collectively, the rhizobia bacteria and the host-derived membrane structure are referred to as a symbiosome, to reflect the view that it now behaves somewhat like a plant cell organelle.^[16] Initially, a symbiosome typically contains a single (or at most two) rhizobial cell(s), at this stage referred to as bacteroids. It should also be pointed out that the symbiosome membrane serves to maintain separation of the rhizobia bacteria from the host plant, avoiding direct contact between the symbionts. This appears to be a common feature for all plant endosymbionts.^[17]

NODULE FUNCTION

Energy Costs

Carbon fixed during photosynthesis (i.e., CO₂) is used as a source of energy and reductant for nitrogen fixation, carbon skeletons for assimilation of fixed nitrogen, and for bacteroid and nodule growth and maintenance. For each gram of N₂ fixed, roughly 5–10 grams of carbon are needed.^[18] In terms of biochemical currency, the nitrogenase enzyme requires at least 16 ATP to reduce one mole of N₂ to 2 moles of NH₃. Part of the high cost of biological nitrogen fixation is due to the production of H₂ that results from the reduction of two protons concomitantly with the reduction of N₂.^[19] Some rhizobia have hydrogenase enzymes that could recapture some of the evolved H₂ and thus theoretically reduce

total energy costs; however, experimental demonstration of the latter has been variable and inconsistent.^[20]

The symbiosome membrane serves a critical role in controlling metabolite traffic between the symbionts. The bacteroids are completely dependent on the symbiosome membrane for supply and flux of carbon substrates, as well as for removal of fixed nitrogen and bacteroid waste metabolites. The symbiosome membrane contains metabolite-specific transporters that are functionally linked with the biochemical activities of the bacteroids. For example, even though glucose and fructose are abundant in the nodule cytosol,^[21] the symbiosome membrane selectively transports organic acids such as malate and succinate,^[22] which are metabolites that the bacteroids are well prepared to utilize.^[20] On the other hand, in most cases the symbiosome membrane transports the aforementioned hexoses relatively poorly. Likely not coincidentally, the biochemical pathways required to catabolize hexoses are found at low levels in bacteroids of most species of rhizobia.^[20]

Oxygen Paradox

The role of oxygen in the symbiosis is somewhat of an enigma. The exquisite O₂ sensitivity of the bacterial nitrogenase enzyme is well known and fairly well understood in terms of enzyme function and genetic regulation. However, bacteroids require oxygen as a respiratory electron acceptor for the generation of the large amounts of ATP (i.e., oxidative phosphorylation) required for nitrogen fixation. The problem is solved by control mechanisms that keep oxygen at low levels, yet maintain a steady flow of oxygen to the bacteroids. The outer layers of nodule cells restrict oxygen flux into the nodule by providing a gas diffusion resistance barrier that, when combined with the oxygen consumption of the bacteroids and the plant mitochondria, results in micro-aerobic conditions.^[23] Leghemoglobin is an oxygen-

carrying protein in the nodule, composing approximately 20% of the total soluble protein.^[24] Its function is similar to that of hemoglobin in blood, serving to transport oxygen throughout the nodule cytoplasm, releasing it as bacteroid and mitochondria respiratory demand requires. Leghemoglobin facilitates increased oxygen flow to the bacteroids and plant mitochondria, without increasing the amount of free oxygen.

Assimilation of Fixed N and Transport to Shoot

Experimental evidence suggests that the ammonium fixed by the bacteroid is released from the bacteroid and exported from the symbiosome,^[25] where it is then assimilated by the host into carbon skeletons.^[5] However, recent work with soybean suggests that alanine may also serve as a shuttle metabolite that transfers fixed nitrogen from the soybean bacteroid to its host.^[26] The ammonia that is released from the symbiosome is immediately incorporated into the amino acids glutamine and glutamate via the host plant enzymes glutamine synthetase (cytoplasm) and glutamate synthase (plastids), respectively.^[27,28] In temperate legumes (e.g., pea or alfalfa), the ammonia is transferred to the shoot primarily as the amide asparagine. In tropical legumes (e.g., soybean and bean), the ammonia is incorporated into ureides (allantoin and allantoic acid) and then transported via the xylem to the shoots.^[27,28]

Symbiotic Nitrogen Fixation: Plant Nutrition

Timothy R. McDermott

Montana State University, Bozeman, Montana, U.S.A.

INTRODUCTION

Symbiotic nitrogen fixation is one of the most fascinating aspects to legumes. This article briefly describes the mutualistic relationship between rhizobia bacteria and host legume plants and the mechanisms that enable plants such as peas and beans to satisfy their nitrogen requirements through this plant-bacteria association. The article explains what is known about the main nutritional requirements for this relationship aside from nitrogen as well as the basic methods for these assessments. Finally, it very briefly reviews the literature on the implications of specific nutrient deficiencies.

THE *RHIZOBIUM*-LEGUME SYMBIOSIS: THE ESSENTIALS

The *Rhizobium*-legume symbiosis forms as a result of a cooperative effort of the rhizobia bacteria and their respective host legume. Beginning with an intricate biochemical dialogue that initiates infection, the bacteria and plant together construct a specialized organ known as the legume root nodule. This symbiosis is viewed to be based on a mutualistic exchange of carbon for nitrogen. The plant utilizes solar energy to fix and reduce CO₂ into carbohydrates, which are subsequently transferred from the leaves to the roots and root nodules. Inside the nodule, these photosynthetic sugars (primarily sucrose) are partially metabolized to organic acids (e.g., malate and succinate), which is the primary form of carbon provided to the bacteroids. The bacteroids utilize these organic acids as an energy source for their nitrogen fixation activity that generates ammonia, which is then released to the plant. The advantage for the legume plant acquiring nitrogen from its symbiosis with the rhizobia bacteria is very clear; nitrogen is most often the limiting nutrient in nonagricultural environments, and thus the plant can gain a competitive advantage in that it does not have to compete for a limited nitrogen pool. For some legumes, the nitrogen acquired from symbiosis can account for almost all of the plant's nitrogen needs. However, many legumes still rely on soil nitrogen (NH₄⁺ or NO₃⁻) to fill the balance.^[1]

ASSESSMENT OF MINERAL NUTRIENT NEEDS FOR THE SYMBIOSIS

Three basic approaches for investigating specific roles of individual nutrients in symbiotic nitrogen fixation are typically used and have been discussed previously^[2,3] (Table 1). Examination of nutrient influences might involve assessing interaction effects with inorganic nitrogen: If a particular element corrects an N deficiency, then a reasonable conclusion is that it impacts, directly or indirectly, on the nitrogen fixation process. Another approach is to examine whether correcting a nutrient deficiency improves nitrogen content in the shoot. Finally, effects of a specific nutrient can be viewed from the perspective of its effect on nodule formation and/or levels of nitrogen fixation as directly measured by acetylene reduction, H₂ evolution, or ¹⁵N isotope dilution.

There are several phases of nodule formation and several aspects of nodule function where a nutrient deficiency can be manifested, and any or all can place a limit on the functioning of this symbiosis. Nutrient shortfalls that directly influence the soil or rhizosphere populations of the rhizobia can in turn impact infection and total nodulation and, thus, potential nitrogen acquired from symbiosis. Some nutrients have been identified to have specific roles at discrete steps in the infection process and nodule formation; furthermore, bacteroid and nodule function may also have unique nutritional requirements. It is not always easy to sort out effects of nutrient limitation on nitrogen fixation per se versus an impact on general host plant growth and well-being that can have ripple effects on nodule function. A legume plant that is metabolically crippled due to a severe nutrient limitation (e.g., S, P, or K) will not be the optimum symbiotic partner. Such an indirect effect is in contrast to the situation where a critical nodule function such as maintenance of optimum oxygen transport functions by leghemoglobin or nitrogen fixation by nitrogenase are specifically dependent upon iron availability.

NUTRIENT REQUIREMENTS FOR OPTIMAL FUNCTION

Nutrient requirements of this symbiosis include host plant requirements as well as the nutrients required for nodule

Table 1 Proportion of total nitrogen acquired by nitrogen fixation for legumes under field conditions

Legume	Percentage
Soybean	50
Bean	50
Lentil	70
Pea	70
Broad bean	80
Alfalfa	90
Clover	90

(Based on Ref. 2.)

biomass synthesis, including bacteroid nutritional requirements. Further, nodule tissue may have specialized requirements or perhaps nonspecific sink activity that may influence overall functioning and health of the legume host plant. The requirements of several nutrient elements have been investigated, and while exact mechanisms may not always be completely understood, roles for some have been identified. Macronutrients such as Ca, P, S, and K and micronutrients such as Fe, B, Co, Cu, Mo, Ni, Se, and Zn have been recognized to have specific minimum functions in certain stages of nodule formation and/or function.^[2] The roles of macronutrient and micronutrient elements in overall plant metabolism are discussed throughout this article, and specific roles of micronutrients in symbiotic nitrogen fixation are discussed by Dalton in the preceding entry. This entry provides a synopsis of Ca, P, S, and K involvement in the *Rhizobium*-legume symbiosis. The role of oxygen is discussed in the preceding entry in this article.

CALCIUM

Early studies showed that Ca deficiency can negatively impact nodule formation on numerous legumes [reviewed in Ref. 2]. Many rhizobia grow well at low Ca concentrations (e.g., 15–30 μM)^[2] although growth of *Sinorhizobium meliloti* (alfalfa symbiont) appears especially sensitive to low Ca, and Ca–P interactions further complicate Ca bioavailability.^[4] Reduced rhizobia populations might be expected in soils that are deficient in Ca or when the prevailing soil chemistry reduces Ca solubility. Reduced rhizosphere populations could potentially translate into reduced levels of infection. Specific roles for Ca during infection and nodule formation have also been demonstrated. A Ca-dependent adhesin is implicated for attachment of *Rhizobium leguminosarum* biovar viciae to pea root hairs.^[5] For clover rhizobia, Ca is also required for *nod* gene expression^[6] and in Nod factor-based signaling between plant and bacteria in the

rhizosphere.^[7] Nod factors are also involved in altering Ca gradients and behavior in the tips of infectible root hair cells, resulting in a Ca spiking phenomenon.^[8] In alfalfa, the Nod factor brings about oscillations of free Ca in the cytoplasm and is not observed in an alfalfa nodulation mutant.^[8]

PHOSPHORUS

In contrast to the other nutrients discussed here, problems of soil P fertility are widespread. Sanchez and Euhara^[9] have estimated that crop production on approximately 33% of the world's arable land is limited by P, with P bioavailability in soil being highly sensitive to the prevailing chemistry. Examples of chronic P fertility problems can be found in the highly weathered soils in the tropics, where acidic pH and high levels of aluminum place significant constraints on P solubility.

Virtually every aspect of the *Rhizobium*-legume association is affected by P bioavailability. In various legumes, P deficiency has been shown to result in reduced nodulation and nitrogen fixation and lower plant N content and dry matter production. The exact mechanism(s) by which P is involved in these responses is not well understood. The uncertainty in part derives from the likelihood that different legumes have varying P requirements for optimum function, as well as the sheer ubiquity of cellular processes that involve or require P. It also stems from our lack of exact understanding of how P deficiency is manifested in this symbiosis, i.e., in nodule-specific activities or as general plant-wide metabolic perturbations that have ripple effects on nitrogen fixation.^[10]

As discussed above for Ca, P deficiency could potentially influence rhizosphere populations of rhizobia because different rhizobia respond varying to low P and have different P requirements for growth.^[11] Infection experiments show that nodulation efficiency by *Bradyrhizobium japonicum* (symbiont for soybean) is reduced when cultures are P-stressed prior to inoculation onto soybean roots.^[12] Further, P stress negatively influences Nod factor production and excretion by clover rhizobia.^[13] Also, extracellular polysaccharide production, which is essential for nodulation by some rhizobia, is also directly controlled by the rhizobial Pho regulon (genetic regulatory system that controls gene expression in response to environmental P levels).^[11]

Limiting P will of course diminish overall plant growth. A general consequence of reduced shoot growth could be reduced photosynthesis, which could negatively impact on total photosynthates available for translocation to the nodules. However, there are studies that suggest such a generalized effect is not applicable to all symbioses.^[10] Soybean P status is positively correlated with

nodule-specific nitrogenase activity (total nitrogen fixation/nodule weight) and with nodule ATP content.^[14] A still more specific example of how P limitation affects symbiosis involves O₂ flux into the nodule. Nodules on P-limited soybeans and alfalfa appear to have increased oxygen permeability.^[15,16] Part of this change in O₂ flux may be due to decreased nodule size (increased surface-to-volume ratio) that is common with P-limited plants. However, Drevon and Hartwig^[16] suggested that this would not account for all of the increase, and other possibilities might include the activation of alternative (i.e., energy wasteful) respiratory pathways that would have the effect of increasing the amount of O₂ consumed. Conversely, however, increased nodule O₂ uptake could perhaps account for experimental observations showing increases in specific nodule activity in clover^[17] under low P growth conditions. The differences in nodule-specific nitrogenase activity between soybean and that of clover is but one example of how the different symbioses respond differently to a nutrient limitation.

POTASSIUM

The importance of K in the symbiosis can be inferred at least at a general level because of its roles in water uptake, enzyme activity, and translocation of photosynthates within the plant. A symbiosis-specific function of K has, however, been observed with *Vicia faba* and *Phaseolus vulgaris*, where low levels (0.1 mM) of K in the nutrient solution eliminated nodulation.^[18] It is also important to note that in this case and others^[19] a supraoptimal K condition was demonstrated in that increasing levels of K increased nodulation without increasing total plant N acquired from symbiotic nitrogen fixation. Other symbiosis-specific functions of K were identified in in vitro studies of *Bradyrhizobium* sp (cowpea) that demonstrated that K is necessary for induction of nitrogenase and heme synthesis,^[20] two activities that are of central importance to bacteroid function during symbiosis.

SULFUR

Soil S deficiency can have profound effects on this symbiosis. For *Sinorhizobium* and some species of *Rhizobium*, sulfated functional groups are important host-specificity components of Nod factors that are required for nodulation,^[21] and a significant amount of S is also required for synthesis of the nitrogenase protein.^[22] Furthermore, experiments with field-grown subterranean clover^[23] have shown that both plant dry matter production and symbiotically derived N are very sensitive to severe S deficiency; incremental increases of applied S

ranging from 0 to 8 g·m⁻² soil resulted in tripling of dry matter productivity and nearly a fourfold increase in N derived from symbiosis. Other experiments have shown variable S responses by different legumes. After S addition to S-limited plants, total plant dry matter increases for *Vicia faba*, *Trifolium pratense*, and *Pisum sativum* were roughly twice that of *Medicago sativa*. For each of these legumes, the proportion of nitrogen acquired from symbiosis appeared to change little in response to the added S, i.e., host plant S requirements were more easily demonstrated than any effect on nodule function.^[24]

CONCLUSION

Some of the variability in plant and symbiosis response to nutrient deficiency observed in the literature may derive from inherent differences between legume species (and/or cultivars of the same species) for the various nutrients. Indeed, additional in-depth studies with different legumes may ultimately demonstrate that such variability among legumes and symbioses may prohibit convenient nutrient effect modeling. Separating host or host nodule nutritional requirements from those of the bacteroids is not always easy, and indeed understanding source-sink relations in this highly specialized plant organ represents a major challenge to plant biologists. Nutrient flow in and out of the nodule and between bacteroid and host remains poorly understood. It will be important for future studies to dissect the potentially very different needs of bacteroids versus host to better understand the exact role of the various nutrient elements. The roles and specific functions of nutrients will likely vary between symbionts and between symbioses.

Symbiotic Nitrogen Fixation: Special Roles of Micronutrients

David A. Dalton

Reed College, Portland, Oregon, U.S.A.

INTRODUCTION

Nitrogen-fixing plants have special requirements for mineral nutrients beyond those of other plants. The most important nitrogen-fixing plants in terms of agriculture are found in the symbiosis between plants of the legume family (Fabaceae) and bacteria of the genus *Rhizobium* (or related genera such as *Bradyrhizobium* and *Sinorhizobium*, collectively referred to hereafter as rhizobia). Additionally, there are 24 genera of nitrogen-fixing actinorhizal plants that consist of symbioses between various woody plants in 8 families and bacteria of the genus *Frankia*. No crop plants are actinorhizal, but the alder-*Frankia* symbiosis is important in forestry. Other actinorhizal plants have significant ecological roles, particularly in enhancing the nutrient status of soil. The complexity of these symbiotic associations results in trace element requirements that are different from those of the individual organisms that participate in the symbiosis. Nitrogen-fixing plants have a unique requirement for cobalt and selenium and an elevated requirement for molybdenum, iron, and nickel, compared to plants that do not fix nitrogen.

COBALT

Cobalt (Co) is essential for all N₂-fixing plant symbioses. This requirement arises from the needs of the endophyte (rhizobia or *Frankia*) rather than those of the host plant per se. Co plays a major role in symbiotic endophytes as a constituent of vitamin B₁₂ (cyanocobalamin). Plants do not contain vitamin B₁₂. Coenzyme B₁₂ is essential for three types of biochemical reactions: 1) intramolecular rearrangements (e.g., the conversion of L-methylmalonyl CoA into succinyl CoA), 2) methylations (e.g., the synthesis of methionine by methylation of homocysteine), and 3) reduction of ribonucleotides to deoxyribonucleotides. Co does not participate directly in the process of nitrogen fixation.

The requirement of nitrogen-fixing plants for Co was established in 1961 (Fig. 1)^[1] using ultrapure nutrient solutions. Symptoms of Co deficiency match those caused

by deficiency of nitrogen (e.g., stunted growth, yellowing of tissues) since the symbiotic bacteria are unable to provide the host plant with nitrogen. Because the amounts of Co required are so small, such deficiencies can be demonstrated only by meticulous exclusion of contaminants. Co deficiencies in the field are rare but have occasionally been observed. In some exceptional cases, dramatic increases in yield can result from addition of supplemental Co to crops.^[2]

SELENIUM

The requirements of nitrogen-fixing plants for selenium (Se) are less straightforward than is the case for Co. Se is an essential component of hydrogenase, a bacterial enzyme that reclaims energy lost as hydrogen gas, which is produced as a by-product of nitrogenase activity.^[3] Although hydrogenase is clearly beneficial to nitrogen-fixing plants, this enzyme is not an absolute requirement. Some rhizobia lack hydrogenase and the plants containing such rhizobia have a reduced yield.^[4] Therefore, the selective use of strains of rhizobia that contain hydrogenase is of practical concern in agriculture. The genes for hydrogenase have recently been introduced into rhizobia that lack them, and such efforts may eventually reach applications in the field.^[5]

MOLYBDENUM

The role of molybdenum (Mo) in nitrogen fixation by legumes has been recognized since 1950.^[6] Mo is a constituent of the molybdenum-iron cofactor (FeMoCo) that is required for nitrogenase activity (Fig. 2).^[7] Mo is also essential for the activity of xanthine dehydrogenase, an enzyme that plays an essential role in the synthesis of ureides (nitrogen transport compounds) in some legumes such as soybean, cowpea, and *Phaseolus* beans. Higher plants and other organisms that utilize nitrates also need Mo for activity of nitrate reductase.

Legumes are particularly susceptible to Mo deficiency (Fig. 3). Symptoms of Mo deficiency have been described

Fig. 1 The effects of cobalt deficiency in soybean plants grown under symbiotic (nitrogen-fixing) conditions. (From Ref. 1.) (View this art in color at www.dekker.com.)

from many parts of the world and are especially common on acidic soils. The application of lime induces changes in soil chemistry that may relieve Mo deficiencies. In some other cases, the response to fertilization with small amounts of Mo can be spectacular.

IRON

Nitrogen-fixing plants have an increased requirement for iron (Fe) related to several key proteins involved closely with nitrogen fixation. Fe is a constituent of both of the two components of nitrogenase: dinitrogenase reductase, also called the Fe protein, and dinitrogenase, also called the MoFe protein (Fig. 2). Fe is also a component of ferredoxin, the proximal electron donor to the nitrogenase complex, and of leghemoglobin, a heme (Fe porphyrin) protein that plays a critical role in binding and delivering oxygen for respiration in such a way that nitrogenase is not inactivated. Leghemoglobin may account for up to 50% of the total soluble protein in legume nodules and is responsible for the dark red appearance of nodule interiors that indicates healthy, active nodules. Further indication of the key importance of Fe in nodules is the fact that rhizobia contain siderophores to facilitate the uptake of Fe and that nodules contain phytoferritin to store Fe. This

storage is critical; although nodules contain large amounts of Fe, the concentration of free (catalytically active) Fe must be kept low because of its ability to promote the formation of damaging forms of activated oxygen such as superoxide and hydroxyl radicals.

NICKEL

Nickel (Ni) has a dual role in the metabolism of nitrogen-fixing plants. Ni is needed for organisms that utilize urea as a nitrogen source and break down urea in their metabolic processes. The breakdown of urea is catalyzed by urease, a Ni-containing enzyme. Urease is widespread in legume leaves and seeds as well as in bacteroids and free-living rhizobia.^[8] The precise metabolic role of urea and urease in regard to nitrogen fixation is not clear, but it is likely that urease is involved in the processing of nitrogenous compounds transported from nodules to leaves. Soybeans and cowpeas grown in purified nutrient solutions in symbiosis with rhizobia develop necrotic leaf tips when the Ni supply is inadequate.^[9] This necrosis is due to high concentrations of urea that accumulate due to the lack of urease activity. Soybeans grown with fixed nitrogen also have a Ni requirement, but the magnitude of this requirement appears to be less.

Nitrogen-fixing symbioses also require Ni as a component of hydrogenase—an enzyme that participates in the conservation of energy as discussed earlier with respect to Se. Ni deficiency in soybean plants results in a significant decrease in hydrogenase activity in nodule

Fig. 2 The structure of the FeMo cofactor in nitrogenase. (Provided by D. C. Rees, CA Inst. of Tech.)

Fig. 3 The effects of molybdenum deficiency in alfalfa plants grown under symbiotic (nitrogen-fixing) conditions. (From Ref. 6.) (View this art in color at www.dekker.com.)

bacteroids. The amount of Ni required by plants is extremely low, and there are no reports of Ni deficiency in the field. However, some soils contain inadequate Ni for the optimum activity of urease in the indigenous soil microorganisms. Furthermore, inoculated soybean plants grown on low-nickel soil exhibited increased activities of urease in leaves and hydrogenase in nodule bacteroids when nickel was provided.^[8]

OTHER ELEMENTS

Rhizobia also require other micronutrients such as manganese, copper, and zinc,^[10] but these elements do not play a direct role in nitrogen fixation. Boron is not required by rhizobia, but is necessary for the formation of legume nodules. Also, it is noteworthy that although some nitrogen-fixing bacteria (e.g., *Azotobacter*) have “alternative” nitrogenases that utilize vanadium instead of Mo, there is no evidence for the presence of such

alternative nitrogenases in symbiotic bacteria such as rhizobia or *Frankia*.

Tobamoviral Vectors: Developing a Production System for Pharmaceuticals in Transfected Plants

Jennifer Lee Busto

Monto H. Kumagai

University of Hawaii at Manoa, Honolulu, Hawaii, U.S.A.

INTRODUCTION

Transgenic crops have played a predominant role in the production of pharmaceuticals and other valuable biological molecules. A more efficient strategy has involved inoculating nontransgenic plants with virus-based vectors that carry foreign genes. With the development of infectious cDNA clones, single-stranded RNA plant viruses have become key players in gene function discovery, metabolic engineering, and biomanufacturing. Viral expression vectors provide epigenetic expression of foreign sequences throughout infected plants, leading to gain- or loss-of-function phenotypes due to overexpression or cytoplasmic inhibition of gene expression.

Plant viruses are powerful transfection tools in molecular farming, producing pure, properly folded and glycosylated proteins in plants faster and more economically than other expression systems. They are a highly desirable alternative to transgenic systems that require protracted periods to transform and regenerate whole plants, and that have variation in the expression levels of heterologous proteins. In transgenic systems, once a particular construct is inserted into the plant genome, it may take several crosses to establish a stable line in an elite cultivar. In contrast, plant viral vectors employed in the large-scale production of therapeutic drugs in greenhouse and field-grown crops directly yield high levels of foreign protein, due to the rapid rate of viral replication. In plants transfected with a recombinant tobamovirus, alpha-trichosanthin, a potential anti-AIDS drug, accumulated to approximately 2% of total soluble protein.

Therapeutic compounds stably produced in transfected plants are numerous, and include antiviral drugs such as human interferon-alpha 2 as well as vaccines, proteins, and secondary metabolites. Plant-derived anticancer vaccines have been produced for treatment of human papillomavirus-induced cancer by expressing recombinant E7 fusion oncoproteins in *Nicotiana benthamiana*. The HIV p24 nucleocapsid protein, used as an antigen in the development of HIV vaccines, has been produced in plant protoplasts using tomato bushy stunt virus (TBSV) vector. For viruses that cannot be grown in tissue culture, such as hepatitis C (HCV), tobamoviral vectors are under devel-

opment to produce a plant-derived vaccine. Recombinant proteins for use in diagnostics have also been expressed in plants. Full-length recombinant monoclonal antibodies (rAbs) directed against a colon cancer antigen and recombinant allergens have been expressed in *N. benthamiana* leaves, using a tobamoviral vector. The binding of IgE from sera of birch pollen- and latex-allergic patients suggests that the plant-produced allergens are properly folded.

TOBACCO MOSAIC VIRUS VECTORS

Several virus groups have been under investigation for design as recombinant plant virus vectors, including geminiviruses, potyviruses, potexviruses, comoviruses, tombusviruses, tobnaviruses, alfamoviruses, and hordeiviruses. Members of the tobamovirus group,^[1-3] are the most widely studied. The autonomously replicating RNA viral vectors based on the tobacco mosaic virus (TMV) genome have been particularly successful as research and commercial tools.

TMV possesses a positive-sense, single-stranded genome of 6396 nucleotides that encodes replicase enzymes, and movement and coat proteins. Viral genes are expressed through the production of both genomic and subgenomic RNA. Essentially designed as cDNA plasmids, TMV vectors are modified to contain a foreign gene sequence. Originally, vectors were constructed with the gene of interest replacing the capsid protein, until it was recognized that these viral vectors do not move efficiently. Presently, TMV vectors are hybrid versions of several different strains of tobamoviruses^[4,5] that include all essential viral genes, a bacterial origin of replication (ori), and an antibiotic resistance marker. Dual heterologous subgenomic promoters from related tobamoviruses have enhanced stability, while an internal ribosome entry site sequence (IRES)^[6] has been incorporated into the design to enable expression of multiple proteins.

The transfection process involves mechanically inoculating recombinant in vitro RNA transcripts from viral cDNA clones onto plants. Recombinant virions are

assembled in the plant and move systemically by associating with plasmodesmata and intercellular cytoplasmic channels, producing foreign protein as they travel. One to two weeks after inoculation, recombinant proteins can be isolated from transfected plants. Interstitial fluid containing the desired product can be quickly separated from other cellular proteins by vacuum infiltration and gentle centrifugation. For large agronomic applications, virions can be purified from transfected plants and used for subsequent inoculations using high-pressure sprayers in the field.

Viral Vector Design Construct

For vaccine production, TMV vectors have been developed as coat protein (CP) fusions,^[7] with the viral coat providing a flexible framework for the recombinant protein. TMV CP fusions include human immunodeficiency virus type I (HIV-I) peptide, influenza virus hemagglutinin epitope, malaria parasite peptide, and hepatitis C virus peptide.^[11] A key technical advance in design has enabled TMV vectors to produce free proteins that are not fused to the coat protein. Instead, genes encoding bioactive compounds are fused to signal peptide sequences that cause the translated protein to be processed via the endoplasmic reticulum and Golgi complex, and to be targeted for cellular secretion. It is recognized that the faithful and efficient expression of such heterologous proteins is influenced by the choice of the signal peptide.

One of the most highly efficient TMV vector constructs fuses the gene of interest to a sequence encoding a rice

α -amylase signal peptide adjacent to a 5' untranslated leader.^[3] Viral vectors containing the rice α -amylase signal peptide ORF have been used to express a wide variety of heterologous proteins including mammalian peptides, blood products, glycoproteins, and cytokines. TMV vectors that incorporate this signal peptide have been used successfully to secrete single-chain variable-fragment (Fv) antibodies for the treatment of non-Hodgkin's lymphoma (NHL). Currently in Phase II/III clinical trials, these highly customized patient-specific vaccines act as antitumor agents.^[8]

The rice α -amylase 5' untranslated leader sequence may help to enhance translation of the heterologous protein. The highly expressed viral coat subgenomic RNA has a 5' cap (m7GpppN) and terminates with a tRNA-like structure instead of a poly (A) tail. The 3' untranslated region (UTR) has two domains, which contain five RNA pseudoknots. It is possible that interactions between the 34-base pair 5' leader of α -amylase and the 3' UTR may cause a synergistic regulation of translation in transfected plants. Significantly, the rice α -amylase signal peptide has been recognized and processed in other transformed organisms, including *Escherichia coli*, *Saccharomyces cerevisiae*, and *Yarrowia lipolytica*, as well as transgenic rice cell suspensions. Subtle differences in the size, source, and sequence of the α -amylase signal peptide can greatly affect the secretion process.

Striving for higher protein yields, researchers are collaborating to develop improvements in vector design for increased production. It is recognized that inclusion of

Fig. 1 Overexpression of phytoene synthase (*crtB*) in leaves of *Nicotiana benthamiana* produces an orange phenotype. (Photo courtesy of Tony Novelozo—Axiom, Davis.) (View this art in color at www.dekker.com.)

foreign genes into TMV vectors reduces efficiencies of replication and movement compared to the wild type. These studies are aimed at improving the ability of these vectors to move and to replicate through gene shuffling of the 30K movement gene.^[9] Visible markers for heterologous gene expression in plants are also under development. Tobacco mosaic viral (TMV) vectors have been engineered to overexpress an enzyme involved in carotenoid biosynthesis in *N. benthamiana* and other solanaceous plants.^[4] As the viral genome is translated, the encoded enzyme, phytoene synthase (*psy*), is targeted to the chloroplast, causing an accumulation of phytoene, a colorless compound. However, transfected plants show a characteristic orange phenotype in the leaves and flower sepals, as early as four days post-inoculation (Fig. 1). If fused to a heterologous sequence in a recombinant vector, *psy* may serve as a useful marker for gene expression, particularly in field applications.

Metabolic Engineering

Although plant viruses that are engineered to produce pharmaceutically relevant proteins have proved to be powerful gene expression tools, they are also valuable tools for use in gene discovery and in the metabolic engineering of existing pathways in plants. The biosynthesis of leaf carotenoids in transfected *N. benthamiana* was altered by forced rerouting of the pathway, resulting in the synthesis of capsanthin, a non-native chromoplast-specific xanthophyll. The ectopic expression of capsanthin–capsorubin synthase (*Ccs*) cDNA caused the plant to develop an orange phenotype and accumulate high levels of capsanthin—up to 36% total carotenoids. By redirecting the existing pathways of plants that produce biologically active compounds, plant virus expression systems can potentially be used to alter or to produce novel enzymes, or cause the accumulation of non-native bioactive compounds.^[10]

CONCLUSION

Plant RNA viral vectors have become intensively utilized in several different plant species for large-scale production of high-value therapeutic proteins^[11–13] and secondary metabolites.^[5] The United States Food and Drug Administration (FDA) has developed a guidance document on plant-derived biologics and has strengthened field-testing controls for permits on those bioengineered traits that are not intended for commodity uses, such as pharmaceuticals, veterinary biologics, or certain industrial products. The human safety of TMV-based expression systems has been documented; plant viruses are not pathogenic to humans. TMV is only transmitted to other

plants through mechanical means; proper cleaning of tools and machinery with bleach contains the virus and TMV-based vectors. In addition, FDA demands for recombinant product purity are rigorous.

To date, at least nine separate field trials using viral-based vector systems for the production of biologics have been conducted in three separate states. Concerns regarding the spread of engineered TMV and the persistence of recombinant viruses have been addressed in these studies, and a recent report indicates that recombinant viruses generally delete the foreign gene, have reduced vigor, and are less competitive and pathogenic than the indigenous TMV.^[14] Plant viral vectors are also effective tools in metabolic engineering, as well as gene function discovery.^[15] Design modifications will lead to improvement of desirable vector traits so that the potential of plant virus vector gene expression systems is fully realized.^[2]

Transformation Methods and Impact

Karabi Datta

Swapan K. Datta

International Rice Research Institute, Metro Manila, Philippines

INTRODUCTION

Transformation (or genetic engineering) has provided a powerful tool to introduce and modify traits desirable for crop improvement. Transgenes can now be incorporated into any cultivars across the genetic barriers for many crop species. Genetic transformation can be achieved by several methods (protoplast, biolistic, *Agrobacterium tumefaciens*, etc.) and a large number of successful crops have now been developed and commercialized. It is now possible to develop crops engineered with genes for built-in plant protection, durable resistance, and nutrition improvement. In the genomics era, gene discovery will accelerate further crop improvement and precision breeding, using high-throughput genetic transformation.

Plant improvement based on genetics has been occurring for years. In traditional breeding, genetic modifications are made by making crosses between related organisms. This depends mostly on reciprocal crossability and selecting for specific desirable traits. With the use of recombinant DNA technology, it is now possible to remove a piece of DNA containing one or more specific desirable genes from any organism and introduce it into another organism. Transformation is the step in the genetic engineering process that involves the incorporation of genes into genomes by means other than fusion of gametes or somatic cells. The incorporation and expression of foreign genes in plants, which is now possible in at least 35 families, was first described in tobacco. The plant transformation approach is being used to produce plants possessing traits unachievable by conventional plant breeding, especially in cases where the gene pool contains no source of the desired trait. Improved transgenic crops have been developed and field-tested in many countries and will have great impact in the developing countries. Seven transgenic crops—maize, cotton, canola, rapeseed, potato, squash, and papaya—are being produced commercially in 12 countries, including the United States, Argentina, Canada, China, and India. Elite transgenic indica rice has now been evaluated. It showed excellent performance against insect pests and bacterial blight.

Different systems have been developed to integrate foreign DNA into plant cells and to carry out the

successive regeneration of transgenic plants, as shown in rice as a model monocot plant. Commonly used methods are based on biological vectors (e.g., *Agrobacterium*, virus), physical techniques (e.g., particle bombardment), and chemical techniques (e.g., PEG-mediated protoplast transformation). Besides the transformation methods, the basic requirements for the production of transgenic plants are: 1) the availability of target tissues to be transformed that are competent for plant regeneration; and 2) a suitable selection system for regenerating transformed plants with reasonable frequency. An efficient system for selecting only a few transformed cells from among a large number of nontransformed cells, and recovery of plants from single transformed cells is essential.

AGROBACTERIUM-MEDIATED TRANSFORMATION

In nature, the gram-negative soil bacterium *Agrobacterium tumefaciens* infects wound sites in dicotyledonous plants, causing the formation of crown gall tumors by a multistep gene transfer procedure. Virulent strains of *A. tumefaciens* and *A. rhizogens* possess the ability to transfer a particular DNA segment (T-DNA) of the extra chromosomal tumor-inducing (Ti) plasmid.^[1] The T-DNA is surrounded by 24-base-pair (bp) border repeats and contains two types of genes, oncogenic genes and the gene encoding for the synthesis of opines. The oncogenic genes encode for the enzymes involved in the synthesis of auxins and cytokinins, whose expression leads to tumor formation. Outside the T-DNA, a large number of other genes (*vir* genes) in Ti plasmid are involved in this transfer mechanism. The T-DNA transfer system is determined by *vir* genes, whereas 24-bp direct repeats act as the recognition signals for the transfer.

Binary Vector System for *Agrobacterium*-Mediated Transformation

On the basis of the naturally occurring gene transfer mechanism of crown gall formation, the *Agrobacterium*

Table 1 Achievements in transformation for crop improvement

Achievement	Transgene	Method	Year of development
Transformation demonstrated in tobacco	<i>gus</i>	<i>Agrobacterium</i>	1983
Transgenic cotton	<i>nptII</i>	<i>Agrobacterium</i>	1987
Transgenic soybean	<i>bar</i>	<i>Agrobacterium</i>	1988
Flavr Savr tomato	polygalacturonase	<i>Agrobacterium</i>	1988
Transgenic japonica rice	<i>hph</i>	Protoplast (Electroporation)	1989
Transgenic indica rice	<i>hph</i>	Protoplast (PEG)	1990
Insect-resistant cotton	<i>Bt</i>	<i>Agrobacterium</i>	1990
Transformation in Brassica	<i>gus</i>	<i>Agrobacterium</i>	1991
Herbicide-resistant rice	<i>bar</i>	Protoplast (PEG)	1992
Herbicide-resistant wheat	<i>bar</i>	Biolistic	1992
Transgenic maize	<i>Bt</i>	Biolistic	1993
Transgenic barley	<i>bar, gus</i>	Biolistic	1994
Insect-resistant sugarcane	<i>cryIA(b)</i>	Biolistic	1997
Tissue-specific gene expression in rice	<i>cryIA(b)/cryIA(c)</i>	Biolistic/Protoplast	1998

Iron-rich indica rice	<i>ferritin</i>	Biolistic	2003

system for plant genetic engineering has been designed. This system is based on a disarmed Ti plasmid with genes responsible for crown gall formation being removed, and various disarmed strains of *Agrobacterium* such as LBA4404 and C58C1 being created. Various genes of interest can be placed in a vector and introduced into the disarmed strain. In the binary vector system for T-DNA transfer, a plasmid provides the virulence functions and a small vector carries the artificial T-DNA. The binary vectors can replicate in *Escherichia coli* as well as in *A. tumefaciens*, which allows easy cloning of genes between the T-DNA borders. pBin19, pGA482, and pBI121 are well known vectors used in the *Agro*-transformation system.^[2]

A range of improved virulent and binary systems has been developed. The supervirulent wider host-range *Agrobacterium* strain A281 possesses a transformation efficiency higher than that of other strains because of the presence of the pTiB0542 plasmid. The strain EHA101^[3] also carries the disarmed version of pTiB0542. In the superbinary system, the *virB*, *virC*, and *virG* genes from the virulence region of pTiB0542 are inserted into a small T-DNA-containing plasmid in addition to the disarmed Ti plasmid with its full set of virulence genes.

Agrobacterium-mediated gene transfer into monocotyledonous plants became possible only recently; efficient methodologies have been reported in rice (Table 1),^[4] banana, maize, wheat, and sugarcane.

Agrobacterium-mediated transformation has the advantage that it is relatively simple and can be applied with suitable tissue culture facilities (Fig. 1). This method ensures that a defined region of DNA is precisely transferred to the host genome. It reduces the copy number of the transgene, thus leading to fewer problems of transgene cosuppression and instability. High-molecular-weight DNA can be transferred through this method, but problems such as the transfer of vector sequences beyond the T-DNA border are frequently noticed.

In Planta Transformation

Successful *Agrobacterium*-mediated transformation has recently been reported in *Arabidopsis*, in which the transformation takes place in planta: The transformed tissue is not removed from the plant but left in a natural condition. In the in planta system, panicles at the early flowering stage are usually used as a target tissue. Successful in planta transformation of the legume *Medicago truncatula*

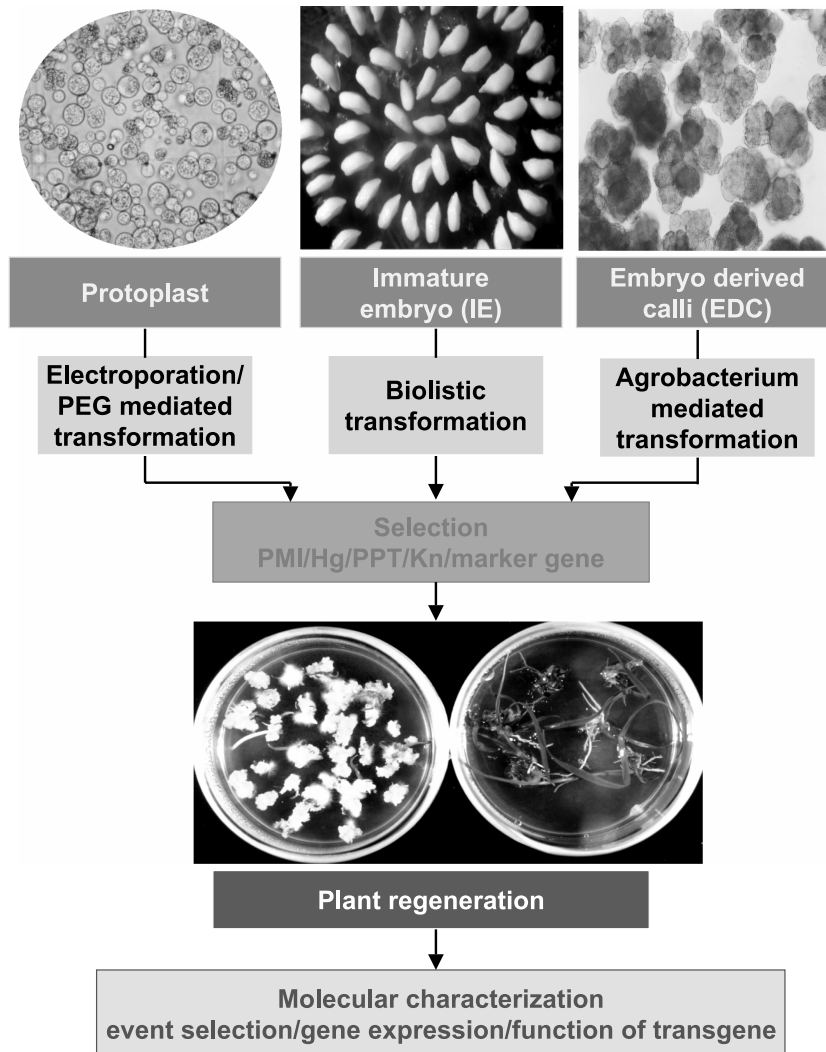

Fig. 1 Development of transgenic plants. (View this art in color at www.dekker.com.)

was also reported recently, showing that the method can be adopted in other species.

BIOLISTIC TRANSFORMATION (GENE GUN) SYSTEM

The biolistic (or gene gun) method for transformation involves the direct physical method of delivering nucleic acids into cells. In this system, metallic (gold or tungsten) microparticles are coated with DNA (transgene construct) and fired into target cells, shot with a particle bombardment machine. The particles are accelerated with an electrical discharge or compressed helium gas. Microprojectile bombardment of immature embryos to deliver

the DNA into plant cells, and recovery of the whole plants from the transformed cells through selection are becoming almost routine (Fig. 1). Because there is no biological limitation to DNA delivery, genotype-independent transformation may be carried out with this method. Different rice cultivars have been transformed by this system.^[5] Bombardment often results in multiple insertions of transgene copies in different loci and extensive rearrangement of the introduced gene, which in some cases lead to expression instability of the transgene.

MICROINJECTION

In the microinjection method, DNA is injected directly into the nucleus of a cell using an ultrafine needle. The

target cells are usually small structures with only a few cells and high regeneration potential (e.g., microspore-derived and zygotic proembryos). This method is not suitable for a plant system but is used routinely to produce transgenic animals.^[6]

LIPOSOME-MEDIATED TRANSFER

DNA is encapsulated in liposomes (lipid micels). Liposomes help the DNA to enter through the plasmodesmata or the lipids to impregnate the cell walls, making it easier for DNA to penetrate. This method is not very efficient in transferring DNA to target cells.^[6]

WHISKERS METHOD

Tiny microscopic needlelike structures with sharp end fibers of silicon carbide (or whiskers) are used in this method of genetic engineering. Embryogenic tissue culture cells, DNA of interest, and whiskers are suspended and shaken together robustly. The collision between the cells and sharp whiskers creates small holes in the cell wall to deliver the desired gene into the nucleus of the cell. This system has been used successfully for maize.

SELECTION SYSTEM

A suitable selectable marker gene is a prerequisite in distinguishing transformed cells from nontransformed ones. *nptII*, *hph*, and *ppt* are the most effective genes encoding neomycin phosphotransferase, hygromycin phosphotransferase, and phosphinothricin acetyltransferase, respectively.^[7] Recently, the nonantibiotic POSITECH™ selection system has been developed using the *phosphomannoseisomerase (PMI)* gene available from Syngenta.^[8,9]

CONCLUSION

Tremendous improvements in basic transgenic technologies have been made, to the extent that all major crop plants are now transformable and available for improvement with these technologies. Transformation protocols differ from one plant to another and, within species, from one cultivar to another. The optimization of transformation methodologies requires the consideration of several important means, such as the use of suitable explants, a

mode of gene delivery, and plant regeneration. Maternal inheritance of foreign genes through chloroplast engineering can be used for those crops in which potential outcrossing is possible. Gene flow or outcrossing is very common in crops such as sunflower and strawberry. This technology is an alternative to overcome concerns regarding nuclear genetic engineering. However, gene flow is a natural phenomenon, and so far has not caused weediness or other negative effect on the environment.

Currently used transformation methods do not allow precise prediction of the position and number of copies of transforming DNA to be integrated into the host-cell genome. The tissue- and development-specific regulation of the gene depends on the choice of the promoter regulating the transcription of the transgene or the transit peptide directing the product to specific organelles. Transgene pyramiding and gene stacking using multiple genes of diverse traits are now possible, and will help in further crop improvement. The *sd1* gene principally involved in the green revolution can now be used to shorten plant height (to avoid lodging) and preserve traditional tall varieties. The main effect of genetic transformation lies in developing an improved product—seeds.^[10,11]

Transgenes (GM) Sampling and Detection Methods in Seeds

Alessandro Pellegrineschi

Applied Biotechnology Center and CRC for Molecular Plant Breeding,
CIMMYT, Mexico City, México

INTRODUCTION

Transgenic plants or food crops are genetically modified organisms (GMOs), meaning that genes have been introduced or silenced in their genomes using methods other than sexual crossing. These genetic modifications can provide a variety of useful traits, including herbicide resistance, pest resistance, and enhanced vitamin content.

Genetically modified (GM) crops were grown on an estimated 58.7 million hectares (145 million acres) in 2002 by from 5.5 to 6.0 million farmers in 16 countries. It is interesting to note that more than three-quarters of the farmers who grew GM crops could be considered small-scale and resource-poor. The principal GM crops during this period were soybean (36.5 million hectares), corn (12.4 million hectares), cotton (6.8 million hectares), and canola (3.0 million hectares).^[1]

Due to recent debates about safety, some countries are requiring disclosure of GM derivatives in foods, creating the need for reliable detection methods.

METHODS FOR DETECTION OF TRANSGENES

Current methods focus on detecting a molecule—DNA, RNA, or other proteins—associated with or derived from the genetic modification of interest.^[2] DNA is the preferred target, because it is very stable and can be purified, and billions of copies of a particular strand can be made in just a few hours using the polymerase chain reaction (PCR), producing quantities large enough for easy detection.^[3,4] Multiplication of RNA and other proteins is slower and more complicated. There is also a linear correlation between levels of GM derivatives in a sample and the DNA, if the genetically modified DNA comes from cell nuclei. No such correlation exists in the case of proteins or RNA.

To detect GM DNA using PCR, the double-stranded helix of the target DNA is separated and mixed in a solution with short pieces of synthetic, single-strand DNA

known as “primers.” The solution contains a cellular enzyme called DNA polymerase, which among other of its natural functions contributes to the repair and replication of DNA. Each primer is “complementary” to one or the other end of the single strands of the target DNA. This means that the sequence of nucleotides (the amino acid building blocks of DNA and RNA) in the primer is such that it will bind to the DNA. The first primer matches the start and the coding section of the DNA to be multiplied, while the second primer matches the end and the noncoding portion of the DNA. The portion of the target strand in between is filled in with nucleotides from the polymerase solution, creating two double-stranded DNA molecules that are perfect copies of the original. By raising and lowering the temperature of the solution, the double strands are newly “unzipped” and the filling-in process begins again, using the complementary strands as templates. For each temperature cycle the number of copies is doubled, resulting in an exponential multiplication of the original DNA sample. After 20 cycles the copy number is approximately 1 million times higher than at the beginning.

One of the most common techniques to estimate the amount and size of DNA or RNA strands in a sample is gel electrophoresis. Prior to this, the DNA may be “digested”—that is, put in solution with enzymes known to cut the DNA at sites where there is a specific sequence of nucleotides, resulting in fragments of particular sizes. A more sophisticated technique involves determination of melting point profiles by means of dyes like SYBR Green I, which emits fluorescent light when it intercalates with double-stranded DNA. When the temperature is increased, the DNA strands begin to separate, reducing the fluorescence in readily measurable amounts. The melting point is more characteristic of a specific DNA sequence than of its size, but complete sequencing—determining the exact order of the nucleotides throughout a DNA or RNA fragment—allows for more specific determination of the origin of the molecule. A fourth alternative is to use short, synthetic molecules called “probes,” which bind to given sites on a DNA or RNA

strand. If appropriately designed, a probe will be able to discriminate between the correct molecule and almost any other DNA or RNA molecule. Labeling with fluorescence, radioactivity, antibodies, or dyes also facilitates detection of the molecules present.^[5]

Protein-based detection of GM derivatives relies on the specific binding between a protein and an antibody, a molecule of the type that protects against bacterial and viral infections in the human body. The antibody recognizes a foreign molecule—the “antigen”—and binds to it. The bound complex is detected in a chemical reaction that causes a particular color to appear. This technique is known as the enzyme linked immunosorbent assay (ELISA) and combines the specificity of antibodies with the sensitivity of simple enzyme assays. ELISA can provide an easy and precise measurement of antigen or antibody concentrations.

One of the most useful of the immunoassays is the two-antibody “sandwich” ELISA. It is a fast and accurate way to determine the antigen concentration in unknown samples. It requires two antibodies that bind to different positions on the same antigen. This can be accomplished using either two monoclonal antibodies—ones that attach to single sites—or a batch of affinity-purified polyclonal antibodies. The antibodies for this technique must be developed using purified samples of the target protein, taken either from the GM derivatives themselves or synthesized, if the exact composition of the protein is known.

RNA based methods rely on specific binding between the RNA molecule and a synthetic RNA or a DNA strand as the primer. The primer nucleotides must again complement those at the starting end of the RNA molecule. Binding results in a double-stranded molecule similar to DNA and, normally, the subsequent conversion of the RNA to a DNA molecule through a process called reverse transcription. Finally the DNA can be multiplied using PCR or transformed into as many as 100 copies of the original RNA molecule and the procedure repeated, using each copy as a template, in a technique called nucleic acid sequence-based amplification (NASBA). The specific primers cannot be developed without knowing the exact composition of the RNA molecule to be detected.^[5]

SAMPLING TECHNIQUES

To date, 72 transgenic varieties have been developed in 17 plant species (Table 1). There is insufficient space here to describe one-by-one all sampling methods to detect GM derivatives in seed; in any case, many methods will likely become obsolete soon, with the rapid development of new

transgenic varieties and detection methods. This aside, there are two key problems in seed sampling that must be understood: 1) the limit of detection and 2) sampling error.^[6,7]

The amount of unreplicated haploid genome (i.e., the 1C value, the amount present in a gamete) in a sample is useful for relating genome copy number to the amount of sample taken. For example, up to 36,697 copies of the haploid *Zea mays* genome (which we will use here as the basis for all examples below) are present in a typical 100 ng DNA analytical sample, given the 1C value of 2.725 picograms. It follows that a single copy of the haploid *Z. mays* genome in a 100 ng DNA sample is present at a level of 0.0027% (wt/wt). Levels of DNA below this threshold cannot be detected reliably in samples of this size.^[4]

Sampling error occurs in a perfectly homogeneous preparation, even if a large amount (say, 50 µg) of DNA is extracted from a laboratory sample and simple random sampling procedures are adopted. As the amount of DNA extracted from the sample becomes lower, sampling error becomes proportionally larger. Thus, replicate 100 ng DNA samples containing GMO material at a level of 0.1% (wt/wt) would produce GM DNA estimates no better than approximately 30% of the mean value 95% of the time. This is a poor level of accuracy, even if we ignore other types of error inherent to a real analytical system.

With lower levels of DNA, the problem is even more critical. For a laboratory sample containing DNA at a level of 0.01%, the 100 ng analytical sample would vary between 0.0027% and 0.0191% nearly 95% of the time. These calculations obviously refer to a “best possible” result, as they assume a single sampling step and a perfect analytical system.

When undertaking a dilution series, the assumption of simple random sampling may no longer be valid, as the number of copies available becomes strictly finite. Indeed, the number of copies used to prepare subsequent dilutions heavily influences the sampling error associated with the series. Consequently, the preparation of any dilution series must be undertaken in such a way as to minimize this bias; ideally, dilutions should be made from the primary laboratory sample.

The classical solution to the issue of sampling error is to undertake repetitions and/or use appropriately sized analytical samples. We recommend that in the construction of a dilution series—for example, to determine the “limit of detection” of a method, or for the generation of standard curves—the nominal number of GM-derived copies in the weakest dilution of analytical sample should be set to approximately 20, thus providing good statistical probability that all repetitions contain relevant DNA.

This chapter endeavors to explain the methodologies used for the detection of transgenes, transgene products,

Table 1 List of the common commercial transgenic plants

Name	Scientific name	Number of transgenic varieties	Traits	Developer(s)
Argentine canola	<i>Brassica napus</i>	15	High laurate (12:0) and myristate (14:0); high oleic acid and low linolenic acid; herbicide tolerance; male sterility, fertility restoration, pollination control system	Calgene, Inc.; Pioneer Hi-Bred International, Inc.; Monsanto Company; Aventis CropScience
Carnation	<i>Dianthus caryophyllus</i>	3	Modified colors; herbicide tolerance	Florigene Pty Ltd.
Chicory	<i>Chichorium intybus</i>	1	Male sterility	Bejo Zaden BV
Cotton	<i>Gossypium hirsutum</i>	6	Insect resistance; herbicide tolerance	Monsanto Company; DuPont Canada Agricultural Products; Calgene, Inc.
Flax	<i>Linum usitatissimum</i>	1	Modification of acetolactate synthase (ALS)	University of Saskatchewan, Crop Dev. Centre
Maize	<i>Zea mays</i>	22	Insect tolerance; herbicide tolerance; male sterility; production of the aromatic amino acids	Syngenta Seeds, Inc.; Pioneer Hi-Bred International, Inc.; Dekalb Genetics Corporation; Aventis CropScience; BASF, Inc.; Mycogen; Monsanto Company
Melon	<i>Cucurbita pepo</i>	2	Virus tolerance	Asgrow; Seminis Vegetable, Inc.; Upjohn
Papaya	<i>Carica papaya</i>	1	Virus tolerance	Cornell University
Polish canola	<i>Brassica rapa</i>	1	Herbicide tolerance	Monsanto Company
Potato	<i>Solanum tuberosum</i>	4	Insect resistance	Monsanto Company
Rice	<i>Oryza sativa</i>	2	Herbicide tolerance	BASF, Inc.; Aventis CropScience
Soybean	<i>Glycine max</i>	7	Herbicide tolerance; high oleic acid; low linolenic acid	Aventis CropScience; DuPont Canada Agricultural Products; Monsanto Company
Squash	<i>Cucurbita pepo</i>	2	Virus resistance	Asgrow; Seminis Vegetable, Inc.; Upjohn
Tobacco	<i>Nicotiana tabacum</i>	1	Herbicide tolerance	Societe National d'Exploitation des Tabacs et Allumettes
Tomato	<i>Lycopersicon esculentum</i>	6	Delayed ripening; delayed softening; insect resistance;	DNA Plant Technology Corporation; Agritope, Inc.; Monsanto Company; Zeneca Seeds; Calgene, Inc.
Wheat	<i>Triticum aestivum</i>	1	Herbicide tolerance	Cyanamid Crop Protection

and the problems associated with reliably detecting a GMO in very large samples. Clearly, these methodologies will rapidly improve with the advance of new technologies. For this reason, the author concentrated more on the theory behind the analyses and statistics than the technologies now in use.

Transgenes: Expression and Silencing of

George C. Allen

North Carolina State University, Raleigh, North Carolina, U.S.A.

INTRODUCTON

It is hoped that transgenic technology will be a solution for feeding the increasing world population. However, as the use of transgenic crops has increased, evidence has accumulated that the expression of a desired transgene may be unstable. To ensure that plants with unstable transgene expression are kept from reaching market, extensive testing is needed, which requires higher production costs. Even this testing is still not a guarantee that an apparently stable trait will remain stable under all environmental conditions.^[1] The purpose of this review is to provide the reader with a greater understanding of the molecular events related to how and why gene silencing occurs. Possible strategies for preventing undesirable gene silencing are also discussed, and examples are given of gene silencing used as a tool to understand gene function.

The discovery of gene silencing in plants laid the groundwork for findings that gene silencing is found in all higher eukaryotes. Historically, unstable transgene expression in plants was ascribed to “chromosomal position effects.” According to the chromosomal position-effect model, transgenes integrated into regions of the genome containing uncondensed chromatin were more likely to be expressed. Conversely, transgenes integrated into regions of the genome containing condensed chromatin were less likely to be expressed. While extensive evidence for chromosomal position effects exists, homology-dependent gene silencing is now also known to be a major determinant for transgene expression.

POST-TRANSCRIPTIONAL GENE SILENCING (PTGS)

More than a decade ago a fortuitous observation was made when Jorgensen and his colleagues attempted to “over-express” chalcone synthase (CHS) in petunia, using a transgene sequence that was identical to the sequence of the natural gene.^[2] To achieve overexpression of CHS, a viral promoter known to give high levels of gene expression was used, with the expectation that purple flowers would be produced. Instead, the CHS overexpressing transgenic plants produced flowers that showed various patterns of purple and white. When the CHS messenger

RNA (mRNA) levels in the white and purple sections were compared, the mRNA levels from white sectors were drastically reduced for both the CHS transgene and the native petunia CHS gene. The result was verified when van der Krol and colleagues tried to overexpress a petunia flavanoid gene.^[3] Both groups concluded that a major requirement for gene silencing was sequence homology between the transgene and the native gene.

Nearly three years later, research on plant virus resistance provided additional clues to the gene silencing puzzle.^[4] For several years, it was known that a transgenic plant expressing a viral coat protein for a specific virus had a higher frequency of resistance to the virus. Such observations led to speculations that the viral coat protein prevented the uncoating of the infecting virus and thus interfered with viral replication. Experiments by Dougherty and colleagues resulted in an alternative explanation, in which high levels of viral mRNA expressed from a plant transgene resulted in virus resistance. The transcription rates were similar for both virus-infected and uninfected plants, but no transgene viral mRNA accumulated, indicating that resistance was at the post-transcriptional level.

The model proposed by the Dougherty group suggested that an RNA-dependent RNA polymerase (RdRP) produced an antisense RNA that led to the degradation of both the viral RNA and the transgene “viral” RNA. We now know that the type of gene silencing observed over a decade ago in petunias was post-transcriptional gene silencing (PTGS), which also has been shown to be a natural mechanism plants use for virus resistance.

To circumvent plant defense systems, many viruses have suppressor systems that interfere with PTGS.^[5] Thus transgenic plants that constitutively express the viral suppressors of silencing have impaired PTGS, which led to ideas that the suppressors could be used for high-level transgene expression. Unfortunately, plants that express the viral suppressors show developmental abnormalities. Such silencing-suppressed plants may be extremely sensitive to viruses under natural growing conditions, because silencing is a defense against viruses.

Recent work has shown that RdRP uses the mRNA template to produce double-stranded RNA (dsRNA), which is then degraded to small RNAs, leading to the initiation of PTGS.^[6] Although the production of the

small RNAs was discovered in plants,^[7] the same pathway occurs in animal and fungal systems. Mutant and biochemical analyses are now increasing our understanding of the genes and signals involved in PTGS.

TRANSCRIPTIONAL GENE SILENCING (TGS)

TGS and PTGS typically are distinguished by nuclear run-on assays that compare transcription rates with the steady-state mRNA levels. A gene silenced by TGS has undetectable transcription and undetectable mRNA, whereas a gene silenced by PTGS is transcribed but has greatly reduced levels of mRNA. Additionally, TGS can be inherited, whereas PTGS requires reactivation in every generation.

To understand TGS it is useful to have a basic understanding of chromatin structure. Chromatin consists of proteins that bind and package DNA into successive levels of higher-order structures, which we eventually see as eukaryotic chromosomes. The structure of chromatin can control access of the transcriptional machinery to the DNA. If the chromatin is uncondensed, the transcription apparatus has ready access to promoters. Condensed chromatin, on the other hand, prevents access to a promoter.

Initial work on TGS demonstrated that when a transgene integrates near a region of condensed inactive chromatin, the inactive chromatin could spread into the transgene and prevent transcription. *Drosophila* studies showed that silencing frequently resulted in variegated expression patterns, known as position-effect variegation. Thus, in typical TGS, the promoter is made inaccessible by the condensed chromatin and cannot be transcribed.

PREVENTION OF TRANSCRIPTIONAL GENE SILENCING

A major limitation in the use of transgenes has been unpredictable variation in expression. To reduce the variation caused by TGS, attempts were made to block the spread of condensed chromatin. DNA elements termed matrix attachment regions (MARs) from the chicken lysozyme gene were used to flank a transgene.^[8] The results showed that transfected mammalian cell lines had higher levels of transgene expression and lacked chromosomal position effects when MARs were used.

Work from the Allen and Thompson lab tested whether MARs could prevent silencing in plants using the beta-glucuronidase (GUS) reporter transgene, either flanked by yeast MARs or lacking MARs.^[9] Comparison of the GUS transgene copy number and expression levels revealed that the GUS expression levels were much higher in tobacco cell lines transformed with MAR-flanked trans-

genes. However, even in the cell lines transformed with reporter constructs using the flanking MARs, a drastic reduction in transgene expression was seen when the transgene copy number increased above a threshold of approximately 20 copies. Similar results were found when a tobacco MAR was used.

We now know that silencing is possible, when gene copy numbers are above a threshold even in cell lines with MAR-flanked transgenes, and that this silencing is likely due to PTGS. In contrast to lines containing MAR-flanked transgenes, the control cell lines were subject to silencing by both TGS and PTGS. When cell lines expressing a suppressor of PTGS were retransformed with reporter genes flanked by MARs, silencing was drastically reduced. Presumably the flanking MARs prevented TGS and the viral suppressor prevented PTGS. Thus, MARs appear to prevent TGS but not PTGS.^[10]

GENE SILENCING AS A TOOL FOR FUNCTIONAL GENOMICS

With genome sequences rapidly being completed for many organisms, attention is being focused on the area of functional genomics. While microarrays provide information on gene expression patterns and possible gene interactions, understanding how a gene impacts phenotype is limited by the lack of tools for producing functional knockout mutants. PTGS (or RNAi) is now providing scientists with a new tool for knocking out specific genes or groups of genes by using dsRNA to induce gene silencing.^[11] The resulting phenotypic knockout can then be examined to determine gene function. By combining the use of high-throughput RNAi with microarray analyses, the effect of knocking out a single gene can be determined for an entire array of expressed genes, allowing scientists to determine the impact the gene has on global gene expression. Thus, gene silencing offers a unique tool for understanding how genes are regulated in complex organisms.

Transgenic Plants: Breeding Programs for Sustainable Insect Resistance

Michael B. Cohen

University of Alberta, Edmonton, Alberta, Canada

INTRODUCTION

Genetic engineering of crops with crystal toxin (Cry) genes from *Bacillus thuringiensis* (Bt) has been a revolutionary development in plant breeding for resistance to insect pests.^[1] Because Bt toxins are highly effective against several important groups of pests, yet are largely benign to non-target organisms, unprecedented measures have been taken in the United States,^[2] Canada,^[3] and Australia^[4] to delay the evolution of pest adaptation to Bt crops. Resistance management strategies for Bt crops depend on proper deployment of Bt cultivars in farmers' fields and on the development of cultivars with appropriate toxin genes and toxin titers. This article provides an introduction to the principles of resistance management and recommends steps that genetic engineering programs and government regulatory agencies can take to promote the sustainable use of Bt crops.

THE REFUGE/HIGH DOSE STRATEGY

There is widespread agreement that the refuge/high dose strategy (Fig. 1) is the most promising approach for protecting the long-term effectiveness of transgenic insect-resistant crops.^[2,5,6] Studies of insect populations have shown that resistance to insecticides, including Bt toxins, is most often attributable to a partially recessive mutation at a single major locus, and that the initial frequency of the resistant allele in unselected populations is low. A high dose in a Bt cultivar is one that is sufficient to make the resistant allele functionally recessive, so that insects heterozygous (RS) at the resistance locus do not survive when feeding on the cultivar. Refuges are non-Bt plants that serve to maintain homozygous susceptible insects (SS) in pest populations. For the refuge/high dose strategy to work, there must be a sufficient number and suitable spatial distribution of SS insects to ensure that the rare homozygous resistant insects (RR) mate with SS insects rather than with each other.

The refuge/high dose strategy has been implemented for Bt corn, potatoes, and cotton in the United States^[2] and for Bt corn in Canada.^[3] Currently available Bt corn cultivars appear to have a high dose of toxin with respect

to the European corn borer *Ostrinia nubilalis*. Farmers who grow Bt corn must plant 20% of their land to non-Bt corn to serve as a refuge. The non-Bt corn fields must be planted at approximately the same time as the Bt fields, be of a similar corn cultivar, and be within approximately 0.5 kilometers (km) of the Bt fields. In Australia, where Bt cotton cultivars do not have a high dose of toxin with respect to the cotton bollworm *Helicoverpa armigera*, larger refuges are required.^[4]

The U.S. Environmental Protection Agency established a working definition of a high dose in transgenic plants as "twenty-five times the protein concentration necessary to kill susceptible larvae," and described five procedures for testing whether this criterion has been met.^[2] A rough guideline for a high dose that can be used in preliminary assessment of transgenic plants has also been suggested.^[7] These authors surveyed the toxin titers of Bt corn, cotton, and potato cultivars that appear to have a high dose based on field performance and noted that these cultivars have titers of at least 0.1–0.2% soluble protein or 1–2 ng/mg fresh weight (see also Table A2 in Ref. 2).

OPTIONS FOR USING MULTIPLE TOXINS

Larvae of Lepidoptera (moths and butterflies) are the target pests for the Bt corn and cotton cultivars that have been released so far and for numerous other Bt crops that are under development. For most lepidopteran pests, there are several Cry toxins that are of sufficient toxicity to achieve a high dose in Bt cultivars. Genetic engineering programs thus face the question of how best to utilize multiple toxin genes. Among the options are sequential release, mosaics, and pyramids. These options have been analyzed using simulation models that incorporate factors such as refuge size, the relative mortality of SS, RS, and RR insects, and the initial frequency of the R allele.^[5,6] Two very robust and important conclusions are supported by simulation analyses of most sets of conditions:

- Pyramiding two toxin genes within a single cultivar provides substantially more total years of plant protection than either sequential release of the two genes (i.e., releasing the second gene after the pest

Fig. 1 How the refuge/high dose strategy works to delay the increase in highly resistant insects (RR) in a pest population. The strategy assumes that the dose in the Bt cultivar is sufficient to make the R allele functionally recessive, and that the initial frequency of R is low ($<10^{-3}$). (Modified from Ref. 7.)

population has adapted to the first) or simultaneous use of two cultivars, each with a single gene, as a mosaic.

- Maintaining refuges and using high-dose plants substantially delays the evolution of pest resistance in all three of the above options.

Toxins that are pyramided in a cultivar should be sufficiently different in their properties to make it unlikely that a single insect mutation would result in the loss of effectiveness of both toxins. Cry toxins must bind to particular brush border membrane proteins of the midgut epithelium as one step in their mode of action. The most common basis of insect resistance to Cry toxins are mutations that result in a change in the binding properties of these membrane proteins.^[8] Competitive displacement assays of toxin binding to brush border membrane vesicles can be used to identify toxins that do not share binding sites and are therefore suitable for pyramiding. Such assays have generally shown that toxins highly similar in amino acid sequence, such as Cry1Ab and Cry1Ac, compete for the same binding sites, whereas less similar toxins do not.^[8]

Broad-spectrum cross-resistance to Bt toxins highly dissimilar in amino acid sequence has been observed only in three lepidopteran species and appears to be caused by resistance mechanisms other than altered binding.^[8] However, alleles conferring such cross-resistance are appar-

ently rare, and there are few circumstances under which cross-resistance would result in a pyramid failing in fewer generations than sequential release of two toxins.^[6] Cotton cultivars with two pyramided Cry toxins are under development in the United States and Australia.

MAINTAINING REFUGES

Resistance management plans in the United States, Canada, and Australia specify the size and locations of refuges that farmers must maintain. Developing countries will generally need to take a different approach to resistance management, due to smaller farm size and limited extension services. In the case of Bt cotton in China, where the principal pest (*H. armigera*) feeds on many wild and cultivated plant species, it has been argued that non-cotton host plants will provide adequate refuges.^[9] Refuges comprised of alternative hosts are not an option for monophagous pests such as the yellow stem borer *Scirpophaga incertulas*, the most important lepidopterous pest of rice in tropical and subtropical Asia. In such cases, innovative approaches to maintain refuges will need to be developed. For example, governments can increase the probability that some farmers will grow non-Bt cultivars if they restrict the number of popular cultivars

that are released in Bt form.^[7] Farmers who grow non-Bt cultivars would in effect provide refuges for neighboring farms. The non-Bt farmers may in turn benefit from the Bt cultivars grown by their neighbors, because local pest populations may decline substantially in areas where large proportions of fields are planted to Bt cultivars.^[10]

Although it is likely that some fields will be planted to non-Bt cultivars in areas where Bt cultivars become available and refuge requirements are not enforced, these fields may be relatively few in number. This highlights another important advantage of cultivars with two pyramided toxins: Such cultivars require smaller refuges. If both toxins are produced at a high dose, then insects able to survive on the cultivar (i.e., an insect homozygous for resistance alleles at two loci) will be extremely rare and thus fewer susceptible insects will be required to reduce the chances of resistant insects mating with each other.

CONCLUSION

The United States, Canada, and Australia have implemented stringent resistance-management strategies to delay the adaptation of pest populations to Bt crops, and these strategies appear to be working. There have been no reports of outbreaks of Bt-resistant pests in these countries since the release of Bt crops in 1996–97. Developing countries may not be able to enforce the use of refuges to the same degree, but can still promote the sustainable use of Bt crops by instituting careful standards for Bt cultivars and limiting the number of popular cultivars that are released in Bt form. For crops in which the target pests are monophagous, it is particularly useful to release Bt cultivars with two pyramided toxin genes—both expressed at a high dose—because such cultivars require smaller refuges.

Transgenic Crop Plants in the Environment

R. James Cook

Washington State University, Pullman, Washington, U.S.A.

INTRODUCTION

In nearly two centuries of agricultural research, no single technology has offered more benefits and less risk to the environment than the transgenic technologies used to develop disease-, pest-, and herbicide-resistant or -tolerant crop plants. Historically, the negative effects of crop production systems on the environment have been the result of the tillage, pesticide applications, and fertilization used to grow crops, and not the direct effects of crop plants themselves on the environment. The use of a transgenic glyphosate-insensitive *EPSP* gene makes it possible to reduce or eliminate tillage; the use of *Bt* genes for insect resistance in cotton and corn, and coat-protein gene resistance to viruses in squash and papaya make it possible to reduce the use of pesticides for these crops. The use of just eight transgenic varieties of crops based on herbicide tolerance or insect or virus resistance reduced the total use of pesticides in the United States in 2001 by an estimated 20 million kilograms (46 million pounds). Moreover, crop plants genetically protected from pests and diseases are healthy, and therefore less likely than pest-damaged or diseased plants to leave nitrogen unused in the soil to leach into groundwater. In addition, they return more organic matter to the soil, which improves soil structure.

Scientists have rigorously focused on public concerns over the possible negative impact of transgenic crops on the environment, including negative effects on non-target organisms. Thus far, the potential negative environmental effects of so-called input traits (i.e., traits that moderate crop inputs, as for weed, insect, and disease control), remain unconfirmed, inconsequential, or disproved. On the other hand, more research and experience will be needed on possible environmental effects of so-called output traits (i.e., traits that affect end-use products—say, that can convert a food crop into an industrial or medicinal crop). Crops with output traits are not yet in commercial use. Meanwhile, the continued adoption of transgenic plants with their novel input traits is fully consistent with the goals of sustainable growth in agriculture.

AGRONOMICAL USEFULNESS OF TRANSGENES

Transgenic crop plants were grown on 50 million hectares (130 million acres) worldwide in 2001.^[1] About two-

thirds of the area planted to these crops is in the United States, followed by acreage in Argentina, Canada, China, South Africa, and Australia. More than 99% of this acreage involves the use of just two agronomically useful genes: 1) a glyphosate-insensitive *EPSP* gene used to make varieties of soybean, canola, and cotton insensitive to the herbicide Roundup[®]; and 2) variations on a *Bt* gene for production of a protein lethal to certain insects, used to make corn resistant to the European corn borer and corn earworm, and to make cotton resistant to the cotton bollworm, pink bollworm, and tobacco budworm. These genes are from bacteria widely distributed in the environment. The remaining <1% of the area planted to transgenic crop plants grow varieties of squash in the eastern United States and papaya in Hawaii, each transgenic for resistance to one or more of their insect-vectored viruses using the coat-protein gene of that virus.^[2]

The traits conferred by these agronomically useful transgenes are commonly referred to as input traits because their use results in a change in the inputs needed to grow the crop. Traits conferred by transgenes intended to improve end use or add value to the harvested product are termed output traits, but are not yet in commercial use.

The rapid adoption of agronomically useful genes is not without precedent. Dwarfing genes *Rht-B1b* and *Rht-D1* for reduced height in wheat and *Sd2* for semidwarf growth habit in rice (introduced by conventional plant breeding) swept into worldwide use in the 1960s. These genes changed the harvest index (ratio of grain/grain + straw) of the plants from about 0.3 to nearly 0.5, thereby sparking what became known as the green revolution. In each of these examples, it is important to understand that, whereas the same or very similar genes are used worldwide, the varieties of wheat, rice, corn, soybean, cotton, and canola with these genes commonly number in the hundreds or thousands. Different varieties are needed for different end uses, and to ensure adaptation of the crop to the local climate, environmental stresses, and diseases. Many if not most of the currently grown transgenic varieties were developed by conventional breeding, wherein the transgene of interest was first introduced by transformation into one line (usually a line easily transformed) and then transferred by standard backcrossing into another line with the desired quality traits, and agronomically adapted to the area where it would be grown. Varieties with transgenes are subjected to the same

rigorous performance evaluations applied to conventional varieties before their release for commercial use.

ENVIRONMENTAL CONCERNS ABOUT TRANSGENIC CROPS

The development of transgenic crops has led to concerns over the possible effects of these crop plants or their new traits on non-target organisms in the environment. Assessments of risk have typically but incorrectly assumed that all factors in the cropping system remain the same except for the replacement of a conventionally bred variety with a transgenic variety. The adoption by farmers of any new variety is invariably accompanied by many modifications in crop management, including changes in date of planting, how or whether the soil is cultivated prior to planting, use of pesticides, and crop rotation. The use of a soybean variety with the glyphosate-insensitive *EPSP* gene results in the use of Roundup^R in place of a mixture of herbicides, and may also result in elimination of pre-plant and postplant cultivation of the soil. The use of a corn hybrid with the *Bt* gene rather than one without it may also eliminate the need for one or more insecticide treatments and will almost certainly result in greater mass of hardy corn stalks left as field residue, due to reduced European corn borer damage. Consideration of the environmental effects of a crop or gene—whether transgenic or not—must thus be in the context of the cropping system as a whole.

Larvae of the monarch butterfly feed on pollen grains that collect on the leaves of milkweed plants within and outside corn fields. Concern for these insects arose when a laboratory test showed that larvae have higher mortality when fed pollen from a corn hybrid with the *Bt* gene than when fed pollen from a corn hybrid lacking the *Bt* gene.^[3] When this risk was examined under field conditions in the context of different cropping systems, management practices such as planting date, weed control, and use of insecticides had large effects on monarch populations, whereas *Bt*-corn pollen from current hybrids had only negligible or no effect on Monarch populations.^[4]

Gene transfer because of outcrossing has been raised as an environmental concern specifically for transgenic crops. There are two kinds of concerns: 1) gene transfer by outcrossing from a transgenic crop in one field to a conventional variety of that same crop species in a neighboring field; and 2) gene transfer to a wild or weedy relative of the crop. The transfer by gene flow of input traits between varieties of the same crop raises mainly economic issues, such as when a transgene occurs at some frequency in a crop intended for certification as organic, or when crop plants produced from seed left in the field (volunteers) are resistant to an herbicide intended for use

in that field. The transfer by gene flow of an output trait between varieties of the same crop could raise safety issues for human health if the trait expressed in a food crop such as corn or soybean is intended for industrial use only. Geographic isolation or obligatory self-pollination to prevent gene transfer will probably be a prerequisite for production of these kinds of crops.

Gene transfer between related species is a rare event, and fertile hybrids produced by such outcrossing are rarer still. Wheat hybridizes with jointed goat grass, its weedy relative common throughout the wheat-growing Great Plains and Pacific Northwest of the United States, but after growing dwarfed wheat varieties in these regions for 40 years, no evidence exists for natural transfer of a dwarfing gene to jointed goat grass. In the great majority of cases, transfer of a gene agronomically useful in a cropping system will provide little or no survival value to that same plant or its wild relatives in an unmanaged or natural ecosystem. Gene transfer is a moot issue for crops grown where there are no wild or weedy relatives (e.g., corn, soybeans, and cotton in the United States) but can conceivably be an issue for corn grown in Mexico within range of pollen flow to its native progenitor, teosinte, depending on the trait.

The adoption of dwarfed varieties of wheat and rice was driven by the quest for higher yields to feed the growing world population. In addition to greater use of nitrogen fertilizer, which continues to have environmental consequences,^[4] the denser crop canopy and lush foliage typical of these cropping systems also led to increased pressures from insects and plant diseases. Where no useful genes for resistance to these pests have been available, or where evolution of the pest into new virulent strains has occurred faster than breeders could develop resistant genotypes of the crop, achieving the high-yield potential of these varieties continues to depend on pesticides.

ECONOMIC INDICATORS FOR TRANSGENIC CROPS

The adoption of crop varieties with the glyphosate-insensitive *EPSP* gene and a *Bt* gene is driven by the quest to increase efficiency through decreased cost of production, although in some cases yields have also increased.^[5] These cost-cutting measures are occurring on two fronts: 1) in use of less or no tillage (no-till), except as required to fertilize and plant the crop; and 2) in use of less pesticide or replacement of several pesticide applications with a single, lower-cost, more effective pesticide. Although driven by economics, these changes are also good for the environment. The use by U.S. farmers in 2001 of eight transgenic crop varieties with a *Bt* gene for insect resistance, the *EPSP* gene for Roundup^R tolerance, or

coat-protein gene for virus resistance reduced total pesticide use in the United States by an estimated 20 million kilograms.^[5]

Of the 75.5 million acres of soybean grown in the United States in 2001, 70% were planted to varieties with the glyphosate-insensitive *EPSP* gene, and therefore relied on Roundup^R as the main or only herbicide for weed control.^[6] Nearly 70% of the U.S. cotton crop in 2001 was planted to varieties with the *Bt* gene for resistance to insects. The trend worldwide because of one or two *Bt* genes is to reduce the need for insecticides on cotton from 12–15 applications per season to only two or three. Moreover, stacking two slightly different *Bt* genes in the same plant, as now done with cotton, can greatly delay if not prevent the pest from adapting to this mechanism of plant defense. About one-fourth of the U.S. corn crop is now produced with hybrids with the *Bt* gene. Due to a combination of new genes for pest resistance and integrated pest management, wherein pesticides are applied based on predictive models and decision guides, the global market for pesticides peaked in the 1990s at about \$30 billion, is now at about \$20 billion annually, and is decreasing at a rate of about 2–3% per year (Ganesh Kishore, personal communication).

CONCLUSION

The negative impact of agriculture on air and water quality results almost exclusively in dust and sediment in water from cultivated land. Sixty percent of the 5.5 million acres of soybean double-cropped with wheat in the United States are now seeded directly (no-till) into wheat stubble.^[7] Of the 70 million acres of full-season soybean in 2001, 31% were direct-seeded into undisturbed soil and residue of the previous crop, usually corn. Of the 80 million acres of corn planted in the United States in 2001, 18% was direct-seeded. The European corn borer survives in corn stalks left on the soil surface, and is therefore a greater risk in direct-seed than in plow-based cropping systems. The European corn borer does not survive in *Bt* corn, however.

No-till cropping systems also result in other changes beneficial to the environment, including greater diversity of soil flora and fauna due to buildup of organic matter; greater water infiltration during intensive rains or snow

melt; more or better habitat for birds and other wildlife; and greater sequestration of carbon dioxide, one of the major greenhouse gases identified with global warming.^[8] These outcomes are made possible by continual improvement in crops and crop management. The current adoption of transgenic plants with their novel agronomic traits is an important part of this continuum and is fully consistent with the goals of sustainable growth in agriculture.

Transgenic Crops: Regulatory Standards and Procedures of Research and Commercialization

Qifa Zhang

Huazhong Agricultural University, Wuhan, P.R. China

INTRODUCTION

The estimated global area of transgenic or genetically modified (GM) crops reached 52.6 million hectares in 2001.^[1] The rapid growth of the area planted to GM crops in both developed and developing countries strongly indicates that GM crops are welcome by growers and consumers alike. Utilization of transgenic crops will be a vital alternative to provide the world with adequate food and other agricultural products.

Although there have been widespread controversies regarding many safety aspects of transgenic plants as crops and food, there is an increasingly strong belief that transgenic plants can provide safe crops and food. This is because, in reality, transgenic technique does not pose any higher risk than traditional breeding methods to the safety of the crop products, and also because of the rigorous governmental regulations implemented by the countries that conduct transgenic research and grow GM crops. This article presents a brief overview of the regulatory standards and procedures for the environmental release and commercialization of GM crops.

REGULATORY STANDARDS AND PROCEDURES FOR TESTING AND CULTIVATING GM CROPS

The development of a transgenic crop consists of the following stages: laboratory research, confined field tests, environmental release, and commercialization. Governmental regulations in general address the following concerns in the process of commercialization of GM crops:

- Is the transgenic plant safe for the environment?
- Is the transgenic plant safe for agriculture?
- Is the transgenic plant product safe for use in foods, feeds, or other consumption?

Several strategies have been widely adopted in evaluating the safety of GM crops and foods. One of the strategies is based on the concept of substantial equivalence.^[2] This approach acknowledges that the goal of the assessment is

not to establish the absolute safety of GM crops and foods, but to evaluate their level of safety relative to their traditional counterparts, where such counterparts exist. Another important strategy commonly used in regulation is that the evaluation be done on a case-by-case basis.

For safeguarding the use of transgenic crops, science- and risk-based regulatory standards have now been established and implemented in many countries, and are being developed in many others. It should be noted that governmental regulation standards are also frequently bound to international agreements. Although there is substantial scientific commonality in the regulatory standards, the procedures followed in one country may be very different from those in another country. The cases of two countries, the United States and China, are given below as examples for demonstrating the common ground and differences in regulation of GM crops.

The United States was the first country to establish functional regulatory machinery for the biosafety of transgenic crops. A coordinated regulatory framework was set up in 1986 that assigned the responsibility to the Environmental Protection Agency (EPA), the U.S. Department of Agriculture (USDA), and the Food and Drug Administration (FDA), based on existing regulatory authorities of the U.S. government. A good starting point for information about regulation in the United States is the Web site "United States Regulatory Oversight in Biotechnology Responsible Agencies—Overview" (<http://www.aphis.usda.gov/ppq/biotech/usregs.html>). The basic premise for regulation of GM crops is that such crops shall not be fundamentally different from unmodified organisms or those produced by conventional methods. The key principle adopted by the regulatory framework is that it is the product, rather than the method of producing the product, that should be regulated.

The regulatory body of the USDA is the Animal and Plant Health Inspection Service (APHIS). This agency regulates the importing, transportation, and field testing of GM crops and determines the likelihood of a transgenic plant having negative agricultural or environmental effects (<http://www.aphis.usda.gov/ppg/biotech>). For common crops and traits, researchers need only notify the agency of their intention to transport or field test a transgenic plant. The researcher is responsible to ensure

that the gene introduced meets certain technical criteria. For less common crops and for genes or traits that may pose greater risk, the researchers are required to file formal applications for permission to transport or plant the materials. Measures are required in field testing to prevent the spread of the transgene to the environment or into the food supply. Before commercializing a transgenic plant, the developer petitions APHIS for nonregulated status, which requires data on the introduced gene construct, plant biology, likely effects on the ecosystem, and field test reports, as well as data and information for any unfavorable effects. APHIS also has the authority to halt the sale of the GM crop if there is evidence that the GM crop is becoming a pest.

The FDA has authority to determine the safety of foods and food ingredients based on the concept of substantial equivalence, and relevant information can be found at the Web site (<http://www.cfsan.fda.gov/~lrd/biotechm.html#label>). The FDA adopts a voluntary consultation process with the GM crop developer, and reviews safety and nutritional data. If the introduced gene is from a known allergenic source, the GM food is required to be assessed for allergenicity. The FDA also has the authority to order the GM food's removal from the market, if there is evidence that it is unsafe.

The EPA regulates transgenic plants that contain plant-incorporated protectants, including plants engineered for insect or disease resistance that the agency refers to as plant pesticides (<http://www.epa.gov/pesticides/biopesticides/>). This is implemented by granting an experimental use permit for testing, plant propagation registration, and full commercial registration, based on extensive reviews of data for the plant pesticide including its biochemical characteristics, toxicity, and environmental effects. The agency may require a resistance management plan in order to prevent or slow the development of resistance in the target pest. The EPA regulates herbicides, but not herbicide-tolerant plants. In the case of engineering a plant for herbicide tolerance, herbicides must be registered for a new use.

In addition to regulation at the federal level, many states in the United States also apply regulations on GM crops that require additional review and approval at the state level. Moreover, most research institutions have biosafety committees that monitor potentially hazardous transgenic research and ensure compliance with biosafety procedures.

In China, the biosafety of GM crops is regulated by the Ministry of Agriculture (MOA) (<http://www.agri.gov.cn/ztl/2001/0820/0820.htm>). The MOA regulates the research, development, field tests, environmental release, and commercialization of GM crops. The MOA also regulates the import of GM crops and their products.

The process from laboratory research to commercialization of GM crops is divided into four stages in the Chinese regulation framework: laboratory research, confined field tests, environmental release, and product demonstration and commercialization. An MOA biosafety committee is responsible for reviewing the applications filed by researchers. In this system, notification of the MOA is required for transgenic research that may pose higher risk. For conducting field tests of a transgenic plant, a formal application must be filed with the MOA, which will be reviewed by the biosafety committee; a permit will subsequently be issued. In filing this application, the researcher is required to provide data about the gene construct, biology of the plant, test site, measures of confinement, and data to be collected. After a two-year field test, the transgenic plant can advance to environmental release when another application is filed with the MOA, submitting all data gained in the field test. Experimentation of environmental release in general will be conducted in another two consecutive years, after which another application should be filed with the MOA to advance the transgenic plant to product demonstration in large scale. At the end of the product demonstration, which usually requires two years to complete, the researcher can apply for a biosafety certificate for commercialization, which may require extensive data and comprehensive reviews. The transgenic plants can be used as parents for breeding purposes only when the biosafety certificate is issued, and the progenies from crosses with the transgenic parent must undergo the product demonstration procedure again and reapply for the biosafety certificate.

Information can also be found at Web sites for regulatory standards and procedures of the European Community (<http://www.biosafety.be/Menu/BiosEur.html>) and Japan (<http://www.s.affrc.go.jp/docs/sentan/>).

LABELING OF GM FOODS

Labeling of GM foods is a widely debated issue in many parts of the world. Although different countries' regulatory standards (described in previous sections) address all concerns of consumers and thus provide strong assurance for food safety, there are still diverse opinions about the necessity of labeling GM foods. Again, countries are divided over requirements and procedures for labeling the GM foods.

As described in the previous section, food safety in the United States is regulated by the FDA. The FDA requires that all labeling be truthful, informative and not misleading, and identifies no characteristics of the GM food would justify labeling it as a special class. The FDA

requires labeling for GM foods in the same way as for other foods, including information about the composition, nutrition, and allergenicity concerns, but does not require special labeling of GM foods. Additional voluntary labeling is allowed, provided that it is truthful, informative, and not misleading. The FDA has recently developed industry guidance on voluntary labeling.

In Japan, implementation of new regulations on GM food labeling was initiated in April 2001 (http://www.maff.go.jp/soshiki/syokuhin/hinshitu/organic/eng_yuki_top.htm). According to the authority, labeling is not for safety concerns but for consumers' right to choose or right to know. The labeling is implemented according to a positive list system, in which a committee is formed in the Ministry of Agriculture, Forestry, and Fishery (MAFF) to review the positive list of foods that should be labeled. In 2001, 15 soybean products and nine corn products were listed. The regulation requires that the food should be labeled if the DNA/protein of the transgene can be detected, the raw materials are among the top three constituents, and the GM materials are 5% by weight.

In China, labeling of transgenic organisms was enforced in March 2002 (<http://www.agri.gov.cn/xxfb/2002/0107/dt0110-2.doc>). Labeling is administered by the MOA, and regulation covers the transgenic organisms included in a list that is updated from time to time. The current list includes soybean, corn, rapeseed, cotton, and tomato. It regulates not only GM foods, but also seeds and other products from GMOs that are sold in the marketplace.

In Europe, a series of regulations applies concerning traceability and labeling of GMOs and of GMO food and feed products. (<http://www.biosafety.be/Menu/BiosEur4.html>). The regulation requires labeling of products consisting of or containing GMOs, foods and food ingredients (including food additives and flavorings produced from GMOs), feed materials, and compound

feeding stuffs and feed additives produced from GMOs placed on the market in accordance with European Community legislation. Traceability requires that information about GMO products placed on the market be transmitted from one operator to the other in transaction, and that operators have in place systems and procedures to allow the identification of persons involved in the transactions for a period of five years.

CONCLUSION

Functional regulatory machinery has been established in many countries in the last decade. However, regulatory standards and procedures are still evolving, even in countries with a relatively long history of GM crop cultivation. With rapidly accumulating large-scale adoption and public recognition of the advantages of GM crops, it is believed that goals, standards, and procedures of regulation will gradually become globally harmonized and will promote the utilization and exploitation of the full benefits of GM crops, in order to better meet the demands of the ever-increasing world population.

Transposons and Allelic Diversity

L. Curtis Hannah

Clifford Weil

Purdue University, West Lafayette, Indiana, U.S.A.

INTRODUCTION

This article concerns transposable elements and their role in altering genes within the genome. Like swimmers in shark-infested waters, genes in genomes with active transposable elements or transposons lie ever susceptible to attack. Whereas transposons were discovered approximately 50 years ago, only recently has the magnitude of transposons' roles in shaping genetic material been realized. It is now clear that the number of ways transposable elements can reshape genes and genomes is almost endless. Here we limit discussion to diversity caused by transposons in individual genes. Transposable element visitation can 1) alter the protein coding information, 2) alter the regulatory information, 3) increase gene number, and 4) potentially give rise to introns. Examples of each form of alteration are given below. Severe space limitations dictate that we limit our discussion to only general overviews and refer only to reviews and recent key papers. Interested readers are highly encouraged to peruse the literature for more detailed information.

WHAT ARE TRANSPOSABLE ELEMENTS?

Transposable elements or transposons were first described some 50 years ago by Barbara McClintock in her seminal studies in maize leading eventually to receipt of the Nobel Prize.^[1-5] Transposons are DNA sequences that can change position within the genome. While classified as transposons, these elements differ in many, fundamentally important, ways. For example, movement or transposition of the element varies, depending on the family of elements. In some cases, the so-called "cut-and-paste" elements, the transposon exits its original position and moves to a new site. Gene function at the original site is sometimes restored. In other cases (copy-and-paste), only a DNA copy of the element moves to a new site, whereas in other systems, RNA copies of the element are reverse-transcribed into DNA which then insert back into the

genome. Elements differ in size, from the small miniature inverted-repeat transposable elements^[5] [a few 100 base pairs (bp)] to elements greater than 10,000 bp. Finally, elements differ in abundance. Most significantly, it is now known that RNA-based transposons make up the majority of many genomes.^[1]

TRANSPOSONS ALTER PROTEIN CODING INFORMATION

A fascinating and likely evolutionarily important property of the cut-and-paste transposons is their ability to create small insertion/deletion polymorphisms within genes.^[6] Upon insertion, these elements duplicate host sequences, the size of which is family-specific. The duplication likely occurs via an initial staggered cut in the host DNA followed by DNA repair after insertion. Subsequent excision of these elements is imprecise, and one commonly finds DNA sequence alterations at the site of integration. These alterations usually involve insertion of part of the host duplication and are influenced by adjacent sequences.^[7]

Insertion/deletion (InDel) polymorphisms of the size made by transposons are quite common in plant genomes.^[3] Whether a particular InDel was, in fact, created by transposons or by slippage in DNA replication or unequal crossing over cannot be determined without complete pedigree information of the sequences in question. However, because the excision frequency of particular cut-and-paste elements can be extremely high (hundreds per generation in a single plant), it is quite probable that transposons are a major source of this type of variation.

Transposon-induced InDel variation likely is quite important in evolution. A particularly straightforward case in which transposon-induced InDel variation was useful for breeding programs comes from maize. A *Ds* (*Dissociation*) insertion into the *shrunken-2* (*Sh2*) gene was isolated almost 35 years ago at Purdue University. *Sh2* encodes one subunit of the allosterically controlled

enzyme, ADP-glucose pyrophosphorylase. Fortuitously, the insertion resided within a region of the gene encoding an allosteric binding site of the enzyme. One excision event, leading to a 2 amino acid insertion, greatly reduced inhibition by an allosteric effector molecule and, in turn, caused a 30% increase in maize seed weight.^[8]

TRANSPOSONS ALTER GENE REGULATION

One of McClintock's basic tenets posited that transposons are involved in gene regulation. This belief led to her nomenclature whereby transposons were termed "controlling elements." It is now quite clear that transposons do not usually act as the controllers of gene expression (promoters, enhancers, and such) that we typically associate with gene regulation (but see below). Nonetheless, there exist ample examples in the plant literature in which a transposon has become intimately associated with control of gene expression.

One of the earliest examples concerns the *A1* (*anthocyaninless-1*) gene in maize and the transposon system (*Spm/En*—*suppressor-mutator/enhancer*).^[6] *Spm/En* is one of several two-element systems in the maize genome. One element, often unable to move on its own, resides at the gene in question and inhibits gene function, whereas a second, autonomous element can activate both itself and the first element to transpose. Specific to the *Spm/En* system, introducing the autonomous element (*Spm/En*) normally leads to mutability (transposition) of a nonautonomous element (*dSpm/I*) but also, in some cases, to inhibition of a leaky phenotype conditioned by the *dSpm/I* insertion when *Spm/En* is not present. One series of mutable alleles arising from the *a1-m2* allele exhibits a different set of phenotypes. Here the mutant alleles actually condition some gene activity in the presence but not in the absence of the *Spm/En* element. Molecular mapping showed that the *dSpm/I* lies in the promoter of the *A1* gene and appears to have commandeered control of gene expression. Additional insertions into the *A1* promoter of nonautonomous

dSpm/I and *Mutator* elements alter how the *A1* gene responds to upstream regulators as well as its tissue specificity. Numerous cases have now been reported of "Mu-suppressible" alleles, in which mutant phenotypes caused by *Mutator* insertions in maize genes lose their mutant phenotype as the transposon becomes inactivated, both somatically and germinally. In several cases, the now-functional gene transcripts initiate within the inactivated transposon.^[9] Outward-reading promoters have also been reported in the termini of *Ac/Ds* elements, suggesting that the ability to seize control of how a target gene is regulated may be a widespread feature of transposons.

TRANSPOSONS INCREASE GENE NUMBER

There exist now a number of reports in the plant literature of various transposable elements capturing and moving gene sequences within the genome. The copy number of these genes then increases along with the transposon copy number. For example, Talbert and Chandler^[10] identified a sequence in a particular *Mutator* element with unambiguous similarity to a maize gene. Similarly, the maize retrotransposon *Bs1* contains portions of at least three maize genes.^[1,11] The tendency of *Ac/Ds* elements to move to nearby sites has allowed the formation of what are termed "macrotransposons."^[4] If the outside borders of two, closely linked *Ds* elements in the same orientation are recognized in a single transposition event, the two elements plus the host DNA lying between them become a single transposon. Recently, a fundamentally different type of transposon was described in plants.^[11] These elements, termed *Helitrons* (Fig. 1), lack terminal repeats, do not duplicate host sequences upon insertion, leave host junction sequences entirely intact, and exhibit very little sequence similarity among family members. They are, however, very good at capturing genes or parts of genes. For example, 12 pseudogenes were found in one, 17.8-kbp maize *Helitron*. Two pseudogenes were found in approximately 10 kbp of another maize *Helitron*. While analysis of these elements is only beginning, evidence favors the

Fig. 1 Diagrammatic representation of the newly described transposable elements termed Helitron. Motifs common to all *Helitrons* are highlighted.

notion that the elements preferentially target active genes for insertion through DNA strand invasion. Moreover, because the termini of the element are not well defined, continued DNA replication through the element can allow for capture of adjacent gene sequences.

Note that transposons of diverse types (DNA-mediated cut-and-paste, RNA-mediated copy-and-paste, as well as the newly described *Helitrons*) all have the ability to capture genes while traveling through the genome. That gene sequences can be multiplied and moved throughout the genome provides a ready explanation for the formation of gene families. Whereas the existence of gene families has been known for decades, they are becoming much more apparent with the recent massive sequencing projects. Because the number of members within different families differs dramatically, it is likely productive to consider transposons as the underlying multiplying mechanism. This is particularly relevant in those cases where polyploidy or unequal crossing over is clearly not causal. Furthermore, the fact that maize inbreds actually differ in the presence/absence of genes in various linkage groups^[12] strongly suggests that gene capture and movement is prevalent in modern genomes.

TRANSPOSONS CAN CAUSE INTRON FORMATION

A truly remarkable property of at least some transposons is their ability to form introns. This has been documented for two cut-and-paste transposon systems, *Ac/Ds* and *Spm/En*, and, with *Ds*, for both orientations of the transposon relative to the gene it is inserted into.^[5] These two facts alone suggest that transposon-induced intron formation is biologically relevant.^[4,13] Significantly, the mechanism by which transposons synthesize introns provides a ready explanation for a hitherto puzzling observation concerning exon/intron borders.

Typical nuclear introns begin with the virtually invariant dinucleotide GT and end with the invariant sequence AG. Whereas there are no apparent constraints on the exon sequences adjacent to introns, unexplainably, exons usually begin with GT and end with AG as well.^[13] An explanation for the dinucleotide exon termini, however, became apparent from analysis of transposon-derived introns. As noted above, most transposons duplicate host sequences upon insertion. In order for a transposon insertion to form an authentic intron, the created duplication must involve either one or both of the intron terminal dinucleotides GT and AG (see Ref. [13] for details). Hence the fact that nuclear exons often begin with GT and end with AG is explained by a

mechanism of intron origin involving duplication of host sequences.

If transposons truly are important in creating new introns, could a system that creates introns in preexisting genes be favored in evolution? We note that many introns enhance gene expression, in some cases, as much as 70-fold. Perhaps the important form of genetic variation created by transposons—and the reason they are tolerated in modern genomes, and even favored—concerns their effects on gene regulation. If so, McClintock may have been right after all (again). Transposons may, in fact, have roles as genuine, gene-controlling elements. That control, however, may be more far-reaching in its variety than even she had imagined.

CONCLUSION

While transposons have been known for almost one-half of a century, their relevance in shaping genomes, causing mutations, increasing gene copy number and controlling gene expression is only presently being realized. It is now clear that transposons make up much of the repetitive DNA sequences, create mutations in coding information, multiply genes through sequence capture and movement, and alter gene expression by insertion into promoters and possibly through creation of introns.

Trichomes

Stephen O. Duke

USDA, University, Mississippi, U.S.A.

INTRODUCTION

Most plants are covered with an assortment of structures, varying in morphology from hairlike to globular. Such structures, usually originating from the plant epidermis and projecting outward from the plant, are termed trichomes. They can be found on any plant part, and several different types of trichomes are sometimes found on the same plant surface. At the microscopic level their varied morphologies are truly amazing.

Trichomes may be classified by various criteria; however, they are generally either glandular or nonglandular with regard to function, depending on whether they produce a secretory product. The cotton fiber represents one extreme of a nonglandular trichome; the large, multicellular glandular trichomes found on many species are examples of the other extreme. The economic value of both fibrous trichomes and the contents of glandular trichomes is large. Furthermore, the negative impact of trichomes or trichome products that cause health problems for animals (including humans) is significant.

TRICHOME ANATOMY AND DEVELOPMENT

Plant trichomes have been the subject of at least three entire volumes.^[1–3] Several reviews on trichome anatomy and development are available (e.g., Ref. 4). The term trichome has generally been meant to include only epidermal appendages originating from the plant epidermis. Root hairs meet this definition and are beginning to be considered trichomes by some molecular biologists and plant anatomists.^[4] Trichome like structures such as the glandular protrusions of several species of *Hypericum* may not originate from epidermal cells, but are considered trichomes by some.

Both nonglandular and glandular trichomes range from unicellular to multicellular (uniseriate, biseriate, or multiserial) (Fig. 1). Nonglandular trichomes can have many forms, depending on the species, and more than one type can be found on a single species. They can be filamentous, stellate, scalelike, branched, tufted, and combinations of these morphologies. Some are only warty protrusions from epidermal cells. At maturity, the cells of most non-

glandular trichomes are dead, with the cell wall and cuticular thickness and composition providing textures ranging from stiff to soft. The cotton fiber is one of the more extreme morphologies of a unicellular, nonglandular trichome. These fibers arise from epidermal cells of ovules, reaching lengths of several centimeters.

Glandular trichomes can be of several types, depending on their morphology and on what they secrete, accumulate, or absorb. The typical multicellular peltate glandular trichome has a specialized secretory cell or cells that secrete products into the space between the cuticle and cell wall of the head cell(s) (Fig. 2).^[5] Very early in development of a plant organ, an epidermal cell begins differentiating and dividing into such a trichome.^[6] The cells of this structure are initially very similar, but differentiate into stalk and head cells that apparently have different functions. Nevertheless, at maturity each cell type is normally filled with cytoplasm containing very small vacuoles, unlike most plant cell types with a large central vacuole. The apical cells of the head secrete material into the space between the cell wall and cuticle. The cuticle then swells to form a balloonlike structure filled with secretory products over the terminal cells. There is good evidence that many of the compounds secreted by this type of trichome are synthesized only by trichome cells.^[7,8] As glandular trichomes age, the cuticle may break, spreading the nonvolatile contents over the plant epidermis. In some species, a new cuticle can form to contain newly synthesized glandular products.

Other specialized types of glandular trichomes are salt glands and nectaries. Salt glands can be of several forms, including bladderlike cells in which salts are compartmentalized in a central vacuole, and epidermal cells that excrete salts into subcuticular spaces or onto the plant surface. Nectaries are glandular trichomes that excrete nectar. They are often associated with flowers, but can also be extrafloral.

The molecular genetics of trichome formation and development is beginning to be understood. More than 20 genes are involved in trichome formation in *Arabidopsis*, and much is known of the genetics of cotton fiber-specific promoters and the genes associated with cotton quality. Some of the genes involved in root hair development are the same or very similar to those involved in trichome development. Genes involved in biosynthesis

and secretions of glandular trichome-specific compounds are also being identified.^[9] Because glandular trichomes appear to be the only location for biosynthesis of many secondary compounds in plants, glandular trichome development and the biosynthetic pathways for these compounds appear to be genetically connected. Knowledge of the molecular genetics and biology of trichomes should eventually provide economic dividends by improving cotton quality and yields, as well as providing the basis for increasing the production of valuable glandular trichome products.

ECONOMIC ASPECTS OF TRICHOME PRODUCTS

Perhaps the most economically important trichome is the cotton fiber. This is the only trichome fiber crop. The contents of glandular trichomes are also often valuable.^[4] Table 1 provides a partial list of valuable trichome products. Glandular trichomes can produce many different types of chemical compounds, including terpenoids, alkaloids, and flavonoids. Essential oils (mostly terpenoids) of many plant species are associated primarily with glandular trichomes. Essential oils are important as flavorings and fragrances. Some specific trichome products, such as the antimalarial drug artemisinin, have high

value as pharmaceuticals, and others contain the psychoactive compounds of tobacco and marijuana.

Trichomes of a few species contain compounds that are problematic for people and livestock. For example, certain nettles (e.g., *Cnidocolus texanua* and *Urtica urens*) bear trichomes that cause a painful sting when touched, due to mild neurotoxins (e.g., leukotrienes). Contents of other glandular trichomes are poisonous if ingested in sufficient quantity. Some people are highly allergic to certain glandular trichome compounds such as the sesquiterpene lactones of some *Parthenium* species. These people

Table 1 Contents of glandular trichomes of selected species with economic value

Plant species	Trichome product
<i>Artemisia annua</i>	Antimalarial drug—artemisinin
Basil (<i>Ocinum</i> spp.)	Essential oil flavor components
<i>Cannabis sativum</i>	Cannabinoids
Hops (<i>Humulus lupulus</i>)	Flavor components
<i>Hypericum perforatum</i>	Hypericin
Marjoram and oregano (<i>Origanum</i> spp.)	Essential oil flavor components
<i>Mentha piperita</i>	Mint oil
<i>Nicotiana tabacum</i>	Nicotine and flavor components of tobacco
Cotton (<i>Gossypium hirsutum</i>)	Gossypol (a male contraceptive)

develop severe contact dermatitis by direct contact with the plant or by contact with windborne plant material.

TRICHOME FUNCTION

Plant species have evolved trichomes in response to both biotic and abiotic selection pressure. Glandular trichomes represent predominantly chemical strategies for dealing with this pressure, whereas nonglandular trichomes offer physical responses to environmental challenges.

The first contact that plant pathogens, insects, and herbivores have with plants is at the plant epidermis. The chemical contents of glandular trichomes are often highly biologically active against many of the biota from which the plant needs protection. The gland content or its exudate can act as a poison or repellent. It can also attract pollinators or other beneficial insects. Table 2 provides examples of the biological activity of some glandular trichome components. Note that a given com-

pound can have multiple effects, depending on its concentration and the species affected. Glandular trichomes provide a means of concentrating these compounds in the proper place to come in contact with target organisms, while partitioning them from other plant tissues. In this manner, glandular trichomes can protect the plant from autotoxicity. They can also protect it from synthetic phytotoxins. For example, cotton is partially resistant to certain lipophilic herbicides used with this crop, due to partitioning of foliar applications of the herbicide into the lipophilic subcuticular spaces of glandular trichomes. Similarly, lipophilic insecticides can partition into glandular trichomes after foliar application, where they are protected from volatilization and degradation, resulting in increased efficacy.

At sufficient densities, nonglandular trichomes can shield a plant from direct sunlight in severe environments, such as alpine ecosystems. Certain nonglandular trichomes can also reduce water loss by shielding the plant epidermis from wind. However, smaller numbers of trichomes can make the boundary layer of photosynthesizing organs more turbulent as air passes over the epidermis. This can increase transpiration while facilitating photosynthetic gas exchange. The silicon content of some trichomes can be so high as to make the plant unpalatable to insects and other herbivores.

UV Radiation Effects on Phyllosphere Microbes

Thusitha S. Gunasekera

Michigan State University, East Lansing, Michigan, U.S.A.

INTRODUCTION

The leaf surfaces (phylloplane) of plants are characteristically colonized by epiphytic communities of bacteria, yeasts, and filamentous fungi. Among the different factors that affect microbial survival and growth in the phyllosphere, solar UV radiation (UVR) plays a central role. Colonization of plant surfaces by microorganisms therefore clearly depends on their ability to tolerate UVR stresses or to avoid such stresses by colonizing protected sites. More recently, UVR has received considerable attention because solar UVB wavelengths (290–320 nm) are increasing as a consequence of stratospheric ozone depletion. Current research has shown that variation in UVB radiation significantly affects many organisms and ecosystems including phyllosphere microorganisms.

CELLULAR DAMAGE AND REPAIR MECHANISMS

Only UVA (320–400 nm) and longer wavelengths of UVB (>290 nm) radiation penetrate to the terrestrial environment. UVR is absorbed by vital cell molecules such as nucleic acids and proteins,^[1] resulting in various forms of damage including the induction of pyrimidine dimers.^[1] UVR-induced lesions distort and deform the DNA helix and interrupt transcription, translation, and replication. However, photodamage by UVR is a wavelength-dependent process. UVA radiation causes indirect damage to DNA, proteins, and lipids through reactive oxygen intermediates. UVB radiation causes both direct and indirect damage because of strong absorption of shorter wavelengths of UVB by DNA. Although the absorption spectra of proteins vary greatly because of variations in content of aromatic amino acids, some proteins are directly vulnerable to UV damage.

Both prokaryotic and eukaryotic organisms have multiple DNA repair pathways. One of the most widely distributed repair mechanisms is photoreactivation (PR), in which pyrimidine dimers are photochemically removed through the mediation of an enzyme, DNA photolyase. Apart from PR, another important and conserved pathway for repair of UV damage to DNA is nucleotide excision repair (NER), which is found in eubacteria, archaea, and

eukaryotes. In this pathway, UvrABC endonuclease removes a short oligonucleotide encompassing the damaged bases, and the gap is resealed with polymerase and ligase. Additional pathways for UV resistance, such as post-replication, recombinational repair processes, and *recA*- and *lexA*-mediated inducible SOS stress responses also exist in both prokaryotic and eukaryotic organisms. These processes can quickly repair DNA damage, but they are error prone and so produce mutations.^[1]

RESPONSE OF PHYLLOSHERE MICROORGANISMS TO UV RADIATION

Available information suggests that large inter- and intra-specific variations in UVR sensitivity exist within phyllosphere microbial communities,^[2–6] with the UVB component of solar UVR being primarily effective (Fig. 1) in regulating microbial populations. Variation occurs on a range of scales. There is evidence that isolates from different geographic regions with contrasting UVB climate vary in UVB tolerance.^[2,3] Large variation was also noticed within the same site or locality. Pathovars of *Pseudomonas syringae* and strains within the pathovar *syringae* have shown large variability to tolerance of UVR.^[6] UVB radiation might, therefore, be an important factor influencing the differential survival of phyllosphere organisms and hence the species composition of the phyllosphere community. The effects of UVB radiation on the phyllosphere community colonizing over a commercial tea crop showed that the leaf colonization of *Corynebacterium aquaticum* and *Xanthomonas* spp was influenced by solar radiation and that during certain periods of the year colonization was significantly higher under a UVB-depleted environment than under the natural environment.^[2] These results were interpreted as seasonal fluctuation of microorganisms on leaves influenced by UVR. UVR-sensitive species or strains, however, can succeed by colonization on the phyllosphere during the less sunny period of the year.

Existence of marked variation in response suggests that mechanisms have evolved that moderate these potentially damaging effects. UVB levels on the plant surfaces are not uniform; mutual shading of the leaves, depressions, veins, and bases of trichomes provide some

Fig. 1 Effects of different wavebands of UV radiation (10 nm action spectrum) on the survival of colonies of (○) *Sporidiobolus* sp. and (●) *Bullera alba*. Survival is related to that in dark control. Bars indicate standard error of mean of five replicates. (For more detail, see Ref. 3.)

protection against the UVB radiation. Colonizing in protected sites would be useful to avoid such high UV fluxes. The avoidance of UVR by colonization of the abaxial surfaces is thus an important strategy adopted by phyllosphere microorganisms.^[51]

Phyllosphere microbes may reduce damage by reducing penetration to target molecules, especially nucleic acids in the nucleus. The most important component of UV protection is the production of UV-absorbing pigments. The putative role of pigments in protecting phyllosphere microorganisms against UVR is supported by the observation that significant numbers of microorganisms isolated from the phyllosphere are pigmented.^[51] Phyllosphere yeasts such as *Sporobolomyces* spp., *Rhodotorula* spp., *Sporidiobolus* spp., *Cryptococcus* spp., and the common phyllosphere bacterium *Erwinia herbicola* are capable of producing carotenoids, which protect cells against UVA wavelength-induced reactive oxygen intermediates.

The third strategy for minimizing UVB effects is via the range of repair pathways available to correct primary UV damage. The importance of these pathways for epiphytic growth has been demonstrated for some phyllosphere microorganisms. The common phyllosphere bacterium *P. syringae* contains native plasmids that were shown to confer elevated survival (20- to 30-fold) to UVR.^[71] Fig. 2 shows the effect on UVB survival of addition of the native *rulAB*-containing plasmid pPSR1 to *P.*

syringae pv. *syringae* FF5 or of an insertional mutation within *rulB* in strain 8B48. The *rulAB* system is also able to promote UV-inducible mutagenesis, suggesting the functional relevance of *rulAB* and its important role in overcoming UVR stress in the phyllosphere.^[81] Significantly reduced susceptibility to UV damage in the presence of white light is evidence for PR in the tested phyllosphere microorganisms^[31] and in the common phyllosphere bacterium *P. syringae*.^[91]

Fig. 2 Response of *Pseudomonas syringae* pv. *syringae* FF5 (○), FF5/pPSR1 (□, *rulAB*+), 8B48 (●, *rulAB*+), and 8B48A (■, *rulBKm*) to UV-B radiation. Cells suspended in saline solution were irradiated as previously described,^[61] and survival was calculated as related to a non-irradiated control. Each point represents the mean (\pm the standard error of the mean) from three replicate experiments.

UVR can also alter the physical and chemical properties of leaf surfaces, with potential indirect effects on colonization of microorganisms on the phyllosphere. These indirect effects are largely unknown. To date, it is not known how UVR affects interactions between phyllosphere microorganisms with specific plant pathogens, but it is likely that such interactions will be complex, depending on host-mediated changes and direct effects on the microbes involved. However, increased understanding of UVR effects on interactions between phyllosphere microbes and pathogens offers the greatest opportunity for exploiting increased understanding of UVR effects on the phyllosphere. Success in controlling plant pathogens, insects, or the ice-nucleation active bacteria depends largely on the establishment of biocontrol agents on plant surfaces. Successful biological control agents should survive and persist in the target sites of the phyllosphere for a long time. UV-resistant strains can possibly be used to increase the efficacy on the phyllosphere. On the other hand, some bacterial pathogens' epiphytic growth is critical for dissemination and their survival away from the host. Therefore, UVR responsible for regulating foliar diseases and more importantly UVR can be used to control UV-sensitive pathogens on plant surfaces.^[10]

CONCLUSION

Available information suggests that phyllosphere organisms display inter- and intra-specific variation in response to UVR and increased UVB irradiation above ambient levels, resulting in alterations of the relative abundance and species composition of microorganisms in the phyllosphere. Increase of UVB radiation therefore may change the microbial balance and possible microbial interactions in the phyllosphere or important host-pathogen interactions. Existing information suggests that the ecological succession of phyllosphere microorganisms is in part driven by UVB radiation. Ecological studies also showed that UV tolerance is a prevalent phenotype among phyllosphere microorganisms and that DNA repair or UV-tolerant mechanisms are vital to the phyllosphere microorganisms for survival in this UVB-rich habitat.

UV Radiation Penetration in Plant Canopies

Richard H. Grant

Purdue University, West Lafayette, Indiana, U.S.A.

INTRODUCTION

Sunlight—or solar radiation—is the ultimate source of all the energy that a plant receives throughout its life. Most would agree that the wavelengths of the solar radiation spectrum utilized by chlorophyll are the most important part of the sunlight reaching plants. There are, however, several other important wavebands of solar radiation that affect plant growth and development—among them, radiation in the ultraviolet (UV) waveband. Solar radiation in the UV band can affect the viability of spores and pollen, the mutation of plant cells, and the chemical composition of plant biomass. Consequently, changes in the intensity of solar radiation in the UV band may have significant impacts on agriculture. We are now experiencing changes in atmospheric ozone that change the intensity of the UV radiation received by plants. How intense that radiation is at the top of the plant canopy, how that radiation is distributed in plant canopies, and the duration of the intense radiation will define how UV radiation will affect crop agriculture.

WHY WORRY ABOUT UV RADIATION IN PLANT CANOPIES?

Solar radiation is largely in wavelengths that the eye can see, but ultraviolet (UV) radiation is in wavelengths shorter than the eye can see. Solar UV radiation reaching the earth's surface is separated into two wavebands: a band from 320 to 400 nm called UV-A (ultraviolet-A), and the band from 280 to 320 nm called UV-B (ultraviolet-B), although some scientific organizations define 315 nm as the division between UV-A and UV-B. Because ozone is the primary absorber of UV-B in the atmosphere, changes in the ozone change the intensity of the UV-B radiation at the earth's surface. Increased UV-B has the potential to decrease the productivity of agricultural crops and viability of spores and pollen in canopies. We will assume here that the plant surface of interest in the canopy could be any phytoelement at any orientation, including stalk, leaf, grain head, silk, or stamen.

ABOVE-CANOPY RADIATION ENVIRONMENT

To understand the penetration of UV radiation into the canopy, we must first consider the nature of UV radiation above the canopy. The atmosphere scatters solar radiation inversely proportional to the wavelength, resulting in more of the direct beam of solar radiation being scattered into the sky hemisphere in the UV than in longer, visible wavelengths. The fraction scattered into the sky, termed diffuse radiation, varies according to atmospheric conditions and solar zenith angle. On a clear day the sky diffuse fraction increases with increasing solar zenith angle, resulting in higher diffuse fractions at the top of plant stands early and late in the day than at midday and at low and mid-latitudes. Generally higher solar zenith angles at higher latitudes result in higher diffuse fractions at high latitudes than at low latitudes for any time of the day.

The slope and aspect of a surface such as a leaf affects the amount of UV-B received above the canopy (Fig. 1). Nonhorizontal leaves at the canopy top receive some diffuse and direct beam radiation reflected off both the canopy phytoelements and underlying soil surface. Irradiance decreases with increasing zenith angle so that leaves (or other phytoelements) perpendicular to the ground and canopy top (erectophile leaves, seed heads, and other vertical phytoelements) have minimal UV-B exposure.^[1]

WITHIN-CANOPY RADIATION ENVIRONMENT

The irradiance in the canopy is the cumulative effect of the downward penetration of diffuse and direct beam radiation, the downward phytoelement-scattered radiation, and the upward scattering of radiation penetrating to and scattered from the soil surface and phytoelements below the level of interest in the canopy. The relative importance of each contributing component of the spectral irradiance in the canopy depends on the optical properties of the canopy phytoelements, the canopy density, and structure.^[2]

Fig. 1 UV-B irradiance on a clear day above a soybean (*Glycine max* L. (Merr.)) canopy, Northern Hemisphere. Surfaces facing north, west, and south are inclined at 45°, a typical soybean leaf inclination. (Modified from Ref. 1.)

Scattering in the Canopy

The radiation that is scattered from phytoelements and soil within and under the canopy (secondary scattering) depends on the incident radiation and the reflectance and transmittance of the phytoelements and the reflectance of the soil surface. The reflectance of adaxial and abaxial leaf surfaces of maize (*Zea mays*, L.), soybean (*Glycine max* L. (Merr.)), common oats (*Avena sativa* L.), winter wheat (*Triticum aestivum* L.), and sorghum (*Sorghum bicolor* L. (Moench.)), as well as apple (*Malus domestica* Borkh.) and Callery pear (*Pyrus calleryana* Dcne.) are nearly constant (0.05 to 0.10) throughout the UV-A and UV-B. There is no reported leaf transmittance in the UV for apple, Callery pear, maize, soybean, winter wheat, oats, or sorghum. The reflectance from soils is similar to reflectance from the leaves, with dry light-colored soils having an average UV reflectance of approximately 0.07. Because UV radiation does not penetrate through the plant leaves, the transformation of direct beam radiation to diffuse within the canopy is solely through phytoelement and soil surface reflections. In contrast to the UV-B waveband, leaf transmission and reflection are significant in the photosynthetically active radiation waveband (PAR), resulting in substantial secondary scattering in the canopy.

Downward Penetration in the Canopy

The downward penetration of UV radiation into the canopy varies spatially and temporally due to the distribution

of plant phytoelements and the orientation of the elements. The vertical penetration is commonly considered to be the mean or median over time with sunlit or shaded periods, or horizontal space with sunlit and shaded areas.^[2,3] If the direct beam radiation cannot penetrate the canopy to a point in the canopy space, then it is considered to be shaded.

The stand density (plants per unit area) influences the view of the sky and the probability of shading in the lower canopy. Low-density canopies typically have large gaps (breaks in the spatial continuity of vegetation) that allow diffuse radiation to penetrate directly to the base of the canopy at all times (in shade) and allow direct beam radiation on occasion (in sunflecks). The size and distribution of gaps depend on the phytoelement orientation, dimension, and clumping. Increasing gap size increases both the diffuse sky radiation received and the probability of the direct beam penetrating the canopy. Shaded areas in the canopy receive only diffuse radiation, and vary from having essentially no irradiance in very dense canopies with no gaps to nearly the same amount of radiation as coming from the sky above the canopy in open canopies (Fig. 2). Sunlit areas (sunflecks) within the canopy have UV-B irradiance varying from the fraction of the above-canopy direct beam UV-B to the global above-canopy UV-B irradiance as the gap increases in size or number (Fig. 2). In sunflecks, the PAR is enriched relative to the UV-B—especially for small gaps with minimal sky view.

For low-density canopies with large gaps, the UV-B penetrates to greater depths than the PAR as a result of the higher fraction of diffuse radiation than in the PAR. In these canopies the UV-B irradiance in shade is closer

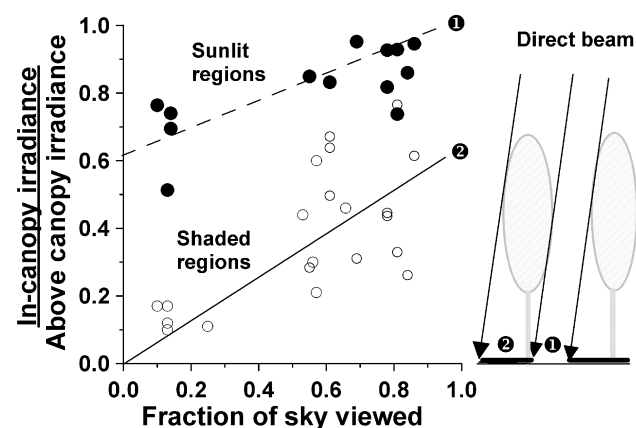

Fig. 2 Effect of sky view on the relative penetration of UV-B radiation in sunlit and shaded regions under tree canopies. Variability is due to the varying solar zenith angle and diffuse radiation fractions. (View this art in color at www.dekker.com.)

to that of sunlit regions than for PAR radiation. Consequently, shaded areas are enriched in UV-B relative to the PAR. Such enrichment is evident in young and old orchards. UV-B enrichment is evident in winter wheat, tall fescue (*Festuca arundinacea* Schreb.), and perennial ryegrass (*Lolium perenne* L.) canopies. Sunlit surfaces in an apple orchard^[3] and in maize canopies^[3,4] had UV-B levels similar to that above the canopy, whereas shaded surfaces had less UV-B than at the top of the canopy—varying with differences in sky view, diffuse fraction, and orientation.

Shading increases with increasing plant stand density and increased cumulative leaf area index (LAI) with depth in the canopy (Fig. 3). The shading in closed canopies (or high-stand densities) is primarily between-plant shading and produces relatively small areas of sunfleck at the stand floor (Fig. 3). In a maize canopy, three distinct radiation regimes were evident for surfaces at a height corresponding to a cumulative LAI of 1; a sunlit regime associated with direct beam penetration through a gap, a deep UV-B shade regime associated with small gaps nearby, and a light UV-B shade regime associated with large gaps nearby.^[4] As depth in the maize canopy increased, the light UV-B shade regime disappeared and there was similar (small) penetration of UV-B and PAR. Similar changes in the frequency of gaps and the sunlit and shaded UV-B levels with depth in the canopy were found for winter wheat (Fig. 3). Planophile canopies such as alfalfa (*Medicago sativa* L.), white clover (*Trifolium repens* L.), and sorghum have

infrequent gaps and equal or greater penetration in the PAR than UV-B radiation through scattering in the canopy.^[5,6]

Changes in UV Penetration During the Growing Season

Crop canopies begin the season as sparse, low-density canopies. However, the vegetation in many crop canopies fills in (having LAI>1) over the course of the season to leave few gaps between plants at flowering or maturity. Consequently, the relative proportion of UV-B and PAR changes as the crop matures. UV-B penetration of low-density stands is typically greater than PAR because the sunlit regions receive approximately the same amount of PAR and UV-B, whereas the shaded regions receive significantly more sky UV-B than PAR. As the stand fills in, the overall penetration of diffuse sky radiation decreases—increasing the importance of secondary scattering in the canopy that is negligible for the UV-B and significant for the PAR. Consequently, over time the relative penetration of PAR increases compared with the UV-B, as documented for white clover and orchardgrass (*Dactylis glomerata* L.).^[6]

CONCLUSION

The penetration of UV radiation into plant canopies is dictated largely by the amount of sky view created by gaps in the canopy. There is little scattering through or off canopy phytoelements within the canopy or off the ground at the canopy base. UV radiation levels in plant canopies are proportional to the size of the gap and view of the sky. Shaded regions near large gaps in the canopy have relatively high levels of UV radiation relative to PAR. Shaded regions near small gaps result in similar levels of UV and PAR. Sunlit regions near large or small gaps typically have greater PAR than UV-B. Increasing stand density corresponds to a decrease in UV-B penetration relative to PAR. Therefore, the highest levels of UV-B occur in the upper portions of dense canopies and in open low-density canopies common to early developmental stages of crops and mature orchards.

Fig. 3 Mean canopy transmittance of UV (open circles) and the probability of sunfleck (solid line) in a winter wheat canopy. Cumulative leaf area index (CLAI) is indicated. Bars represent the range in UV-B from shaded (low end of bar) to sunlit (high end of bar) regions in the canopy. (View this art in color at www.dekker.com.)

Vaccines Produced in Transgenic Plants

Hugh S. Mason

Arizona State University, Tempe, Arizona, U.S.A.

INTRODUCTION

It is difficult to underestimate the potential of modern biotechnology for improving human health. We can easily contemplate the development of foods with enhanced nutritional content, new medicines, and vaccines for prevention of infectious diseases. Vaccines are one of the great successes of modern medicine, e.g., worldwide control of poliomyelitis, measles, and smallpox. However, the development and implementation of new vaccines remains prohibitively expensive for economically depressed countries where such measures are needed most. Plant-produced vaccines provide a promising new strategy that combines the innovations in genomics, medicine, and plant biotechnology to create affordable biological products. In the past decade, a growing number of research groups worldwide have studied plant expression and oral delivery of vaccine antigens, some showing very promising potential.

ADVANTAGES AND CHALLENGES OF PLANT VACCINES

For more comprehensive reviews of vaccine antigens produced in plants, please see Refs. 1–4. The development of technology for genetic transformation of plants has provided the opportunity to use agriculture for the production of recombinant proteins. Field production using a stable transgenic line would not require large investments in hardware and culture media, thus making scale-up more economical than fermentation culture. Analysis of the economic potential of different crop plants for production of recombinant proteins^[5] provides a basis for comparison and suggests real value in the technology. Moreover, plant systems are much less likely to harbor pathogenic microbes than are mammalian cell or whole animal systems. An attractive possibility with edible plants is the ability to deliver vaccine antigens orally, thus obviating the costly purification process required of injectable vaccines. The delivery of vaccines to mucosal tissues (epithelia that line the gastrointestinal, respiratory, and

genitourinary tracts) also has the ability to stimulate secretory IgA at those surfaces, which is rarely observed with injectable vaccines.^[6]

The biggest challenge for orally delivered vaccines is the digestive system, whose acidic and proteolytic environment may be too severe for all but the most gut-stable proteins and may require encapsulation of antigens. Furthermore, a robust mucosal vaccine must be readily transported across the epithelium for presentation to the underlying lymphoid tissues. Such transport likely requires special epithelial cell-binding qualities that are not universally present in proteins. Nonetheless, a growing number of candidate vaccine antigens have been shown to be orally active.

PLANT EXPRESSION SYSTEMS

There are two main systems for recombinant protein expression in plants: stable genetic transformation and transient expression. Stable transformation causes integration of foreign DNA into the nuclear or chloroplast chromosomal DNA; these lines can be propagated vegetatively or by seeds and thus can be readily scaled up for protein production. Transient expression uses a plant virus that carries the vaccine gene, which is replicated and expressed during systemic infection of the plant host.^[2] Such virus-based expression amplifies gene copy number, often resulting in higher expression than stable transformation. However, the larger foreign genes may be unstable in plant virus systems, which results in deletion of the foreign DNA.

Stable nuclear transformation is often achieved using *Agrobacterium tumefaciens*, which can efficiently transport DNA into plant cells and cause chromosomal integration resulting in Mendelian inheritance. DNA delivery by the “biolistic” method (microprojectile bombardment) is frequently used for plant hosts that are recalcitrant to *Agrobacterium*. The biolistic method often causes multiple site integration that may enhance expression, but excessive copies or very high mRNA levels may cause gene silencing.^[7]

Stable transformation of the chloroplast genome can yield high levels of recombinant protein^[8] due to the high genome copy number. The chloroplast-derived chromoplasts of tomato fruit can also express foreign proteins. Other advantages of chloroplast transformation include maternal inheritance, which limits the potential for transgene escape by dissemination of pollen, and absence of gene silencing. Many foreign genes have been expressed in transplastomic plants, including the vaccine candidate cholera toxin B subunit (CT-B).^[8] A limitation for this strategy is that some eukaryotic cellular processing events (e.g., glycosylation) may not be obtained in chloroplasts.

Tobacco and potato are frequently used as convenient systems for vaccine expression because transformation and regeneration of plants are readily achieved. If purification of antigen for injectable delivery is the goal, tobacco is an attractive choice because of its high biomass production. However, the use of edible plant tissues permits oral delivery, wherein one may avoid extensive and costly purification procedures. Raw potato has been used for both published human trials in the United States,^[4] but a more palatable system is needed. Tomato is a good alternative and was used to express orally immunogenic respiratory syncytial virus (RSV) fusion (F) protein in fruit. Other fruits, including banana, may be useful if efficient transformation systems can be developed. A study of various economic factors suggests that soybean, alfalfa, and corn are the most efficient systems for recombinant protein expression.^[5] A further important consideration is the need to stringently regulate the production of biologicals in plants, in order to prevent the contamination of human food supplies. Thus, the potential for transgene escape by outcrossing must be carefully studied for any potential production system.

ANIMAL AND HUMAN STUDIES

A growing number of vaccine candidates have been expressed in plants and tested in animals, resulting in immune responses after oral delivery.^[2,3] In most cases, there was no challenge with infectious pathogens to determine the efficacy of the immunization, but a few reports describe protection from viral or toxin treatment. In a notable recent study,^[9] a peptide from a rotavirus enterotoxin fused to cholera toxin B subunit (CT-B) was co-expressed in potato with a peptide from an *E. coli* fimbrial adhesin fused to CT-A, resulting in assembly of functional ganglioside-binding complexes. Pups of mice immunized by ingestion of transgenic potatoes were partially protected from challenge with rotavirus. The transmissible

gastroenteritis virus envelope spike (S) protein was produced in transgenic corn and fed to piglets, resulting in 50% of virus-challenged animals free of diarrhea.^[3] These studies show potential for edible vaccines as alternatives to injectable vaccines for animals, but they also indicate the need for further optimization of dosage levels or timing to increase efficacy.

Other potential uses for plant-expressed, orally delivered antigens include therapies using autoantigens. For example, treatments for autoimmune disease could be provided by consumption of autoantigens, such as pro-insulin fused to CT-B expressed in potato and fed to NOD mice.^[10] Reduced inflammation of pancreatic islets in the treated mice suggests that cytotoxic T cells that kill islet cells in NOD mice had been restricted by immune tolerance. Immunization for the treatment of cancer is the subject of promising studies, e.g., single-chain antibodies from B-lymphocyte malignancies expressed in plants with viral vectors, yielding protection from a lethal injection of tumor cells in treated mice.^[11]

Only three studies of edible plant vaccines in human subjects have been published,^[12-14] each using a different antigen. Two vaccines were directed against agents of gastroenteritis (enterotoxigenic *E. coli* and Norwalk virus), whose protein antigens are considered the most likely to succeed by oral delivery due to their gut stability and mucosal cell-binding capacity. The other vaccine targeted hepatitis B virus, not usually considered an enteric pathogen.

Cholera and enterotoxigenic *E. coli* (ETEC) cause diarrhea by secretion of cholera toxin (CT) and labile toxin (LT), respectively, which target epithelial cells via their B subunits' ability to bind G_{M1} gangliosides present on cell surfaces. LT-B expressed in transgenic potatoes produced toxin-protective gut antibody responses after ingestion by mice.^[4] The LT-B potatoes became the first human test for plant vaccines^[12] in which subjects ate 100 g of raw LT-B potato slices containing 750 µg LT-B at each of three weekly doses. The production of toxin-neutralizing serum antibodies in 10 of 11 subjects proved that ingestion of transgenic plant material could be used effectively to deliver a vaccine in humans.

Most cases of viral gastroenteritis are caused by rotavirus and Norwalk-like viruses, which are potential targets for oral subunit vaccines owing to the ability of their capsid proteins to assemble virus-like particles (VLP). These recombinant VLP can mimic the structure and cell-binding of the authentic virus particles, are acid-stable, and stimulate serum responses in humans. NVCP expressed in plants formed VLP that were orally immunogenic in mice,^[4] and NVCP potatoes were used in a second clinical trial.^[14] The volunteers ate 150 g of

raw potato containing up to 750 µg NVCP. Although the average antibody levels were less impressive than in the LT-B potato study, 19 of the 20 subjects showed significant immune responses. The main conclusion of this study was that a recombinant plant-derived protein lacking the ganglioside-binding activity of LT-B can stimulate oral immunization in humans.

The currently used vaccine for hepatitis B is recombinant viral surface antigen (HBsAg) purified from transgenic yeast cultures. Plant-derived HBsAg was described in the first report of a plant vaccine^[15] and showed VLP that were immunogenic by potato ingestion in mice.^[16] HBsAg expressed in transgenic lettuce and delivered to humans by ingestion of 250 g (containing approximately 1 µg antigen) caused production of serum antibodies at protective levels in two of three volunteers.^[13] Since the dose was quite low, it is likely that the HBsAg had assembled into VLP structure, which enhanced sampling by M cells of the gut-associated lymphoid tissue.^[6] Another clinical trial used transgenic HBsAg potatoes delivered to volunteers who had been vaccinated earlier with the commercial injectable HBsAg, in order to test the boosting effect of ingested antigen. The results were promising and are now being prepared for publication.^[17]

CONCLUSION

Studies during the past 10 years have shown faithful expression of many different vaccine antigens in plants, and many of these have stimulated antibody responses when eaten by humans or animals. A few reports showed partial protection from challenge with infectious pathogens, indicating a strong potential for plant vaccine technology. However, low expression of antigens in transgenic plants limits the dose that can be delivered in crude material; thus, improvements in plant expression technology are needed. Because doses must be uniform and concentrated, the plant stock will be processed to yield a stable product, such as dried powder that can be formulated with adjuvants and perhaps encapsulated for passage through the stomach. Production systems must maintain rigorous containment to prevent contamination of food supplies; thus, pollen-mediated gene flow should be limited (e.g., with male-sterile lines or chloroplast expression), and post-harvest processing facilities must be dedicated for pharmaceutical production.

Viral Host Genomics

Steven A. Whitham

Iowa State University, Ames, Iowa, U.S.A.

INTRODUCTION

The roles of individual virus-encoded proteins have been established for the key steps of virus life cycles. However, the detailed mechanisms of how viruses cause reduced fitness, quality, and yield are yet to be revealed. A thorough understanding of viral pathogenesis requires that host–virus interactions be understood equally well from the plant side of the interaction. Recent developments in plant genomics promise to provide new insights into the ways that viruses perturb host plants. Broadly defined, genomics includes genome sequencing and subsequent study of genome organization and structure (structural genomics) and gene function (functional genomics). This article discusses the application of functional genomics approaches to study host–virus interactions as well as the exploitation of viruses as useful functional genomics tools to probe plant gene functions.

WHAT IS FUNCTIONAL GENOMICS?

Functional genomics studies use genome-wide, global, and/or high-throughput systems to simultaneously study functions of large numbers of or virtually all genes of an organism. The methodologies rely heavily on computational biology, bioinformatics, and statistics to manage and analyze the enormous data sets that are generated. Viral host genomics encompasses pathogenicity, resistance, and discovery of plant gene functions, and has become possible because of two major factors. First, researchers now have access to the complete genome sequences of many viruses and a few plant species (including rice and *Arabidopsis*), and extensive sequences are available from crop species like maize, wheat, soybean, and tomato. Second, these sequences enable the development and application of new technologies previously not possible to explore the functions of plant genes.

Important technologies for assessing functions of plant genes that have become available recently include DNA microarrays and reverse genetics tools such as insertional mutagenesis (e.g., T-DNA tagging), RNA-induced gene silencing, and virus-induced gene silencing (VIGS).^[1] DNA microarrays consist of DNA sequences that are most commonly spotted onto glass slides or synthesized

directly onto a silicon or glass substrate.^[2] All genes of an organism can be represented on one or a few microarrays, which allows the expression of all genes to be studied in parallel in response to a given condition. Reverse genetics tools, which will be described later in more detail, involve the disruption of genes followed by examination of the effects of loss of gene function on the organism. This suite of technologies allows systematic studies that first associate genes with a plant process and then subsequently determine their roles in that process by observing the mutant phenotype.

FUNCTIONAL GENOMICS APPROACHES TO UNDERSTAND VIRAL PATHOGENICITY

Although viruses are simple entities, interactions with their hosts are relatively complex. Viruses and plants engage in a variety of offensive, defensive, and counter-defensive interactions that ultimately determine the level of colonization.^[3] Some specific examples of modifications that plant viruses make in their hosts include gating of plasmodesmata by movement proteins and suppression of RNA interference (RNAi) triggered by replication of viral genomes.^[4,5] Viruses also elicit significant changes in patterns of host gene expression—which is expected to influence plant susceptibility and symptom development—and may be a direct result of activities such as gating of plasmodesmata, suppression of RNAi, or interference with other processes.^[6]

Recent studies employing genomics approaches have documented changes in the expression of many host genes in response to diverse viruses and viroids. Whitham et al.^[7] used Arabidopsis GeneChip[®] microarrays to assay the expression of about 8300 genes over a five-day infection time course in the susceptible *Arabidopsis* plants. The viruses were ORMV (oilseed rape tobamovirus), TVCV (turnip vein clearing tobamovirus), CMV (cucumber mosaic cucumovirus), PVX (potato virus X), and TuMV (turnip mosaic potyvirus). At least 114 genes were induced more than twofold in response to five viruses at one or more time points over the time course. The results demonstrated that diverse viruses induce the expression of common sets of host genes in inoculated leaves, as has been observed in a pea cotyledon system.^[8] Further

analysis of the expression of these 114 genes placed them into seven clusters based on their expression profiles. One interesting cluster was composed of only heat shock genes: HSP70, HSP83 (similar to HSP90), HSP17.6, HSP17.4, and HSP23.6. These heat shock proteins shared the characteristic of being induced by ORMV and TVCV (both tobamoviruses) at one day after inoculation, although they were not induced by the other viruses until later times. This result suggests that tobamoviruses might specifically induce HSP expression early. Another interesting cluster of genes was composed largely of plant defense-related genes. In general, the viruses induced the expression of defense-related genes beginning at 2 days after infection. The differential expression of heat shock and defense-related genes indicates that distinct signaling pathways are modulated in response to viruses in susceptible interactions.

Potato spindle tuber viroid (PSTVd) was shown to elicit a variety of changes in tomato gene expression, some of which occur also in tobacco mosaic virus infection in the same host.^[9] Unlike viruses, viroids do not encode proteins. Therefore, the RNA genome of viroids is sufficient to cause symptoms in susceptible plants and elicit changes in host gene expression.

Table 1 lists the functional classes of plant genes induced in response to RNA viruses and viroids in the two studies cited above.^[7,9] Direct comparisons of the genes induced in the experiments involving viruses and viroids should be made with caution because the nature of the pathogens, time courses, and experimental methodologies were different. Nevertheless, it is intriguing to point out the induction of stresslike responses observed in both studies. For instance, approximately one-third of the genes induced by PSTVd in tomato and by various viruses in *Arabidopsis* plants are associated with known defense and

stress responses. These include genes functionally associated with oxidative stress, heat stress, pathogen stress, defense responses, and transcription factors involved in defense and stress responses. From the *Arabidopsis* study, it is clear that these sets of genes are expressed differentially over time, suggesting that a variety of host-signaling pathways is modulated as infections proceed. Furthermore, the ability of diverse viruses and viroids to elicit these changes suggests that a conserved feature of virus–host interactions triggers them. At this time, the mechanisms responsible for these gene expression changes are uncharacterized, and their significance remains to be determined. Reverse genetics approaches will be valuable for addressing these issues.

VIRUS-BASED TECHNOLOGY FOR DISCOVERY OF PLANT GENE FUNCTION

Virus-induced gene silencing (VIGS) is being exploited to study the functions of plant genes in disease resistance pathways, development, and other processes.^[1] VIGS is a form of posttranscriptional gene silencing (PTGS) that utilizes viruses engineered to carry sequences from plant genes to disrupt the expression of the cognate plant genes. VIGS is based on the principle that viruses are targeted by PTGS leading to degradation of their RNA. Once PTGS is induced against a specific sequence, it can degrade that sequence from any source, such as a virus in the cytoplasm or a plant mRNA encoded by a nuclear gene. Thus, the engineered VIGS virus will trigger degradation of itself, the foreign plant sequence it carries, and the corresponding mRNA from the endogenous plant gene. These events lead to a loss of function of the plant gene. The plasticity of viral genomes allows them to accommodate virtually any sequence, enabling most plant genes to be disrupted. VIGS is particularly advantageous for plant species that are not easily transformable (most crops) or not genetically tractable, because of the potential to rapidly generate mutations to facilitate functional analysis of a gene by virtue of a virus infection.

VIGS vectors derived from potato virus X and tobacco rattle virus have been most widely used in dicot species such as *Nicotiana benthamiana*, tobacco, and tomato; many other viruses hold promise for similar applications in other species.^[1] Recently, a VIGS vector was developed from barley stripe mosaic virus, demonstrating the utility of this approach in monocots.^[10] VIGS is not only useful in the study of individual genes, but is also adaptable to high-throughput genomics-scale experiments, as illustrated in Fig. 1. The first step in the process is to create a library of plant copy DNA (cDNA) clones by extracting mRNA from plant cells and converting mRNA to cDNA with the enzyme reverse transcriptase. These cDNA sequences are then cloned into the VIGS vector to

Table 1 Functional classification of genes induced by viruses and viroids

Functional class	Percentage (%) of genes in each functional class	
	RNA viruses (<i>Arabidopsis</i>)	PSTVd (tomato)
Defense/stress	30.7	29.8
Cell wall	2.6	6.4
Chloroplast	0	8.5
Energy	2.6	0
Metabolism	14.9	0
Signaling	14.0	0
Protein destination	7.9	21.3
Transcription	7.9	0
Miscellaneous	0	19.1
Unknown	19.4	14.9

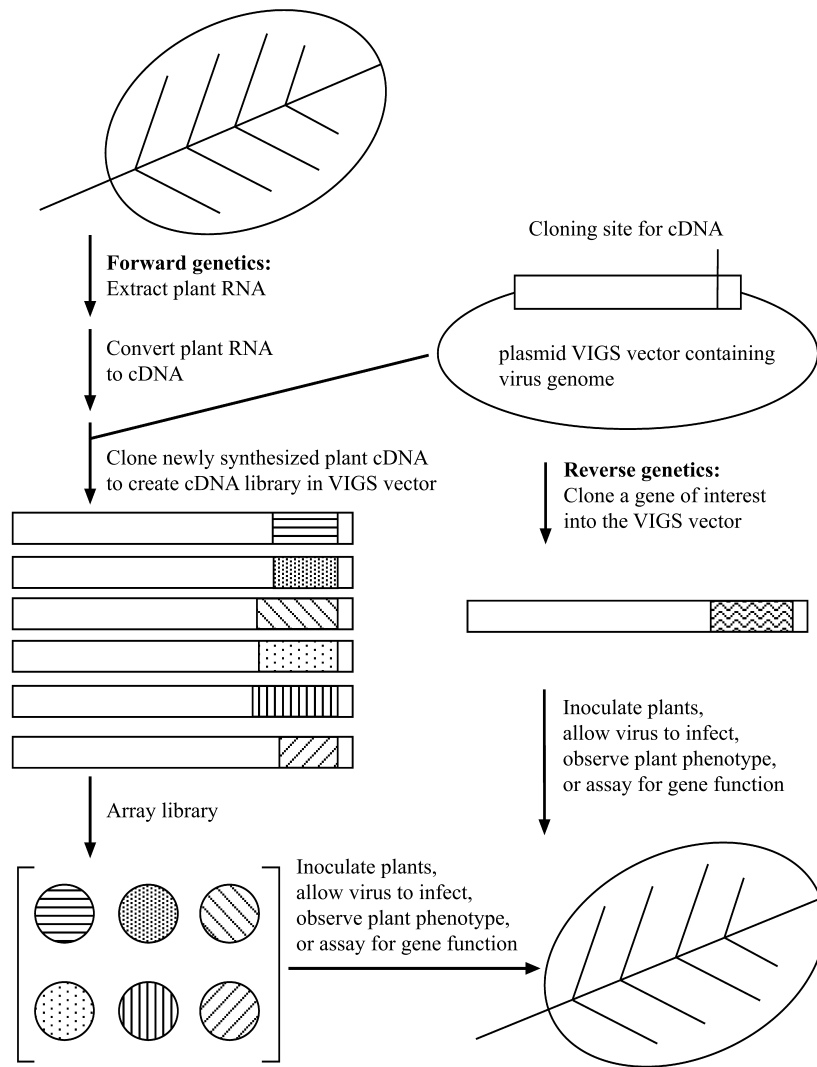

Fig. 1 Use of VIGS for forward and reverse genetic studies to discover plant gene function. See text for description.

create a VIGS library. The libraries can be arrayed so that it is possible to preserve each clone, determine its sequence, and return to it for further analyses. In this example, individual clones are used to inoculate plants to silence the corresponding plant gene and subsequently screen for changes in phenotype. Alternatively, VIGS can be used to systematically study the effects of disrupting selected genes, as illustrated in Fig. 1.

CONCLUSION

Genomics technologies such as DNA microarrays are just beginning to be applied to plant–virus interactions. From initial published report it appears, not surprisingly, that plants are stressed in a variety of ways as viruses invade susceptible hosts. As microarray data are accumulated for

both pathogenic and resistant interactions, it will be interesting to compare and contrast the signaling pathways modulated during pathogenesis and resistance. The availability of full genome microarrays will further illuminate ways that viruses perturb the expression of host genes. Reverse genetics tools such as T-DNA insertion lines, RNA-induced gene silencing/RNAi, and VIGS will enable researchers to discover the significance of these gene expression changes and identify genetic components of the signaling pathways involved in regulating the changes. Such integrated studies are expected to reveal mechanisms associated with pathogenesis, onset of disease, and resistance.

On the flip side of the coin, viruses are themselves serving as useful tools for genomics research. Newly developed VIGS vectors include features such as the Gateway™ cloning site, which allows genes and libraries to

be shuttled in and out of VIGS vectors. Such systems are expected to enable the production of complete VIGS libraries from which an investigator can order the VIGS clone corresponding to any gene of interest.^[1] Comprehensive VIGS libraries will facilitate rapid assessment of a gene's function once it has been associated with a plant trait or response such as viral pathogenesis or resistance.

Virus Assays: Detection and Diagnosis

Clarissa J. Maroon-Lango

USDA—ARS, Beltsville, Maryland, U.S.A.

INTRODUCTION

Plant viruses and viroids cause significant direct or indirect economic losses. Specific losses attributed to certain viruses have been tabulated and reviewed.^[1] Early detection of the causal viruses and accurate diagnosis of disease are important in preventing or minimizing such losses. Current methods for detecting viruses and viroids are classified into serological assays, nucleic acid-based techniques, bioassays, and electron microscopy. Generally, the choice of detection method depends on the causal agent (indicated by the symptoms on the plant), the kind and number of samples, the availability of reagents and/or equipment, the time frame available for testing, and the cost. This article discusses some of the techniques used in detecting viruses and viroids, and their applicability in routine testing of plants.

SEROLOGICAL ASSAYS

Serological techniques for detecting plant viruses involve the use of either polyclonal or monoclonal antibodies raised to detect specific viruses. The serological methods that have been applied in the detection of plant viruses include enzyme-linked immunosorbent assay (ELISA), rapid immunofilter paper assay (RIPA) (also known as lateral flow assay), dot immunoblot assay (DIBA), tissue-blot immunoassay (TBIA), and immunosorbent electron microscopy (ISEM).

ELISA—In direct ELISA, the virus is immobilized by either an uncoated or antibody-coated solid phase (usually a polystyrene wall). The immobilized virus is recognized by an enzyme-labeled antibody, and the reaction is visualized by the addition of an enzyme substrate. In indirect ELISA, the virus is reacted with an unconjugated specific antibody, which is in turn detected by an enzyme-labeled anti-immunoglobulin antibody or antibody fragments. The resulting complex is visualized by the addition of an enzyme substrate.^[2] Since its introduction into plant viral diagnosis less than thirty years ago, ELISA has been widely used in routine testing of plants because of its relative sensitivity, cost-effectiveness, and ease of use.

RIPA—An increasingly popular technique for detecting plant viruses is based on RIPA.^[3] In the commercially

available format of RIPA (known as lateral flow, strip, or stick test), a virus-specific antibody is immobilized on the capture line near the top of a membrane strip. A mixture consisting of the tracer virus-specific antibody conjugated to either dyed latex or colloidal metal is applied to a defined region (conjugate pad) just above the lower end of the strip. When the sample (sap) is applied at the lower end of the strip, the virus moves by capillary action through the conjugate pad forming a labeled antibody-virion complex. The moving virion complex is trapped by the immobilized antibody on the capture line and the capture line develops a positive color reaction. In addition to being a rapid test (results occur within minutes), its design makes it suitable for on-site (greenhouse or field) use. Additionally, the sensitivity of RIPA is similar to that of ELISA. The use of RIPA for detecting viruses is limited, however, by the availability of tests in the commercially available format. To date, only 18 specific virus tests are offered in such a format (e.g., ImmunoStrips, Agdia, Inc; Spot \sqrt Check LFTM, Adgen, Ltd, UK).

DIBA and TIBA—These virus detection methods involve spotting plant sap (DIBA) or blotting freshly cut tissue (TIBA) on a membrane that is probed directly or indirectly with a virus-specific antibody.^[4] The addition of a suitable substrate results in a positive color reaction. Whereas these techniques may be ideal for routine testing because of their suitability for processing a large number of samples on site, they may not be very reliable due to background (false positives) in certain antibody-host combinations.

ISEM—Another serological detection method involves electron microscopy. The virus is visualized by electron microscopy using leaf dips or purified viral preparations on carbon-stabilized, polyvinyl formal-coated grids pretreated with a specific antibody.^[5] This technique is suitable for high titer viruses, but is limited by the uneven distribution of the virus in the plant. Furthermore, because ISEM requires sophisticated equipment, its application in commercial virus testing has been very limited.

NUCLEIC ACID-BASED TECHNIQUES

Techniques have been designed to detect viruses and viroids based on their genome. Double-stranded (ds) RNA

analysis, hybridization, and amplification reaction-based assays are some of the nucleic acid-based techniques used in routine virus and viroid testing. The choice of these assays is usually dictated by the need for significantly increased sensitivity and versatility, or the lack of a suitable serological test.

dsRNA Analysis—As a broad-spectrum assay for detecting RNA viruses, dsRNA analysis entails the electrophoresis of dsRNA isolated from infected plants and its visualization on the gel by ethidium bromide staining. The resulting dsRNA pattern suggests the causal viral group,^[6] the identity of the virus can be confirmed by cloning and sequencing. Although the assay is not ideal for large volumes of samples, it offers advantages because it does not require the use of antibodies, sequence information, or probes.

Hybridization—In hybridization, the viral nucleic acid is detected by annealing it with a complementary strand of either RNA or DNA, referred to as the probe. The labeled probe allows visualization of the formed hybrid by autoradiography, fluorescence, or enzymatic reaction. Samples may be in the form of membrane-spotted sap or enriched preparations in dot blot hybridization (e.g., viroids) or membrane-squashed tissue in squash blot hybridization (e.g., geminiviruses). A large number of samples can be tested simultaneously by these assays due to simple sample processing. Alternatively, DNA or RNA may be separated on a gel by electrophoresis and transferred to a membrane for Southern or Northern blot hybridization, respectively.

Amplification—Offering significantly enhanced sensitivities are amplification-based tests such as polymerase chain reaction (PCR) and nucleic acid sequence-based amplification (NASBATM). PCR is the amplification of a segment of DNA bound by two regions of known sequence. The process involves numerous (25–40) cycles of denaturation of the target DNA, annealing of primers (oligonucleotides that are complementary to the regions bordering the sequence), and primer extension by Taq polymerase or similar heat-resistant polymerases.^[7] In the case of RNA viruses, PCR is preceded by the synthesis of cDNA by reverse transcription (RT). In the isothermal amplification method, NASBATM, cDNA synthesis is carried out using a primer containing a T7 RNA polymerase promoter. The RNA in the cDNA:RNA hybrid is digested, allowing the synthesis of a dsDNA using a second primer. With the resulting dsDNA as template, T7 RNA polymerase transcribes amplicons to form multiple copies of antisense RNA, which are used as templates for more cycles of amplification.^[8] Amplicons resulting from both PCR and NASBATM are routinely electrophoresed on gels and visualized either by ethidium bromide staining or hybridization upon transfer to a membrane. In addition, amplicons may be cloned and sequenced.

Aside from their marked sensitivity, both PCR and NASBATM can be designed to be strain-, species-, or group-specific tests.^[9,10] RT-PCR has been particularly useful in detecting numerous viruses of herbaceous and woody plants, whereas NASBATM has been used effectively to detect the various strains of PVY.^[10] Despite the advantages offered by amplification-based tests, their applicability in routine testing and high throughput analyses is limited by laborious and expensive pre- and post-amplification manipulations. Methods to simplify sample processing (e.g., direct binding or immunocapture of virions) have been evaluated. Detection of RT-PCR-derived amplicons has been simplified by sandwich hybridization in enzyme-linked-oligosorbent-assay (ELOSA) in the case of PVY.^[11] ELOSA involves a capture probe covalently linked to the wall of a microtiter well and a 3'-biotinylated-specific detection probe, both of which hybridize to resulting amplicons. The formed hybrid is reacted with a streptavidin-enzyme conjugate that results in a color reaction when given the appropriate substrate. Alternatively, amplicons derived by either PCR or NASBATM may be specifically detected and quantitated in real time using a probe labeled with fluorescent and quencher dyes at either end (e.g., TaqMan and molecular beacons).^[10,12] When the labeled probe binds the amplicon, a sequence-specific fluorescent signal is released in real time with intensity increasing proportionally.

BIOASSAYS AND ELECTRON MICROSCOPY

When serological and nucleic acid-based techniques are unavailable, alternative detection methods include bioassays and electron microscopy. Bioassays entail the grafting or inoculation of certain woody and herbaceous plant species (indicator plants) with cuttings or sap from the infected plant materials. The indicator plants exhibit symptoms characteristic of certain host-virus systems within days or months. In electron microscopy, ultrathin tissue slices or plant sap are examined for viral morphology and cytopathology. Based on these observations, the group to which the causal virus belongs is identified.

CONCLUSION

Increased sensitivity combined with simplified and inexpensive assays should be the goal in developing tests for effective viral detection and diagnosis. These characteristics should extend the applicability of such tests in routine testing of high volumes of samples. Currently, serological lateral flow assays offer the simplest test format, whereas amplification-based tests prove to be the most sensitive. An assay with both of these properties was

developed to detect a human pathogen in water. The specific detection assay involved solid phase-based extraction coupled with RT-PCR, and amplicon detection by hybridization in a lateral flow format.^[13] The development of a similar assay for detecting plant viruses and viroids will be a practical and effective tool for disease management.

Virus-Induced Gene Silencing

S. P. Dinesh-Kumar
Rajendra Marathe
Radhamani Anandalakshmi

Yale University, New Haven, Connecticut, U.S.A.

INTRODUCTION

The profusion of genome sequences and expressed sequence tags (ESTs) has revealed the existence of a large number of novel genes whose sequences provide few clues as to their specific functions. Therefore, techniques that aid in the quick study of functions of these genes have significant practical value in the post-genomic era. From this perspective, virus-induced gene silencing (VIGS) and RNA interference (RNAi) techniques are promising, as they enable the researcher to link a gene to its function reliably and quickly by silencing its activity.

WHAT IS VIGS?

VIGS was first observed when plants infected with an engineered virus vector carrying host gene sequences showed suppression of the activity of the corresponding endogenous gene.^[1] This inhibition of the gene activity was due to a posttranscriptional gene silencing (PTGS) mechanism similar to co-suppression in plants, quelling in fungi, and RNAi in animals. All these related processes involve sequence specific degradation of RNA via highly conserved cellular machinery.^[2]

PTGS is currently understood as a form of defense that plants employ to protect themselves from invading foreign nucleic acids such as transposons and viruses, and it is targeted against double-stranded RNA (dsRNA). Most plant viruses make dsRNA intermediates during their replication. The defense machinery of the plant is able to sense the presence of viral dsRNA and cleave it into small RNA (siRNA) by the nuclease activity of enzymes such as DICER.^[2] siRNAs help in the priming and amplification of the silencing signal, which then spreads systemically in the whole plant. When a recombinant virus harboring any plant gene sequence is used to infect a host, the dsRNA formed will be homologous to the transcripts from the target gene. Destruction of this dsRNA by PTGS and the formation of the siRNAs will eventually result in the systemic silencing of the target gene's expression. The phenotype of the plant silenced for a particular gene by VIGS

mimics its loss-of-function mutant phenotype. Silencing of phytoene desaturase (PDS) gene using a TRV-based VIGS vector is shown in Fig. 1. The photo-bleaching effect seen is comparable to mutant PDS.

VIGS VECTOR

Several plant viruses have been used to develop VIGS vectors. VIGS vectors derived from tobacco mosaic virus (TMV), potato virus X (PVX), tomato golden mosaic virus (TGMV), and tobacco rattle virus (TRV) have shown varying degrees of success to silence genes in *Nicotiana benthamiana*, which is a very good host for most plant viruses. When choosing a virus to develop a VIGS vector, several factors need to be considered. Ideally, the virus should spread uniformly and rapidly throughout the plant, including the meristematic regions of the plant, without producing infection symptoms. Viruses that encode strong silencing suppressors such as HC-Pro in potyviruses or protein 2b in cucumber mosaic virus are undesirable to use as VIGS vectors.

The TRV-based vectors have several advantages over other virus vectors, as TRV-based vectors do not induce chlorotic or necrotic symptoms on plants, which are typical to virus infections. This makes the identification of the VIGS-induced phenotype much easier. In addition, TRV invades every cell of the plant and thereby induces uniform silencing.^[3,4] PVX and TMV are unable to reach the meristematic or growing regions of a plant, but TRV and TGMV can induce silencing of genes in the meristems and flowers.^[3,5]

TRV is a bipartite positive sense RNA virus. RNA-1 encodes the replicase and the movement protein and thus can multiply and spread in the absence of RNA2 (Fig. 2). The TRV-based VIGS vector has the cDNA clones of RNA1 and RNA2 inserted into a T-DNA expression cassette. The multiple cloning sites (MCS) created in RNA2 allow the cloning of target gene sequences for VIGS.^[3,4] When *Agrobacterium tumefaciens* bacterial cultures containing TRV RNA1 and RNA2 constructs are mixed and infiltrated onto the leaves of *N. benthamiana*, viral RNA is

Fig. 1 Silencing of the PDS gene. Infection of recombinant TRV carrying the PDS sequence silences endogenous PDS in *N. benthamiana* and causes inhibition of carotenoid biosynthesis resulting in photo-bleaching phenotype. On the left, the whole plant; on the right, an enlarged single leaf. (View this art in color at www.dekker.com.)

synthesized. These RNA transcripts then serve as templates for the further replication of viral RNA by the RNA-dependent RNA polymerase encoded by RNA1. Systemic infection by the recombinant TRV then brings about VIGS of the targeted plant host sequences.

VIGS AS A FUNCTIONAL GENOMICS TOOL

Several techniques are available to study gene function in plants including T-DNA and transposon-based insertion mutagenesis.^[6,7] These methods have limitations such as gene target bias and difficulty in disrupting or tagging all

genes. In addition, the high degree of gene duplication in plant gene families often results in insertion or deletion mutants of a single gene lacking an observable phenotype. Finally, lethal mutations in the above approaches are almost always lost. Recently, a single-stranded self-complementary (hairpin) RNA was successfully employed to suppress gene function.^[8] All of these approaches, however, rely on the generation of transgenic lines, which is time consuming and even challenging in many economically important plants.

VIGS is a more desirable approach to study gene function.^[9] It enables a specific gene to be silenced if its sequence is known. Moreover, it is conditional; hence, loss of mutations due to organismal lethality is less likely

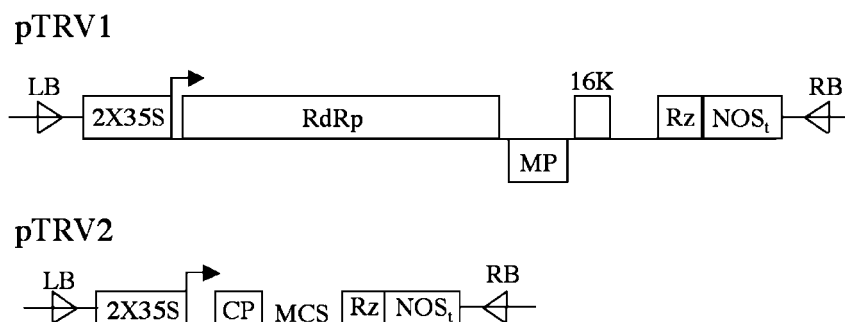

Fig. 2 TRV-based VIGS vectors. TRV cDNA clones were placed in between duplicated CaMV 35S promoter (2X35S) and nopaline synthase terminator (NOS_t) in a T-DNA vector. RdRp, RNA-dependent RNA polymerase; 16K, 16 kDa cysteine-rich protein; MP, movement protein; CP, coat protein; LB and RB, left and right borders of T-DNA; Rz, self-cleaving ribozyme; MCS, multiple cloning sites.

to occur. It is also an excellent system to study gene function in plants that are recalcitrant to Agrobacterium-mediated transformation. VIGS is fast, reliable, and specific. Once a VIGS vector is assembled, any host gene and its close sequence homologues could be efficiently silenced in 2–3 weeks to study its biological function.

VIGS APPLICATION

The VIGS has been successfully used in plants to knock out both endogenous genes and transgenes. VIGS of different components of the signaling pathways in flowering, disease resistance, and cell proliferation has helped in the identification of key factors. For example, suppression of the signaling proteins EDS1, NPR1, Rar1, and Sgt1 and of the COP9 signalosome by VIGS compromised the function of the TMV resistance gene *N* and showed that these proteins are essential for the resistance mechanism to operate.^[4,10,11]

HERITABLE VIGS

One of the main disadvantages of the VIGS approach is that the phenotype observed cannot be transmitted to the next generation. Because of this, it is not possible to perform genetic crosses, suppressor or enhancer screens, and other genetic manipulations based on transmissible phenotypes. However, transgenic expression of a replicating PVX (termed PVX amplicon), containing plant exon sequences, consistently induces the silencing of the corresponding endogenous gene in subsequent generations.^[12] Therefore, the generation of transgenic lines containing a VIGS vector-based amplicon will provide an invaluable resource for further genetic analyses.

CONCLUSION

Even though VIGS has been used successfully to study gene function in plants, it has not been applied in systematic studies at the whole-genome level. Two impressive studies in nematodes utilized the RNAi approach successfully to investigate loss-of-function phenotypes of all the predicted genes on chromosomes I and III.^[13,14] Therefore, in future, we need to develop VIGS vectors that could be used to silence genes *en masse* in fully sequenced genomes, such as those of *A. thaliana* and rice. The VIGS approach, in conjunction with the available collection of insertion mutants, will help us to understand

the function and interplay of genes that control plant growth, development, and responses to the environment.

ACKNOWLEDGMENTS

Virus Movement in Plants

Richard S. Nelson

Xin Shun Ding

Shelly A. Carter

Samuel Roberts Noble Foundation, Inc., Ardmore, Oklahoma, U.S.A.

INTRODUCTION

Plant viruses cause the greatest damage to their host and maximize their potential for spread to uninfected hosts through movement from the initially infected cell. Virus systemic movement in plants is a multistep process, consisting of local spread from the initially infected cell (i.e., cell-to-cell movement) and later vascular-mediated spread to all plant tissues (i.e., vascular-dependent movement). Early studies detected virus spread through the appearance of a visual symptom, followed by biological assay to confirm virus presence. Later, the ability to detect virus components in sampled tissue using antibodies and microscopy enhanced the visualization of virus movement at the cellular level. More recently, the availability of confocal microscopes and fluorescent reporter genes expressed from cloned viral sequences has allowed near real-time observation of virus movement in living cells. Combining these resources with molecular and genetic techniques, viral and host factors involved in virus movement have been identified. Results from recent studies support the dictum that the lack of virus accumulation in systemic tissue is due to one of two causes—either the lack of a virus or host factor necessary for virus movement or the lack of a virus or host factor necessary to defeat or support host defenses. With further advances in methods to visualize virus movement in real time, to harvest and analyze the content of specific host cells, and to manipulate host and viral gene expression, scientists will be able to fully understand how viruses move in plants.

METHODS TO ANALYZE VIRUS ACCUMULATION AND MOVEMENT

A still useful method to estimate the rate of virus movement from an inoculated leaf to the remainder of the plant is by detachment of the inoculated leaf at various times postinoculation. Virus exit from the inoculated leaf is assumed by the appearance of visual symptoms in the remainder of the plant. Steam girdling, wherein phloem

tissue in the vasculature is killed by heat treatment, is also used to study virus movement in specific vascular tissue (i.e., through phloem versus xylem tissue). For both leaf detachment and steam girdling studies, the presence of virus in the symptomatic tissue can be verified by inoculation of extracts from putatively infected tissue onto hosts known to yield visible lesions after virus infection (i.e., indicator hosts; see Fig. 1A).^[1] Indicator hosts are also useful for estimating the rate of cell-to-cell virus spread by observing the expansion of the visible lesion. Virus movement is now determined more precisely through detection of virus-expressed proteins with microscopy.^[1,2] Initially, virus movement at the cell level was determined using fixed and wax- or plastic-embedded tissue probed with antibodies specific to a virus protein (e.g., Fig. 1B and C). Newer techniques take advantage of our ability to insert and express reporter genes from cloned virus genomes.^[2] The use of genes whose protein products fluoresce (e.g., green fluorescent protein (GFP)) allows the monitoring of virus movement in near real time within living cells (i.e., a signal appearing approximately one hour after synthesis of GFP) (Fig. 2).

CELL-TO-CELL MOVEMENT OF VIRUS

Virus transport between cells requires both viral and host factors. Identification of viral factors necessary for virus cell-to-cell movement has progressed rapidly owing to our ability to alter viral sequences within a cloned full-length genome or an isolated gene followed by infection or transfection of plants to observe the movement of the virus or viral gene product. In addition, our increased understanding of the structure, location, and composition of plasmodesmata (PD)—the intercellular tunnels that connect plant cells to each other—has aided the interpretation of results (Fig. 1D).^[3,4] Viral factors necessary for cell-to-cell movement are reviewed in detail by others.^[2–4] For most viruses, at least one viral protein that is required for virus cell-to-cell movement has been identified. For an increasing number of viruses, more than one protein is required for this activity. Consideration

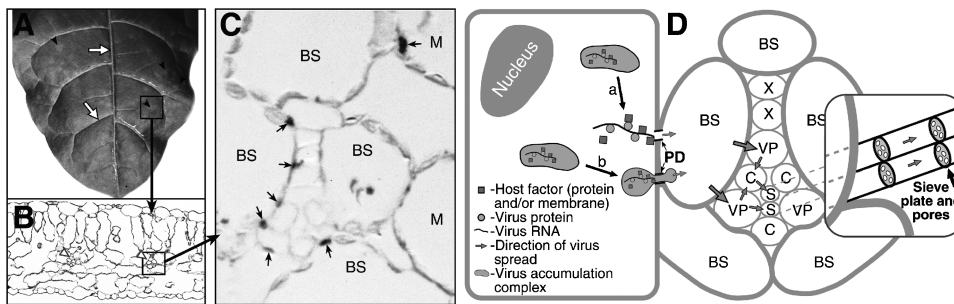

Fig. 1 Virus movement in *Nicotiana tabacum* (tobacco) after inoculation with *Tobacco mosaic virus*. (A) Local symptoms (chlorotic lesions indicated by arrowheads) on the inoculated leaf at 4 days postinoculation; major veins indicated by open arrows. (B) Cross section of a tobacco leaf showing location of minor veins (open arrowheads) relative to nonvascular cells. (C) Magnification of a minor vein showing location of virus movement protein within vascular cells (small arrows pointing to dark bodies). M = mesophyll cell, BS = bundle sheath cell. (D) Diagram indicating potential routes and methods (a and b) of spread by virus into and through phloem sieve elements for its rapid vascular transport. a: transport of virus movement form from replication complex to next cell, b: transport of virus movement form within a replication complex to the next cell. Sieve elements, plates, and pores shown in expanded view at right edge of panel. VP = vascular parenchyma cell, C = companion cell, S = sieve element, X = xylem vessel, PD = plasmodesmata. (View this art in color at www.dekker.com.)

is now given to the exciting prospect that cell-to-cell movement of some viruses may be coupled to the existence of virus accumulation complexes at the PD (Fig. 1D).^[5]

Only recently have host genes been identified that are necessary for the cell-to-cell spread of viruses.^[3,6] One recent example is the identification of a host protein that

interacts directly with a viral protein necessary for virus cell-to-cell movement.^[7] The host protein also interacts with a host enzyme thought to affect PD size and virus movement through its ability to alter callose deposition. Thus the host protein is proposed as an intermediary between a virus movement protein and a host enzyme considered important for PD-dependent virus movement.

Fig. 2 Detection of *Tobacco mosaic virus* (TMV) accumulation along major veins in a developing, systemically infected tobacco leaf. TMV was modified to express green fluorescent protein whose fluorescence (green areas) was detected using confocal microscopy. Virus was associated with major veins (arrows) but not with minor veins (dark areas, arrowhead). (Photo courtesy of N.H. Cheng (Samuel Roberts Noble Foundation).) (View this art in color at www.dekker.com.)

VASCULAR-DEPENDENT ACCUMULATION OF VIRUS

The vasculature in plants is complicated tissue, regulated in its deposition and composed of many cells with unique structures, implying unique functions for each cell (Fig. 1A–D).^[1] Within leaves, vascular tissue is often divided into two groups—minor and major veins—based on their structure and function (Fig. 1A and B, Fig. 2). Minor veins are sites of photoassimilate loading in mature leaves, whereas major veins are sites for the transport and release of photoassimilate in, respectively, mature and developing tissues. Using clones of viruses modified to express GFP, it was determined that both minor and major veins in mature leaves function as initial sites for vascular spread from nonvascular cells.^[8,9] In addition, exit and accumulation of virus from developing leaves is from major veins only (Fig. 2),^[3,8,9] with some exceptions.^[10,11]

Virus transport through vascular tissue is either cell-to-cell via PD, or vascular via sieve tube pores, depending on the location of the virus within the tissue (Fig. 1D). Movement between the various cell types (e.g., bundle sheath cells to vascular parenchyma cells, etc.) may require viral and host factors different from those required for

movement between nonvascular cells (e.g., mesophyll cells to mesophyll cells). Many viral proteins are necessary for vascular-dependent accumulation.^[11] Some of these proteins, however, are also known to defeat a host defense response (discussed later). Further work is needed to determine the relationship between vascular transport and host defense suppression functions for all viral proteins required for the systemic accumulation of viruses in plants. Very few host loci have been identified whose function is required solely for vascular-dependent virus accumulation.^[12]

HOST DEFENSIVE AND VIRUS COUNTER-DEFENSIVE MEASURES DURING VIRUS MOVEMENT

The preceding discussions highlight how viral and host factors actively support virus movement throughout a plant. Virus accumulation in systemic tissue also may be affected by the ability of the host to prevent virus accumulation and the ability of the virus to defeat the host defense. Such a host-defense/virus-counter-defense system can yield a vascular-dependent virus accumulation pattern similar to that displayed when factors actively supporting virus movement interact. Some host genes have been identified that prevent vascular-dependent accumulation of virus, but allow its cell-to-cell movement.^[13,14] Viral genes that combat the effects of these genes have not been identified. However, the concept of host defensive and virus counter-defensive genes has been more fully developed through the identification of a host enzyme pathway that identifies, targets, and destroys aberrant or overexpressed RNA, including plant virus RNA.^[15] RNA silencing is the term for this surveillance system. Recently it was determined that viral proteins, called suppressors, can defeat the surveillance system through multiple ways.^[15] Many of the viral proteins that function to defeat RNA silencing were previously shown to support the vascular-dependent accumulation of particular viruses. Thus, in order to understand virus movement it is important to realize that the accumulation of virus in systemic tissue can be influenced by the ability of the virus to interact with host factors necessary for movement and the ability of the virus to avoid host defense factors.

CONCLUSION

Initial studies of virus movement identified strains of viruses with altered movement abilities and loci in plants that controlled movement. In the last 15 years, our understanding of virus movement has increased dramatically

due to our ability to clone and alter virus genes and then express these genes alone, as a transgene, or from an infectious virus in plants. Reporter genes such as GFP have aided the analyses of virus spread by allowing near real-time imaging of virus accumulation patterns. Using these technical breakthroughs, researchers have determined rates and routes of virus movement. Systemic accumulation of virus is a balancing act between the expression of viral and host factors that actively support virus movement and those that defend the host or virus from deleterious effects. There will be continued research directed toward identifying viral, and especially host, factors that support or prevent virus accumulation in systemic tissue. However, the next major step in understanding virus movement will be to understand how these factors interact within single cells and at each cellular interphase to control this phenomenon.

Viruses and Viroids: Evolution

Marilyn J. Roossinck

The Samuel Roberts Noble Foundation, Ardmore, Oklahoma, U.S.A.

INTRODUCTION

Viruses and viroids are genetically the simplest of biological entities and are obligate intracellular parasites. They typically have evolutionary rates that are several orders of magnitude greater than those of their hosts. The significance of this rapid evolution is that resistance to viruses, both engineered and naturally occurring, is often short-lived in field crops. On the other hand, this rapid evolution has allowed plant viruses to be used as model systems for the study of molecular mechanisms of evolution. Unlike the evolution of their hosts, which is often measured in millions of years, virus evolution can be measured in as little as 2 weeks. This article will discuss recent studies on the evolution of plant viruses and viroids that have important implications for crop sciences and will explore the current theories about the possible origins of viruses and viroids.

RNA VIRUSES AS QUASISPECIES

The majority of plant viruses are single-stranded RNA viruses. These viruses encode RNA-dependent RNA polymerases that are generally thought to be much more error-prone than the enzymes involved in DNA replication. Error rates for plant viruses have not been measured directly, but for animal RNA viruses, they are about 1 in 10^4 nucleotides copied.^[1] Combined with the short generation times of RNA viruses, this can lead to highly diverse populations within a single host, known as quasispecies. However, the level of genetic diversity in individual quasispecies varies among closely related viruses and among hosts infected with the same virus.^[2,3] In addition, not all RNA viruses generate detectable levels of variation in their populations.^[3] This indicates that quasispecies population structure is more complex than the simple accumulation of mutations, but factors that control virus population diversity are still unknown.

The practical implication of a highly diverse quasispecies structure is that the virus will most likely be more adaptable to new environmental challenges, such as breeding for resistance or engineered resistance, because more fit variants may already be present in the population. The level of diversity has been correlated to the size of the

host range.^[3] High levels of diversity could also account for the rapid emergence of introduced viruses in crops.

ORIGIN OF PLANT VIRUSES

The numerous RNA viruses of plants can be divided into a small number of supergroups and taxonomic families based on the structure of the genome and nucleotide sequence identity. Some supergroups, such as the alpha-viruses, have species that infect plants and others that infect animals. It is likely that these viruses have a common ancestral origin, possibly an insect virus. The plant viruses in the Bunyaviridae family, as well as several other plant virus taxa, replicate in both their plant host and their insect vector, and at least in some cases, the adaptation of the virus seems more closely directed by the insect than the plant. Other plant virus families, such as the Potyviridae, contain only members that infect plants.

Plant viruses have different requirements for systemic infection than animal viruses because they must be able to move between cells with cell walls. Hence the viruses contain specific genes encoding movement proteins that enable the virus to move from cell to cell. It seems likely that these genes were originally acquired from the plant host because plants encode proteins that act in a very similar manner.^[4]

Most plants also contain very low titer viruses known as cryptic viruses. These are double-stranded RNA viruses that are unable to move from cell to cell and only replicate poorly. They are disseminated through cell division and by seed or pollen transmission. These viruses may represent precursors to plant viruses that have not yet acquired movement proteins. One possible source of cryptic viruses is from endophytic fungi, which are very often infected with double-stranded RNA viruses. During the plant-fungal symbiosis, it is possible that on rare occasions, some virus escapes into the plant cells, where it can replicate, albeit poorly, but has no mechanism to move. This theory is supported by the similarity in the RNA-dependent RNA polymerase between Beet cryptic virus and the fungal virus *Discula destructiva* virus (unpublished data) and by the observation that Brome mosaic virus, with some manipulation, can replicate in yeast cells.^[5]

When phylogenetic analyses are performed with individual genes of RNA viruses, the trees are often incongruent, indicating separate evolutionary histories for different genes. This strongly supports a modular evolution theory for viruses, although there are also different host constraints on different genes that may also influence their evolution. The most conserved regions are three domains in the proteins that make up the viral components of the replicase: methyl transferase, helicase, and polymerase (Fig. 1). The movement proteins also exhibit conservation of structure, but little conservation of primary sequence, and hence it is not clear if they are similar as a result of divergent or convergent evolution. If they are indeed derived from plant genes, it is possible that they have a common root that is much deeper than that of the replicase genes, and hence the evolutionary history is obscured.

Of the plant DNA viruses, the geminiviruses are among the most economically important. These viruses replicate by making use of the host DNA polymerase, but still manage to establish highly diverse populations when different field isolates are compared. There is extensive evidence of modular evolution in these viruses, similar to what is seen in RNA viruses, with recombination and reassortment common themes in the evolution of both groups.

The origin of the geminiviruses is unclear. Some geminivirus sequences have been found integrated into plant genomes, while other studies have shown that geminiviruses can replicate in *Agrobacterium tumefaciens*, suggesting a bacterial origin (reviewed in Ref. [6]). Other DNA viruses, most notably some of the pararetroviruses, are not only found integrated in plant genomes, but can also excise and establish episomal infections.^[7] While integration does not necessarily indicate

a plant origin for the virus, it does suggest a long association between virus and host.

EVOLUTION AND ORIGIN OF VIROIDS

Viroids rely on the host RNA polymerases for replication, enzymes that are also much more error-prone than DNA polymerases. Hence viroids also exist as highly diverse populations or quasispecies. A large number of pathogenic viroids have been described and analyzed, but viroid diseases were not described before the 20th century. It is thought that viroids entered crop plants with the advent of worldwide plant movement and monoculture practices in agriculture from wild plant hosts where they were likely nonpathogenic.^[8] Viroids contain ribozyme structures that resolve the concatemers generated during replication and hence have been characterized as molecular fossils, representing the earliest forms of life on earth. There is an ongoing debate concerning the monophyletic nature of viroids, but the most recent studies indicate that despite enormous nucleotide sequence diversity, the conservation of structural elements, especially with regard to position in the viroid genomes, does indicate a common ancestor.^[9]

CONCLUSION

Plant viruses are an increasing threat to crops, and the effectiveness of methods for long-term control is not known. However, while the evolutionary potential of viruses may mean that control measures are ineffectual, the plasticity of viral genomes allows them to be exploited as tools for genetic engineering. Virus expression vectors may be the simplest and most appropriate method for expressing foreign genes in plants.^[10] Hence virus evolution can be both a menace and a benefit to crop sciences. Long-term control of viral diseases in plants may include methods for control of viral symptoms, rather than eradication of the virus.

Water Deficits: Development

Kadambot H. M. Siddique

The University of Western Australia, Crawley, Australia

INTRODUCTION

Despite water being the earth's most abundant compound, water deficit is the single most important factor limiting crop yields worldwide. Of the earth's water supply, 97% is saline and 2.25% is trapped in ice, leaving only 0.75% available in freshwater aquifers, rivers, and lakes. Agriculture is the major consumer of fresh water worldwide (69%). Increasing demands being placed on both food and water resources throughout the world require that agriculture be more efficient in its water use without sacrificing production. To enable more efficient distribution and utilization of water resources, a greater understanding is required of plant-water relations, in particular the way in which water deficits develop and affect plant growth and productivity.

THE SOIL, PLANT, AND ATMOSPHERE CONTINUUM

The plant-water deficit that develops in any particular situation is the result of a complex combination of soil, plant, and atmospheric factors, all of which interact to control the rate of water absorption and loss.^[1] In plants, water deficits develop as a consequence of water loss from the leaf as the stomata open to allow the uptake of CO₂ from the atmosphere for photosynthesis. The water lost by transpiration from the leaf mesophyll cells is replaced by water drawn from the soil through the root, stem, and leaf via the xylem. The movement involves both symplastic and apoplastic pathways, i.e., from cell to cell via the symplasm and along the cell walls and xylem vessels, respectively. Both pathways create resistances to flow between the soil and leaf. This pathway of movement is a continuum between the soil, plant, and atmosphere.

It is generally accepted that water moves through the soil-plant-atmosphere continuum along a gradient of decreasing water potential from the soil, through the plant, to the atmosphere. The driving force for the upward movement of water is the negative hydrostatic pressure (tension) that develops in the xylem of transpiring plants. Except for halophytes, the solute content of the xylem sap is usually very low, and thus its solute potential is very

close to zero. Water forms a continuous liquid system from the soil up to the evaporating surfaces in the leaf mesophyll. When water evaporates from the leaf cells, the reduction in potential at the evaporating surface (the leaf cell walls) causes movement of water from the xylem to the evaporating surface, which in turn reduces the pressure of water in the xylem and causes the ascent of water. This reduced pressure is transmitted throughout the liquid continuum to the root surfaces, where it reduces the root water potential and causes uptake of water from the soil.

Changing water availability has the greatest effect on the soil-root boundary that forms an interface between the plant and its environment.^[2] The difference in water potential between the plant and the soil depends on the evaporative demand, the extent to which the plant can meet that demand, and the water-conducting properties of the soil and plant. It was previously thought that there was no direct relationship between the water potential in the leaf and the water potential in the soil, with the soil-water potential acting only to establish an upper limit of recovery possible by the plant during the night.^[1] However, current evidence suggests that plant growth regulators such as abscisic acid (ABA) may play an important role in transferring the message of increasing soil and root water deficits to the shoot.

WATER STATUS OF CROP PLANTS

The water status of a crop plant is usually defined in terms of its water content, water potential, or the components of water potential. The total water potential can be partitioned into components consisting of the osmotic potential, turgor pressure, matric potential, and gravitational potential.^[1] In addition to water moving from the soil to the atmosphere, the lower water potential in the leaves and stems results in water moving from the leaf mesophyll cells and the parenchyma cells surrounding the xylem and phloem. This water not only acts as a reservoir of water buffering the plant against diurnal changes in water deficit, but also induces changes in cell volume. Seed growth is the final plant process affected by soil water stress (e.g., in grain legume species the water relations of the embryo are isolated from the water relations of the maternal

plant). There is a close coupling of pod- to plant-water status, but a clear isolation of seed-from pod-water status. This results in relatively constant seed coat turgor despite changes in the water potential of the maternal plant environment. It is thought this homeostasis may be part of a mechanism to ensure continued seed filling and assimilate redistribution, even when low water potentials have reduced the current availability of assimilates from the leaves.^[3]

Plants are in a position to extract water from the soil only when their water potential is lower than that present in the soil. Thus water in the plant is seldom in equilibrium with water in the soil. In fact, water deficits occur in the tissues of all transpiring plants as an inevitable consequence of the flow of water along a pathway in which frictional resistances and gravitational potential have to be overcome.^[1] At times during the day, all plants (with the exception of those in humid climates) are undergoing some degree of water deficit. The extent of any imbalance between transpiration and water uptake is limited by the storage capacity of the plant: For crop, forage, and pasture species this is usually less than one-third of daily transpiration.

The difference in water potential between the plant and the soil depends on the rate of uptake of water from the soil and the water-conducting properties of the soil and plant. The progressive changes in soil- and plant-water potential as the soil dries out are presented schematically (Fig. 1).

Fig. 1 Schematic representation of changes in leaf-water potential (Ψ_{leaf}), root-water potential (Ψ_{root}), and soil-water potential (Ψ_{soil}) as transpiration proceeds during a drying cycle. The same evaporative conditions are considered to prevail each day; the horizontal dashed line indicates the value of Ψ_{leaf} at which wilting occurs. (From Slatyer, R.O. 1967. *Plant-Water Relations*, Academic Press, New York.)

EVAPOTRANSPIRATION

Evaporation from plant communities is frequently termed evapotranspiration, to signify the combined soil-plant nature of the evaporating surfaces. The evaporation of water, whether it be from a free water surface, wet soil, or as transpiration from plants, is an energy-dependent process involving a change in state from the liquid to the vapor phase; the rate is a function of the vapor pressure gradient, the resistance to flow, and the ability of the soil and plant to transport water to the sites of evaporation.^[4] The primary source of energy for this process is provided by radiation from the sun. Secondary sources include scattered and reflected radiation from the sky and clouds, as well as sensible heat transferred from the adjacent air, crop, and soil. The transport of water vapor molecules from the wet surfaces to the atmosphere occurs by molecular diffusion and turbulent eddy movement.^[5]

MECHANISMS FOR CONTROL OF WATER TRANSPORT

The relative magnitude of water supply and water loss appears to determine the degree to which plants are water-deficient. However, because plants are living organisms, it is important to realize they do not provide solely a pathway for the movement of water from the soil to the atmosphere. Plants possess mechanisms for osmotic regulation that effectively control the flow of water according to their water status.^[4]

The additional resistance encountered when evaporation occurs via plant surfaces is of great ecological importance and greatly affects evapotranspiration. In well hydrated plants, resistance is very small. Thus, the evapotranspiration from a soil completely covered by vegetation well supplied with water is very close to the evaporation from an open water surface and is called potential evaporation. Evapotranspiration from non-stressed crops is largely governed by meteorological conditions in the atmosphere external to the soil-plant system rather than by plant and soil factors. Crop canopy photosynthesis, transpiration, or leaf extension growth usually do not show midday depressions caused by high evaporative demand unless the soil water supply is depleted below a threshold of ca. 50% of total extractable soil water. The exact point of the threshold water content is difficult to distinguish and is usually extrapolated from measurements taken when evapotranspiration/maximum evaporation is clearly reduced by drought.^[6]

The plant, in contrast to the soil, does exercise control over water loss through its stomatal and cuticular resistances in the water pathway and also through its ability to

reduce the radiation load through active and/or passive changes in leaf orientation. Because these controls are located at the leaf surface, the internal water status of the plant is closely coupled to that of the soil and less closely coupled to the atmosphere.^[1]

Regulation of stomatal conductance enables the plant to reversibly modify gas exchange with the atmosphere, with a time scale of only a few minutes. This short-term regulation may both optimize the dry matter production and offer some protection from xylem embolism or other detrimental effects of very low leaf water potential.^[7] Stomata do not respond to changes in leaf–water potential or relative water content (RWC) until a critical threshold level of these parameters is reached, and then the stomata close over a narrow range of leaf–water potential or RWC. There is now considerable evidence to support the theory that a chemical message—originating in dehydrating roots and conveyed by the water flux towards the stomatal complex—can control stomatal conductance.^[8]

Because stomata act as regulators for CO₂ exchange, water deficits sufficient to close stomata must also depress photosynthesis. Photosynthesis declines initially as a result of stomatal closure, but prolonged and severe water stress can lead to depression of chloroplast and enzyme activity and to nonstomatal effects on photosynthesis.^[1] In shoot tissues, when water deficits limit the supply of CO₂ for photosynthesis, a number of reversible mechanisms down-regulate the efficiency of excitation energy transfer to Photosystem II.^[2] Dark respiration is depressed whenever the water deficit is sufficiently great to close stomata and decrease photosynthesis, but the decrease in dark respiration is less than that of net photosynthesis.^[1]

A high cuticular resistance is associated with either thicker cuticles or with cuticles enriched with hydrophobic materials. Although the plant cannot flexibly control this, cuticular resistance has been found to decrease with increasing temperature and atmospheric relative humidity.

MEASUREMENT OF PLANT–WATER RELATIONS

Any study of plant–water relations requires accurate methods for measuring them. Indirect methods that have been used to characterize the leaf water status include visible wilting, color change, leaf rolling, leaf temperature, leaf thickness, stomatal conductance, photosynthetic rate, and leaf permeability. Direct measurements can be undertaken using standard equipment such as the pressure chamber, psychrometers, and infrared gas analyzers. These have now been joined by newer technologies, such as the pressure probe, acoustic emission

sensors, portable photosynthesis and fluorescence meters with solid-state circuitry, in addition to sophisticated modeling techniques for extrapolation to larger scales.^[2]

Mass spectrometers can be used to trace source water through the measurement of a combination of stable radioactive carbon isotopes suspended in water, and may also have the potential to reveal the quantitative contribution to atmospheric fluxes of transpirational water derived from vegetation. Other approaches such as mass-balance techniques, micrometeorological methods, and measurement of liquid flow and vapor fluxes can be used as a basis for scaling up to the level of canopies and stands of vegetation.

EFFECTS OF WATER DEFICITS

Long-term severe water deficits can have a negative effect on crop growth and yield, and may even result in senescence of the plant. It has been suggested that drought resistance of crops may be improved via breeding for specific phenological, morphological, physiological, or biochemical characteristics that improve yields in water-limited environments. These characteristics include early vigor, transpiration efficiency, stomatal control, abscisic acid accumulation, proline accumulation, osmotic adjustment, carbon remobilization, rapid grain growth, changes in hydraulic conductance, membrane stability, and lethal water potential.^[9] It is, however, important to note that water deficits do not always lead to detrimental effects on yield. Mild or early water deficits may in fact increase yields or at least have no effect on yield, especially in indeterminate species.

CONCLUSION

The global atmospheric CO₂ was in a steady state at a concentration of about 280 μmol/mol 150 years ago and has been rising steadily since then as a result of human activity. Over the past 20 years, the annual rate of increase has varied, depending on global economics, between 1 and 2 μmol/mol.^[10] The rise in atmospheric CO₂ concentration is likely to affect global climate and to cause regional changes in air temperature and humidity, length of growing season, precipitation, and evaporation, all of which will affect plant water relations.^[10] At a plant scale we may expect to see substantial but rather variable increases in plant growth and changes in the phenology of growth processes.

Stomatal conductance has long been known to decrease at high levels of CO₂. Empirical data suggest that

increases in plant size, particularly in leaf area, may offset any possible advantages to water economy resulting from stomatal closure. There is also evidence to suggest that the growth-enhancing effects of elevated CO₂ may to some extent offset the growth-reducing effects of water stress.^[10] Changes in land use and regional climate brought about by anthropogenic incursions mean that crop productivity in more marginal rainfall areas will be of increasing importance in world agriculture. Expansion to these areas requires the ability to identify and breed for characteristics that better enable crop plants to cope with limited water availability.

Water Movement Through the Plant

Jonathan Comstock

Boyce Thompson Institute for Plant Research, Ithaca, New York, U.S.A.

INTRODUCTION

Terrestrial plants have tremendous water transport capacities to support photosynthesis in an aerial environment. Because photosynthetic capture of CO₂ begins with gas-phase diffusion between the ambient air and leaf intercellular spaces, there is no selective barrier to allow CO₂ uptake while preventing a proportional water loss (transpiration). Consequently, 95% or more of total plant water uptake is simply lost again to the atmosphere during the photosynthetic process, and plant water requirements for net growth are very high. Support of the transpiration stream requires both an extensive root system for extraction of soil water and also highly specialized long-distance transport tissues (xylem) that maintain a continuous, high-capacity pathway for the flow of water reaching all tissues in the plant body.

COMPARTMENTATION AND TISSUE SPECIALIZATION

The distinction is often made between symplastic and apoplastic water movements in plants. Apoplastic space is defined as external to living cells. Because plant cell walls lie external to the bounding cell membranes, this includes the porosity of cell walls, surface films adhering to them, and all intercellular spaces. Also considered part of the apoplast, but quite distinct in its characteristics, are the highly specialized conduits of the xylem tissues, which form a system of hollow, nonliving capillaries at functional maturity. Symplastic pathways are those within the boundaries of living cell membranes, including cytoplasmic and vacuolar volumes and the interconnections of living cells by plasmodesmata. Movement of water between apoplastic and symplastic compartments is usually determined by gradients in total water potential—a thermodynamic measure influenced, most importantly, by both pressure and osmotic concentration. However, water movement within a single compartment, such as through porous walls or in xylem conduits, is driven primarily by the pressure term alone and not by total water potential.

Long-distance water movement within plants occurs predominantly in the specialized conduits of the xylem—the tracheids and vessels. Tracheids are conduits that develop from a single living cell and are rarely more than a few millimeters in length, whereas vessels are multicellular in development and range from several millimeters to several meters in length. Both tracheids and vessels are dead at functional maturity, have open lumen without cellular contents, and ultimately have sealed ends. The open lumen provides a low-resistance pathway and allows xylem tissues to have six or more orders of magnitude greater conducting capacity for water transport than an unspecialized tissue such as parenchyma in the root cortex or leaf. However, after flowing for a while in a conduit lumen, the sealed ends require that water must move laterally through the overlapping sidewalls in specialized regions of the thin and porous primary wall—referred to as a “pit membrane.” Because of this requirement for lateral passage, whole conduits are not stacked end to end in series but overlap with the next axial component over a substantial fraction of their length.

The tracheid is considered to be monophyletic in origin and is present in most vascular plants. In contrast, the vessel is polyphyletic in origin and is lacking in many important groups of plants. When both conduit types are present, as in most angiosperms, the longer, larger-diameter vessels will usually provide most of the transport capacity. This is because the hydraulic conductance of the lumen of an individual conduit increases with the fourth power of its radius, so xylem tissues with large-diameter conduits can have much higher hydraulic conductance per unit xylem cross-sectional area. However, as tracheid diameter increases, hydraulic conductance may become limited by the tremendous number of pit membrane crossings between the root and the shoot. Xylem with small-diameter tracheids has more total wall surface area for enhancing pit membrane connections, whereas lumen and pit membrane resistances to flow can be kept balanced by an increased conduit length in vessels.^[1]

Initial absorption of water from the soil must occur radially across the root cortex before entrance into the centrally located root xylem for long-distance transport. The pathway of radial movement can be rather complex—involving a combination of apoplastic and symplastic

transports across the cortical tissues. Water may move repeatedly from symplastic to apoplastic space during this transit, and the hydraulic conductance of individual cell membranes becomes very important.^[2] Cell membranes tend to have rather poor hydraulic conductance, unless they contain specialized proteins (aquaporins) that form pores, allowing the passage of water but not solutes. The density and spatial distribution of aquaporins can be very important in facilitating water movement through living tissues. Similarly, water exiting xylem in the leaf most often moves, at least briefly, through living parenchyma cells.^[3]

Quantitatively, most xylem transport end in the extensive network of fine leaf veins, although flowers, fruits, and other organs are all vascularized to some degree. Phloem tissue is also present in this veinal network, collecting photosynthate from the leaves and repackaging many of the mineral nutrients initially traveling in the xylem from the roots. These materials, together with some volume flow of water, are then delivered to all the “sink tissues” of the plant. In a few cases, such as a heavily cutinized fruit with few stomata, sink tissues may actually receive most of their water requirements from phloem transport. Such water has still first traveled from the root to the shoot in xylem, and the necessary hydration volume of such nontranspiring tissues represents a very small part of the total water economy of a plant.

MECHANISMS OF WATER MOVEMENT AND XYLEM FUNCTION

Water movement within the xylem conduits is always down a pressure gradient, but the nature, origin, and maintenance of this pressure gradient can differ dramatically under different circumstances, and sometimes as part of a regular day/night cycle. The pressure throughout the xylem plumbing network may sometimes be positive with respect to the atmosphere, like water in household pipes. Positive xylem pressure arises from a phenomenon called root pressure, and is generally associated with conditions of very low transpirational demand, such as stomatal closure at night or the leafless condition of perennial winter-deciduous plants in the early spring. More often, and especially during periods of high transpiration, the absolute pressure throughout the xylem is negative with respect to atmospheric pressure, like water being pulled through a straw under tension.

Root pressure depends on the ability of the endodermis (a specialized layer of the innermost root cortex with suberized radial walls) to act as an organ-level semipermeable membrane surrounding the central xylem tissues.

The endodermis restricts apoplastic exchange between the root xylem and cortical apoplasts, both enabling the capacity for differential uptake of soil solutes into the xylem and creating the potential for osmotic pressures between xylem and cortical tissues. If the xylem is actively loaded with solutes associated with mineral nutrient uptake, an osmotic pressure may build up in the root xylem, which draws in water as well, generating a positive pressure throughout the xylem conduits. Many herbaceous plants in wet soil at night actually excrete water droplets from the ends of minor veins on the edges of leaves—a process referred to as guttation. However, plants do not take up nearly enough solutes such that the large volume of daytime transpiration can be supported primarily by this osmotic mechanism.

The large volumes of water needed to support transpiration move through the xylem primarily under a gradient in tension (pressure below atmospheric) ultimately created by the process of transpiration itself.^[4] When water is lost from a leaf through the stomatal pores, the water vapor in the leaf intercellular spaces is replaced by evaporation from the wet cell walls. This creates a water deficit in the cell walls, and water retracts into the micropores of the wall. However, due to its surface tension, water resists assuming the tortuous curves associated with retraction into pores with radii that are only a fraction of a micron. Thus transpiration generates a tension in the apoplastic water bounding the intercellular air spaces. This lowers the water potential of the associated cells and is ultimately transmitted, both through apoplastic and symplastic connections, to the leaf xylem. The tensions first reach the xylem conduits at pit membranes that separate the peripheral conduit lumens from the surrounding bundle sheath parenchyma.^[3] Once transmitted into the sap of the conduit lumen, the tension develops into a continuous gradient, pulling water up through the interconnected conduit water columns from the root, and ultimately from the soil. This is facilitated by the very special characteristics of the xylem conduits derived from their sealed ends and the fact that passage of water (or air) in or out of the lumen can only occur through the micropores of the pit membranes. Tension develops in the vessel lumen, but there is little change in water volume because the water adheres strongly to the conduit walls and fills the lumen completely without void or gas spaces. In such a closed capillary, water actually has a substantial tensile strength sustaining tensions of -5.0 MPa or more without undergoing cavitation, or sustaining spontaneous rupture of the water column to allow vapor-filled void spaces. When cavitation does occur, it is generally not from spontaneous failure of water cohesion, but rather from the aspiration of an air bubble entering into the conduit through a pit membrane pore.

The critical tension that can be sustained without failure is determined by the diameter of the pit membrane pores. The xylem conduits themselves must also be heavily reinforced with thick secondary walls to withstand these large forces without collapsing inward. The tensions that can be tolerated in the xylem are highly species-specific, varying several fold depending on wall dimensions and pit membrane morphology.

INTEGRATION OF WATER TRANSPORT AND TRANSPIRATIONAL DEMAND

Plants show an almost surprising consistency in their shoot water potentials during transpiration when they are growing in moist soil. Dynamic water stress, the total pressure drop from the root to the shoot arising from frictional resistance to transport, rarely exceeds 0.5–1.0 MPa. Because plants show tremendous variation in their actual transpiration rates, this means that there must be a strong positive correlation between maximal stomatal opening and hydraulic conductance. This has been demonstrated in both wild and crop species.^[5] For the xylem conduits, which are dead at functional maturity, most of this coordination must be achieved during growth. Some plants also appear to fine-tune the hydraulic conductance of their existing xylem by subtle alterations of solute content in the xylem sap, affecting pit membrane permeability. Aquaporins, especially in the root cortex, have also been shown to undergo diurnal fluctuations in synthesis correlated with diurnal fluctuations in the hydraulic conductance of root membranes.^[6]

Careful regulation of dynamic water stress is needed because of the danger of cavitation in the xylem.^[7] The same tension gradients that are the fundamental driving forces for xylem transport also define the limits to transport without cavitation. When cavitation occurs, almost all water will drain out of the conduit, which loses its ability to transport water, but the closed end walls and the pit membranes serve as check valves, limiting the spread of dysfunction and requiring that cavitation only propagate by independent events, conduit by conduit. Nonetheless, exceeding the limits for sustainable tension could result in a catastrophic collapse of the transport process, and yet plants appear to approach these limits regularly. Cavitation of a limited fraction of the conduits is a common phenomenon. Some herbaceous species even show a regular diurnal pattern of partial cavitation, and use root pressure at night to help refill the conduits. Less well understood are a smaller number of plants that have been shown to be capable of xylem refilling even under conditions where the surrounding xylem is still under tension.

Ultimately, the coordination of hydraulic conductance and maximal transpiration also requires extensive stomatal control and feedback that are sensitive in various forms to the tensions developing in the apoplast. Stomata are the gates through which most water loss occurs, and it is they, and not any of the intervening points of water transport, which can control the actual magnitude of transpiration. They open to allow the entry of CO₂ for photosynthesis, but may exhibit partial closure in response to numerous signals. Dry ambient air, which would cause excessive transpiration, often results in partial stomatal closure to maintain a stable maximum transpiration rate through the day. Water stress experienced by the roots results in hormonal signals released into the transpiration stream itself and modulating stomatal conductance,^[8] and evidence exists as well for feedback loops directly between leaf water potential and stomatal behavior.^[9] This control, avoiding excessive fluctuation in maximum transpiration and xylem tension, is essential to maintain the integrity of xylem function and stable water transport to the shoot.

CONCLUSION

Most water transport within the plant serve to support the transpiration stream and photosynthetic activity. Long-distance transport from the roots to the foliage occurs in the xylem conduits, which have the somewhat unique property of being dead hollow tubes at functional maturity. Much shorter but equally important pathways for water movement occur in both roots and leaves as water moves through various kinds of living tissues between the soil and the root xylem, and between the leaf xylem and the sites of evaporation. Very active areas of current research include the regulation of membrane properties, especially aquaporin distribution and gating; the limits to xylem function, including the dynamics of cavitation and variation among species in mechanisms of cavitation repair; and the specific signal transduction mechanisms that regulate stomatal aperture and transpiration within the existing limits of the water transport system.

Water Use Efficiency Including Carbon Isotope Discrimination

Anthony G. Condon

CSIRO Plant Industry, Canberra, Australia

INTRODUCTION

Less water available for irrigation and the demand for ever-greater productivity from rainfed and irrigated agriculture are major challenges for the 21st century. Agronomic and engineering improvements can help meet these challenges. There are also several plant attributes that have potential to be exploited for greater water use efficiency of crop production. In this overview, plant attributes and agronomic practices that may contribute to greater water use efficiency of rainfed agriculture will be emphasized, although many are also important for irrigated agriculture. Examples will be highlighted from current research with temperate cereals.

AVENUES FOR GREATER WATER USE EFFICIENCY

The term “water use efficiency” has a variety of definitions.^[1] In agronomic contexts, most of these definitions describe a ratio of grain yield and some measure of water used or water available for crop growth.^[1] Yield formation of rainfed crops grown on a finite supply of water can be described more explicitly as a function of 1) the amount of water used by the crop (ET); 2) the water use efficiency for biomass growth (W); and 3) the harvest index (HI), i.e., how much of the final biomass is partitioned to grain.^[2] Closer dissection^[3,4] reveals two important avenues for improving crop W: increasing the amount of total water use that is actually transpired by the crop rather than lost as evaporation from the soil surface and improving crop transpiration efficiency (W_T), i.e., biomass production per unit water transpired.

MAXIMIZING TRANSPIRATION

Restricting Evaporation from the Soil Surface

Evaporation from the soil surface can account for between 20 and 70% of growing-season water use, varying with how frequently the soil is rewetted and the rate and extent

of canopy closure. So, restricting water lost by evaporation from the soil surface can dramatically improve crop W. A reduction in soil evaporation to promote greater transpiration is most easily achieved through the rapid development of leaf area to shade the soil surface from direct solar radiation.^[3,4]

Good stand establishment and vigorous early plant growth will both contribute to rapid leaf area development. Good stand establishment is best achieved by plants with vigorous growth of the primary shoot that extends to the soil surface, i.e., either the coleoptile or the hypocotyl. Desirable traits are primary shoots that reach the soil surface more quickly if seed is sown relatively shallow; shoots that reach the soil surface much more consistently if seed is sown deep, such as when farmers are seeding into receding moisture; and shoots that are better able to penetrate crusted topsoils and retained stubble.^[4]

Once plants have emerged, traits important for vigorous early leaf area growth may be associated with a larger embryo size, a greater relative growth rate, or a greater investment in leaf area per unit plant growth. Barley, for example, has a much faster rate of early canopy growth than bread wheat due to a larger embryo size and higher specific leaf area. These desirable traits have been combined in a wheat breeding program in Australia to produce new parental lines with early leaf area growth that is double that of current varieties.^[4] Soil shading may be further enhanced by more prostrate leaf display.

Agronomic practices such as retention of residues from previous crops can be effective in shading and insulating the soil surface to restrict soil evaporation. Sowing an adequate density of large, healthy seeds at the optimum depth in a well-prepared seedbed will promote good stand establishment. Vigorous leaf area growth can be promoted and sustained by providing adequate levels of major nutrients such as N and P, removing imbalances of minor nutrients and pH, controlling shoot and root diseases, and minimizing soil compaction and waterlogging.

Capturing and Extracting Subsoil Moisture

Water that drains beyond the depth of rooting is lost for dry matter production by the crop. Practices that minimize

drainage in irrigated and rainfed agriculture are important, not just for greater water use efficiency but also for avoiding environmental degradation. Water extracted by the crop from depth will all be used in transpiration, and so extracting available subsoil moisture is important for increasing W .

Management practices and plant attributes that promote vigorous shoot growth will generally also promote vigorous root growth, encouraging water capture. In many rainfed and irrigated cropping systems, there may be constraints, such as waterlogging, compacted soil layers, nutrient or pH imbalance, and root pathogens, that restrict the depth of rooting or water uptake from depth. Growing “probe” genotypes known to be susceptible to or tolerant of a particular condition can be a useful way of identifying a particular subsoil constraint.

MAXIMIZING TRANSPIRATION EFFICIENCY

At its most basic, W_T may be defined as the ratio of the instantaneous rates of CO_2 assimilation (A) and transpiration (T) at the stomata.^[5] These instantaneous rates can be described by relatively simple equations.

$$A = g_c(c_a - c_i) \quad (1)$$

$$T = g_w(e_i - e_a) \quad (2)$$

Eqs. 1 and 2 both consist of two components: the stomatal conductance (g) to CO_2 (g_c) or water vapor (g_w) and the concentration gradient of CO_2 ($c_a - c_i$) or water vapor ($e_i - e_a$) between the air and inside the leaf.

Leaf-level W_T can be closely approximated by Eq. 3, which combines Eqs. 1 and 2 and in which the factor 0.6 refers to the relative diffusivities of CO_2 and water vapor in air.^[5,6]

$$W_T = 0.6c_a(1 - c_i/c_a)/(e_i - e_a) \quad (3)$$

Eq. 3 indicates two main avenues for improving W_T . One is to reduce $(e_i - e_a)$, the driving gradient for transpiration. The other is to reduce c_i (c_a being assumed constant) to increase the gradient of CO_2 concentration.^[1,5]

Changing the Driving Gradient for Transpiration

The most effective way to improve crop W_T is to achieve a larger proportion of crop growth when evaporative demand is low,^[1,4] i.e., when e_a is high relative to e_i . Choosing an appropriate crop or variety for the location and sowing the crop at the recommended time are vital management activities. Crop or variety choice can be

expanded by breeding to adjust sowing time and crop phenology. Eliminating disease susceptibility may present additional breeding opportunities to adjust sowing time and phenology. Promoting greater early leaf area growth in temperate cereals increases transpiration when evaporative demand is low.

Leaf temperature determines the value of e_i , so traits that reduce leaf temperature will help to reduce e_i . Evaporative demand is usually greatest during the second half of the day. Diurnal changes in stomatal conductance, leaf rolling, and other leaf movements may reduce water loss, although they are also likely to reduce carbon gain.

Changing the Leaf Internal CO_2 Concentration

In theory, large gains in W_T are possible for relatively modest changes in c_i .^[5] According to Eq. 3, changing c_i/c_a from 0.7 (a typical value for nonstressed plants of C_3 species) to 0.6 should result in a gain of 33% in W_T , recalling that W_T is a function of $(1 - c_i/c_a)$. Measuring genotypic differences in c_i/c_a is tedious. Thus, any rapid, indirect measure of variation in c_i/c_a has great appeal. Carbon isotope discrimination provides such a measure.^[5,6]

Carbon Isotope Discrimination

Carbon isotope discrimination ($\Delta^{13}\text{C}$) is a measure of the ratio of the stable isotopes of carbon ($^{13}\text{C}/^{12}\text{C}$) in plant material relative to the value of the same ratio in the atmosphere.^[6] Approximately 1% of atmospheric CO_2 contains ^{13}C . Plants of C_3 species contain fractionally less than this, primarily because of discrimination against ^{13}C during two processes: firstly, during diffusion of CO_2 into the leaf through the stomata and, secondly, during the first key step in CO_2 fixation by C_3 plants, catalyzed by the enzyme Rubisco (ribulose-1,5-bisphosphate carboxylase).^[5]

Theory and experimental data indicate that discrimination against ^{13}C is proportional to c_i/c_a (Eq. 4).

$$\Delta^{13}\text{C} = 4.4 + 22.6c_i/c_a \quad (4)$$

Eq. 4 indicates that $\Delta^{13}\text{C}$ and c_i/c_a are positively related, whereas Eq. 3 indicates a negative relationship between W_T and c_i/c_a . Thus, $\Delta^{13}\text{C}$ and W_T should be negatively related.^[5,6] This negative relationship has been confirmed in numerous glasshouse studies with genotypes of several C_3 crop species.^[6,7] Genetic variation in $\Delta^{13}\text{C}$ is substantial in all C_3 crop species tested. It is likely that $\Delta^{13}\text{C}$ is under the control of many genes^[7,9] because low $\Delta^{13}\text{C}$

(high W_T) may result from low stomatal conductance and/or high photosynthetic capacity. Nonetheless, the heritability of $\Delta^{13}C$ has often been found to be high.

Relationships Between Yield and Carbon Isotope Discrimination

Despite the apparent utility of $\Delta^{13}C$, complications have arisen in scaling up from the leaf and plant to W and yield in field stands.^[7–10] There have been few examples where low $\Delta^{13}C$ has been associated with higher yield.^[8,10] Examples with cereals have been studied in environments where rainfall is very seasonal, crops were sown after this rainfall, and crop transpiration has dominated total crop water use. For one species, peanut, field studies consistently show greater biomass production to be associated with higher W_T .^[11] Positive relationships between yield and $\Delta^{13}C$ have been observed in many instances with cereals and other species, contrary to expectations from the negative relationship between W_T and $\Delta^{13}C$ found in the glasshouse.^[7,8,10] Many of these studies have been with temperate cereals in environments where water supply was not a major limitation to growth or in relatively favorable Mediterranean-type environments with substantial rainfall in the pre-anthesis phase.

Several factors could account for the dominance of positive relationships between yield and $\Delta^{13}C$. Low $\Delta^{13}C$ tends to be associated with slower growth rate in the absence of water stress (not the case in peanut). Slow growth rate might be expected if low $\Delta^{13}C$ is associated with low stomatal conductance. Faster crop growth rate associated with high $\Delta^{13}C$ may give a yield advantage if soil water is replenished by rainfall or irrigation or if greater transpiration is compensated by less soil evaporation.^[3,9] Low $\Delta^{13}C$ tends to be associated with lower harvest index and later flowering.^[8,10] A recent study with wheat has shown that many of these associations may be overcome by using back-crossing to transfer low $\Delta^{13}C$ into high-yielding backgrounds.^[10]

CONCLUSION

Maximizing Transpiration

Vigorous early growth to reduce evaporation from the soil surface in favor of transpiration should be targeted in environments where the soil surface is frequently rewetted. Vigorous early growth may risk exhausting soil water reserves too rapidly. Combining earlier flowering with vigorous early growth may help reduce this risk.^[4] An alternative strategy may be to combine faster early growth with higher W_T (low $\Delta^{13}C$),^[10] but achieving the combination may be difficult in practice.

Exploiting Variation in Transpiration Efficiency

Environment and species combinations should be identified for which changes in crop phenology can be made that maximize growth under conditions of low evaporative demand. Promoting vigorous growth at low evaporative demand through effective crop management and targeted breeding will also prove useful, provided consequent risks are minimized.

Exploiting Variation in Carbon Isotope Discrimination

If $\Delta^{13}C$ is to be used for improving crop W_T , it is likely to have ready application in dry environments where transpiration accounts for a large proportion of crop water use.^[8,10] Low $\Delta^{13}C$ is unlikely to be important in environments where a large proportion of water is evaporated from the soil surface unless it can be combined with faster early leaf area growth (see “[Maximizing Transpiration](#)”). More consistent yield advances from selecting for low $\Delta^{13}C$ may be made by identifying those species or genotypes of species in which the association between $\Delta^{13}C$ and crop growth rate is positive, as in peanut. Conversely, it is possible that selection for high $\Delta^{13}C$ may be useful to maximize assimilation rate of C_3 crop species grown in irrigated or moist environments, or if selection for high $\Delta^{13}C$ results in faster canopy growth in short-season environments or where evaporation from the soil surface is substantial.

Wax Esters from Transgenic Plants

Kathryn D. Lardizabal

Monsanto, Calgene Campus, Davis, California, U.S.A.

INTRODUCTION

Wax esters are long-chain linear esters of fatty acids and fatty alcohols. They are commonly found as a component of the cuticle that covers plant surfaces where they help provide protection against stresses such as desiccation, wetting, and pathogen attack. A small number of plants produce and store wax esters in the seed instead of the more commonly found triacylglycerols. These seed storage lipids provide energy for use during germination. Of these plants, jojoba (*Simmondsia chinensis*) is the only one that is commercially cultivated; however, the economics involved in the growth and harvesting of this crop have limited the use of jojoba oil as an industrial feedstock. With the advent of biotechnology, the opportunity arose to overcome this limitation and produce wax esters in a temperate crop, such as *Brassica napus*, which is grown on far greater acreage with more favorable economics. The genes involved in the production of wax esters in jojoba were cloned and introduced into *Brassica napus* in order to produce wax esters transgenically.

WAX BIOSYNTHESIS IN JOJOBA

Jojoba (*Simmondsia chinensis*) produces long-chain wax esters exclusively as a seed storage lipid rather than triacylglycerols.^[1-3] A cross section of developing jojoba embryos reveals the presence of lipid bodies analogous to those present in all oilseeds.^[4] Two proteins are responsible for this biosynthesis.^[5,6] A fatty acyl-CoA reductase (FAR) carries out the four-electron reduction of an acyl-CoA to form a primary alcohol. The enzyme requires NADPH as the electron donor and prefers very-long-chain (C20–C24) fatty acyl-CoA substrates. This preference is reflected in the wax composition of jojoba, where greater than 93% of the fatty acids are C20–C24. Though the reaction proceeds through an aldehyde intermediate, free aldehyde is not released in the process. Next, a fatty alcohol acyltransferase (wax synthase, WS) transfers a second acyl-CoA molecule to the primary alcohol to form the wax ester (Fig. 1). Since the FAR prefers very-long-chain substrates, an efficient mechanism for fatty acid

elongation system is essential.^[7] The endoplasmic reticulum contains such a system, which involves four enzymatic activities; however, the first enzyme, beta-ketoacyl-CoA synthase (KCS), was found to be the rate-limiting and chain-length-determining step.^[8]

IDENTIFICATION OF THE GENES RESPONSIBLE FOR WAX BIOSYNTHESIS

The enzyme activities involved in wax production in jojoba were described in the late 1970s; however, the membrane-associated nature of the proteins hindered their identification for another 20 years. Following cell fractionation of developing jojoba embryos, the activities are found in both the membrane and floating wax fractions. Purification of the proteins was achieved by detergent solubilization of the activities and chromatographic separation of the proteins followed by peptide sequencing and cloning of the corresponding genes.

The jojoba FAR was identified as a 1.7 kb gene that encoded a protein with a molecular mass of 56.2 kD and a pI of 8.76.^[9] Hydrophathy analysis suggested the presence of 1–2 transmembrane domains. Expression of the protein in *E. coli* resulted in the production of a small amount of primary alcohol in the cells. The jojoba FAR was expressed in *Brassica napus* in combination with the KCS from *Lunaria annua*, in order to maximize the substrate available to the enzyme. Low levels of alcohol were detected to about 6%. Further investigation, using nuclear magnetic resonance spectroscopy and GC/mass spectroscopy, showed that a majority of the alcohols were esterified to fatty acids, though the presence of unesterified alcohol indicated the incorporation into wax was incomplete.^[9] This confirmed the ability of the jojoba FAR to produce alcohols transgenically in another plant and also identified the presence of an endogenous wax-ester-forming activity in *Brassica napus*.

The jojoba WS was also purified from membrane fractions.^[10] This enzyme proved to be more versatile, demonstrating activity toward a wide range of acyl-CoA and alcohol (C8–C24; saturated; monounsaturated and polyunsaturated) substrates in *in vitro* assays. It was also more difficult to purify due to its inhibition by detergents

Fig. 1 Wax biosynthetic pathway in jojoba.

and a requirement for phospholipid reconstitution in order to restore enzymatic function. The jojoba WS was identified as a 1.3 kb gene that encoded a protein with a molecular mass of 40.2 kD and a pI of 9.86. Hydropathy analysis suggested the presence of 7–9 transmembrane domains. The jojoba WS was cloned and expressed in the model oilseed plant *Arabidopsis thaliana* in combination with jojoba FAR and *Lunaria* KCS. All three genes were under the control of napin regulatory sequences that directed gene expression to the seed and coordinated the timing of expression to coincide with fatty acid deposition during embryo development. Intact wax levels were determined on seed pools using ^{13}C -NMR. The highest expressing plants stored approximately half of their lipid in the form of wax. Further analysis showed that up to 68% wax was produced in individual seeds.^[10]

Table 1 Data from the first (R1) generation of plants transformed with cDNAs encoding wax biosynthetic enzymes

R1 transformant	% Wax
8559-26	13.79
8559-13	9.91
8559-32	9.10
8559-28	7.85
8559-16	5.82
8559-34	5.05
8559-3	4.71
8559-8	4.36
8559-37	3.24
8559-1	3.24
Reston control	0.22

PRODUCTION OF WAX ESTERS IN *Brassica napus*

Identification of the genes involved in wax production provided the tools necessary to produce wax esters transgenically in a commercial crop. The three-gene construct (jojoba WS: jojoba FAR: *Lunaria* KCS) was transformed into *Brassica napus* var. Reston, and a range of wax levels (0.2–14%) was detected in the transgenic R1 seed pools (Table 1). Single seed analysis of the highest

Fig. 2 The weight percent of very-long-chain (VLC) fatty acids and alcohols of individual half-seeds of transgenic *Brassica* determined by GC analysis is plotted against the estimated weight percent wax determined by GC analysis. Data from the first (R1) generation of seed (8559-13) and data from the second (R2) generation of seed (8559-13-9).

wax-containing lines indicated that up to 33% wax ester and 68% very-long-chain-fatty-acids (VLCFA) were made. Selected lines were advanced to the next generation (R2) where wax ester content increased to 64% and VLCFA content increased to 75%. It is important to note that wax and VLCFA levels for a given population represent an average of the single seed content. In R2 seed, wax levels range from 28–64% with an average of 49%, and VLCFA levels range from 64–75% with an average of 70% (Fig. 2).

CONCLUSION

Overexpression of wax biosynthetic genes (WS, FAR, KCS) in the seeds of *Brassica napus* resulted in the storage of approximately 50% of the lipid as wax ester. In jojoba, these genes contribute to the high levels of wax esters (50–60% by weight of the seed) found there. The proteins encoded by these genes clearly are optimized for this production since wax esters represent the entire stored form of lipid in jojoba seeds. Since acyl-CoAs are the substrates for both wax ester biosynthesis and triacylglycerol biosynthesis, the achievement of a 50% diversion of substrate, in developing *Brassica* seeds, into a novel storage product (wax ester) indicates that the wax biosynthetic enzymes compete efficiently for these substrates. The stored wax ester also appears to be stable and nontoxic to *Brassica* embryos since the seeds can be propagated.

The capacity to produce wax esters resides in the genetic makeup of nearly all plants since they are found as a component of the cuticle. In *Brassica*, expression of the jojoba FAR in combination with the *Lunaria* KCS produced a limited amount of wax ester in the absence of jojoba WS. A similar observation was made in *Arabidopsis*. The source of this wax-ester-forming activity was presumed to come from one or more of the seven genes identified in *Arabidopsis* that share homology to jojoba WS, an indication that these genes are present in *Brassica* and, most likely, other plant species.

Many waxes found in nature are used in the lubricant, food, and cosmetic industries. In particular, jojoba oil is used in cosmetics because of its moisturizing ability, despite its high cost. By demonstrating the production of high levels of wax esters in transgenic *Brassica*, the

possibility for commercial production of wax esters in a temperate crop has become reality.

Weed Management in Less Developed Countries

Peter R. Hobbs

Robin R. Bellinder

Cornell University, Ithaca, New York, U.S.A.

INTRODUCTION

Weeds cause yield losses in both developed and less developed countries (LDCs). The difference between the two groups of countries lies in the degree of technology available to and utilized by farmers. The primary method of controlling weeds in LDCs continues to be hand weeding. Although farmers utilize crop rotations, intercropping, and mulches to suppress weeds, their wives and children, hired laborers, and the farmers themselves continue to hand-weed crops of significant economic value. With the increasing influence of satellite TV, youth in LDCs are becoming disenchanted with the drudgery of farming and are leaving the villages for jobs in urban centers. The cost of hand weeding is escalating and becoming too expensive. LDC farmers are interested in exploring the use of new tillage and mechanical weeding tools, planting strategies, herbicides, and genetically modified crops.

WEED LOSSES

Crop yield losses due to weeds are difficult to estimate because of interactions with insects, diseases, soils, crops, and the environment. Nevertheless, a 10% yield loss is accepted as a global figure.^[1] Pathak et al.^[2] calculated that yield losses in transplanted rice range from 10–50%, and from 50–90% in upland rice.

TRADITIONAL WEEDING STRATEGIES

Since the beginning of agriculture, the major weed-control strategy has been hand weeding, and the same is still true today in most LDCs. Farmers employ family members or hired labor using an array of hand tools that have been developed for local conditions, crops, and weeds present. There are differences in weed control strategies between larger commercial farms and smaller farm households in LDCs. In subsistence situations, farmers rely on family labor for weeding and often use weeds for animal fodder or even as human food. Commercial farmers with larger land holdings use more hired labor and herbicides, be-

cause with them weed control is easier and less costly. LDC farmers, subsistence and commercial, do understand the need for integrated weed control and use crop rotations, mulches, stale seedbed systems, water, and in some cases herbicides to control weeds.

Although hand weeding is a traditional system, it is also tedious, grueling, and often done by resource-poor labor, especially women and children. In a way, it perpetuates poverty because the employment opportunities it provides hardly compensate for the labor and the long hours in the field (Fig. 1). Crops that receive the highest priority for hand weeding in LDCs are high-value vegetables, paddy rice, and row crops like maize, cotton, and sugarcane. Estimates of time and cost for hand weeding vary depending on weed populations present, when the crop is grown (wet or dry season), and labor availability. Average figures for rice are 30–40 labor-days per hectare, with more for maize and less for wheat. Labor rates also vary with country but are usually below one U.S. dollar per day. It is estimated that one-third to one-half of the labor in rice production is for weed control. With young male labor migrating to cities in search of less tedious and better paying jobs, labor rates for weeding are increasing, making this method of weed control less and less profitable. This same phenomenon happened in developed countries at the time of the Industrial Revolution.

INTEGRATED WEED-CONTROL SYSTEMS

In many LDCs, especially in the tropics, slash-and-burn agriculture is still practiced. As soil fertility declines and weeds increase, farmers abandon land and let it rejuvenate while they move to new, reclaimed land. As agriculture becomes less mobile and farming concentrates on the same piece of land, integrated weed-control systems are needed. In situations where the same crop is grown repeatedly, weeds specific to that system will start to predominate and require control. In the rice–wheat areas of South Asia, where continuous cereal production is practiced, the grassy weed *Phalaris minor* has proliferated and created problems for control, including development of resistance to herbicides.^[3,4] Farmers are aware of this problem, and as hand-weeding labor becomes more

Fig. 1 The tedious nature of agriculture in developing countries: (A) Woman threshing, (B) Women transplanting rice, (C) Men handweeding. (View this art in color at www.dekker.com.)

costly, many decide to change crops, introducing ones that will better compete with existing weeds. An example of this change is using sugarcane in the rice–wheat rotation in South Asia. Similarly, use of a fodder crop that is cut multiple times can help keep weeds under control. Sieving is another tool for weed control because it effectively separates weed and crop seeds (Fig. 2).

Tillage is another practice designed to control weeds. Using a stale seedbed approach, the first flushes of weeds germinate, and are then plowed down before planting the crop. However, tillage also brings more seed to the surface, enabling germination simultaneously with the crop. There is a movement to introduce new systems that reduce tillage in LDCs^[5] which will require innovative integrated weed management strategies. However, it has been shown that when zero-till wheat follows paddy rice, fewer weeds germinate than in conventional tillage.^[6] Mechanical weeding also can be introduced to control weeds after germination if crops are line-sown in straight

rows. In some LDCs where crop or farm residues are available, farmers use mulch to suppress weeds. However, crop residues are valuable for animal feed, cooking fuel, or thatching and may not be available for weed-control. Selection of competitive varieties is another integrated weed control factor.

Rice is a major crop in LDCs, and there are many ways to grow rice. When it is grown under upland conditions like other cereal crops, weeds are a major problem and cause low yields. Tillage is commonly combined with hand weeding to control weeds in dryland rice. Competitive rice varieties are also favored since they are less affected by weeds. However, most rice in LDCs is grown under lowland conditions, where seedlings are raised in separate beds, uprooted, and then transplanted into soils that have been puddled (plowed when wet). Puddling restricts water percolation so that water can be ponded more easily in the field, and standing water is then used to control weeds. However, new weeds appear under this

Fig. 2 Sieving and mechanical weeding in developing countries: (A) Sieving out weed seed, (B) Rotary weeder in use, (C) Rotary weeders on display. (View this art in color at www.dekker.com.)

Fig. 3 Traditional (one-nozzle) spray boom (left) and improved (three-nozzle) spray boom (right). (View this art in color at www.dekker.com.)

system and will need to be controlled as weed populations shift. Some farmers plant rice seedlings in rows so that mechanical weeding can be done between rows, using simple, locally manufactured rotary weeders (Fig. 2). Additionally, most rice growers in LDCs will hand-weed the crop at least once, and many do so twice, with 30–40 workdays per hectare commonly needed for weeding. This labor-intensive job is often done by female workers and children.

HERBICIDE USE IN LDCs

Herbicides are also used in LDCs to complement other weed control measures. Use of low-dose herbicides followed by hand weeding can be very effective and less costly than using only hand weeding. Herbicides are used quite extensively in LDCs for transplanted, puddled rice. These are frequently granular formulations that are mixed with soil or sand and spread by hand. Isoproturon (for wheat in South Asia) and butachlor (for rice) are both mixed and applied this way. In many instances herbicide efficacy is variable, and in some cases poor, because of the lack of proper spray equipment and poor knowledge of proper herbicide application methods, with non-uniform distribution as a result. Many farmers apply herbicides the same way they apply insecticides and other plant protection chemicals—with single nozzle booms (Fig. 3). Spray coverage is poor, with many missed plants. What is urgently needed is instruction in how to apply herbicides. Farmers need training in the use of proper nozzle tips, multiple nozzle booms^[7] that can be made locally (Fig. 3), and pressure regulators that will improve application uniformity and accuracy. Safety issues and health hazards

also need to be part of the training program for farmers and applicators.

GM CROP USE

Herbicide-resistant GM crops (maize, rice, canola, wheat, and sunflower) are not presently grown in LDCs, although interest among farmers is high. Farmers want to reduce the drudgery of farming, including weeding. Governments are wary of the implications that growing GM crops might have for their export markets and so are waiting to see how global markets adapt to these crops. Several LDCs, such as China and India, have invested heavily in research so they are ready with GM crops when acceptance is assured. These crops would be a boon to farmers in LDCs because they would enable farmers to overcome one of the most arduous tasks in farming, that of hand weeding. Direct-seeded rice would be much more feasible and would mean that rice farmers would not have to degrade their lands through puddling, which would contribute to more environmentally sustainable production systems over time.

CONCLUSION

Farmers in LDCs, like farmers in any country, are aware of the losses in yield from weeds. They have traditionally used hand weeding as the major means to control them, but as costs for labor increase and young laborers shun the drudgery of agriculture, alternative integrated systems—including the use of herbicides and herbicide-resistant crops—will be welcomed by LDC farmers, just as they are by commercial farmers in developed countries.

The key to their use and success will be the availability and proper training in their use.

Weed Management in Organic Cropping Systems

Ilse A. Rasmussen

Danish Institute of Agricultural Sciences, Slagelse, Denmark

INTRODUCTION

The aim of this review is to provide an overview of weed control methods available for organic farming systems based on research mainly from Europe and North America, but measures mentioned here are not necessarily allowed in organic farming. Biological control of weeds is not considered in this review.

BACKGROUND

Synthetic herbicides are not allowed in organic farming systems.^[1] Therefore weed management relies on a combination of preventive measures and direct control to prevent severe yield losses because of weeds. Because the obtainable efficacy of each preventive or direct weed control method is lower than in conventional weed management systems, weed management measures must be combined and planned, not only for the current crop but for a number of years covering the whole crop rotation system.^[2] The crop rotation system is primarily determined by choice of crops, which is in turn determined by, first, the type of farm (feed production for animals, cash crops, horticultural crops, etc.)^[3] and, second, by the level of weed infestation in the fields.

PREVENTIVE METHODS

Preventive as well as direct control measures can be used at many points in the cropping cycle and thus affect weed population dynamics at different growth stages (Fig. 1). The main target for each measure is listed in Table 1. However, impact on any one phase will influence the next or all the following phases (e.g., increased crop competitiveness will decrease weed biomass, which will in turn reduce weed propagation, resulting in a reduction of new propagation structures into the soil and, consequently, reduction of weed infestations in succeeding crops). Different preventive weed control strategies are currently available and will be described in the following sections.

Increasing Crop Competitiveness

Crops and weeds compete for light, water, and nutrients. The farmer can assist the crop in competition by a range of measures. In cereals, varieties with a taller canopy, faster growth rate, or denser canopy may reduce weed biomass by as much as 25%.^[4] Attributes such as early and deep rooting pattern,^[5] early vigor, larger leaf size, and allelopathic ability further increase cultivar competitiveness.^[2] Giving crops, rather than weeds, better access to nutrients augments crop competitiveness. Because most annual weeds germinate from the top few centimeters of the soil,^[6] nutrients broadcast on the top of the soil, or worked into the top 5 cm, will give the weeds equal opportunity to utilize these nutrients together with the crop. Nutrients placed with precision in relation to the crop seed can be utilized by the germinating crop earlier and more efficiently than by the weeds, resulting in up to 50% reduction in weed biomass.^[4] Higher crop density results in better competitiveness of the crop.^[7] Crops planted in rows allow for weeds to utilize the light between the rows, whereas crops that are uniformly distributed are better at competing with the weeds, resulting in a 30% decrease in weed biomass.^[7] Crop plants that emerge earlier than weed plants have an advantage in competition,^[2] whereas the opposite is the case if the weed emerges first.^[8] The seedbed or planting bed should be made for the best establishment of the specific crop,^[2] and crop seeds, which have high vigor and germination capacity, should be used.^[9] Growing different crops such as cereals and pulses together can augment crop competitiveness, although weed suppression alone is unlikely to justify this strategy.^[2]

Reducing Numbers of Weed Propagation Structures

The density of weeds found in a crop is proportional to the density of weed propagation structures present in the soil. The density can be decreased by reducing input, which can be attained by controlling the weeds through added competition or mortality before they mature. A second option is to remove or destroy reproductive structures by harvesting the crop before the maturity of the weed seeds

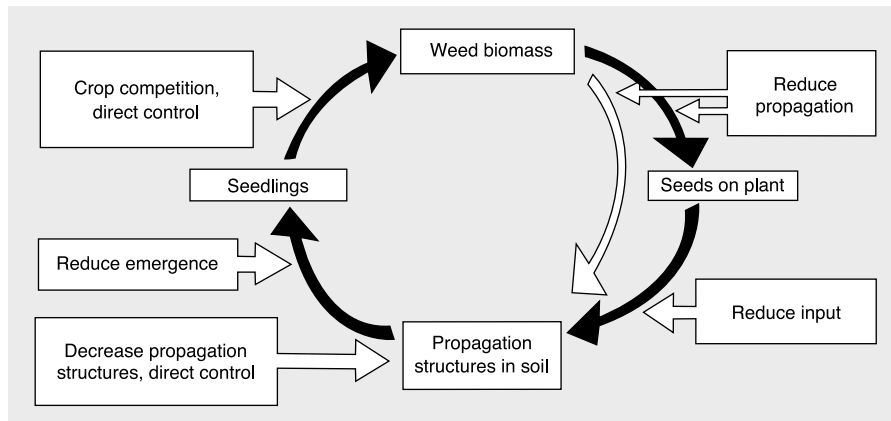

Fig. 1 Population dynamic cycle of weeds showing major life stages (boxes connected by filled arrows; open arrow: perennial weeds) and points of possible prevention or direct control (boxed arrows). Perennials may propagate both sexually and asexually. (View this art in color at www.dekker.com.)

(e.g., silage), by cutting off the flowering weeds above the crop,^[2] or by collecting the weed seeds together with the crop seeds at harvest. However, weeds often mature before the crop, and a large proportion of the seed may be shed before harvest. A third option is to leave seeds shed on the ground undisturbed, as these are then at risk: if they are not dormant, they may germinate and be destroyed at the next tillage operation; they may be eaten by wildlife or other fauna; or they may lose their viability in other ways.^[2] Thus the input to the soil seed bank from the seed shed can be reduced by leaving the field untouched as long as possible because tillage will incorporate the seeds on the soil surface.^[2] Burial of the seeds by tillage can induce dormancy and prolong their persistence, depending on species.^[2] New input of seeds with machinery, etc. should be avoided. Finally, cover crops intercropped with the main crops can compete with the weeds where the soil would otherwise be bare, thus reducing weed propagation.^[2]

Reducing the Emergence of Weeds in the Crop

Many weed seeds have a requirement for light to germinate.^[2] Soil tillage can supply many weed seeds with the required light stimulus. To avoid this, soil tillage operations preceding sowing can be carried out in the darkness, or by covering the tillage implement to prevent light from reaching the soil. This technique has reduced weed seed germination in experiments by up to 70%.^[2] Steam kills weed seeds, and steaming over the row prior to sowing or planting row crops reduces the density of weeds in the row.^[9] Mulching with cover crops, plant residues, or covering material such as paper or polyethylene prevents germination.^[2] Weeds have specific germination

patterns over the seasons according to species, and delayed sowing time in winter cereals decreases weed biomass by up to 75%.^[4] Investigations indicate that perennial crops such as grass and clover mixture reduce weed emergence in the following crop.^[10] The reasons for this could be a combination of weed seed mortality and the lack of new weed seed input in the grassland, better nitrogen availability for the following crop, or allelopathic effects of the grass and clover residues.

Avoiding Propagation

Some weeds are particularly well adapted for propagation in specific crops. Typical weed problems may result from repeated cultivation of one crop in the rotation. Crop rotations with alternation of crops with different life cycles (annual or perennial, spring-sown or autumn-sown, early harvest or late harvest, broadcast or row crops, fertility building or fertility-depleting crops) help to avoid this problem.^[11] Computerized models can aid in the understanding of the effect of crop rotation and other interventions on the population dynamics of weeds.^[12]

DIRECT CONTROL METHODS

In Crop

Direct control in the crop must be carried out in such a way that either the implement or the way it is used is selective, so that the weeds are killed whereas the crop is not. This ideal situation is not always possible. In row crops, weed control can be carried out between the rows without damaging the crop. Total control can be achieved in that part of the field where there are no crops, but this

leaves weeds growing within crop rows unaffected. Flaming can be used to kill weeds that emerged earlier than the crop in crop rows or in heat-tolerant crops.^[2] Implements that work very close to the crop plants in the rows are being developed, such as finger weeders and torsion weeders. Hand weeding, hand hoeing, and rousing are still important methods in high-value row crops. In broadcast crops, control can be carried out by a spring-tine harrow. If the crop plants are larger than the weeds, the weeds will be damaged more by the harrow.^[13] Crops have different sensitivities to disturbance; monocots such as cereals are less sensitive than dicots, and high crop density in the rows causes the tines to move away from the rows, thereby making the control selective.^[13]

Uncropped Soil

When there are no crops, such as after harvest or before sowing, there is ample opportunity to carry out direct weed control, as there is no crop that can be damaged. This is used in a false seedbed, where a seedbed is prepared 1–2 weeks prior to sowing, and germinating weeds are killed before the actual sowing of the crop,^[2] in fallow, where a cropping season, or part of one, is used for intensive cultivation against perennials as well as annuals,^[2] and in stubble cultivation and tillage against perennial weeds, including plowing.^[2]

CONCLUSION

Weed management in organic farming systems is based on a combination of preventive and direct control measures, and the success of weed control depends on this combination. Future prospects include better understanding of weed population dynamics, so that the long-term effects of different weed management strategies can be predicted and new methods for more precise direct weed control can be developed.

Weeds in Turfgrass

John C. Stier

University of Wisconsin, Madison, Wisconsin, U.S.A.

INTRODUCTION

Weeds are the primary pest problem in most turf areas, particularly in lawns. Cultural management including mowing, fertility, and irrigation, along with site and turfgrass species selection, can be used to minimize most weed problems. Herbicides are used for both pre- and postemergent weed control although relatively few active ingredients are available compared to compounds used in conventional agriculture.

IMPORTANCE OF TURF

Turf is a contiguous community of plants, usually grasses, that can withstand routine defoliation (mowing) and traffic. Turf acreage is increasing in the United States, with approximately two-thirds in home lawns. No reliable figures exist for determining the value of turf but the industry is actively growing and annual management inputs are at least \$20 to \$30 billion.^[1] In 1999, turf maintenance costs for Wisconsin's 486,000 hectares (ha) were 1.9 billion.^[2] The social and environmental benefits of turf include green space for relaxation and recreation, reduction of stormwater runoff and groundwater recharge, pollutant absorption, dust and erosion control, and oxygen production (Fig. 1).^[3]

WEED CONCERNS IN TURF

Unlike agronomic crops, turf is grown for quality, not yield. Thus, weed tolerances are typically low and an aesthetic rather than an economic threshold is used for justifying weed control measures. Weeds are the major pest in lawn areas but on golf courses are less important than diseases. Weeds may pose health hazards directly, as in poison ivy or sandburs when in flower, and indirectly through poor traction on athletic fields or as allergens when in flower.

TYPES OF WEEDS

Most turf weeds are herbaceous, low-growing plants, because mowing prevents high-growing weeds. Turf

weeds include both dicots (broadleaves) and monocots (grasses and sedges). Most are perennials, although a few annuals such as annual bluegrass (*Poa annua* L.) and crabgrass (*Digitaria* spp.) are ubiquitous and survive in many well managed turfs. Desirable turfgrasses may be considered weeds when they occur in swards of a different species.

WEED MANAGEMENT

The purpose of a turf dictates weed acceptance levels. A highway median has up to 100% weed tolerance, whereas a golf course putting green has near zero weed tolerance.

Cultural Management

Many weeds can be avoided by using certified, weed-free seed and mulch for establishment. Imported topsoil may contain weed propagules such as quackgrass (*Elytria repens* L.) rhizomes and seeds. The establishment period allows many types of weeds to develop and may cause the seeding to fail because weed seeds germinate and establish faster than most turfgrasses. Weed problems are minimized by planting cool season grasses in late summer/early fall and warm season grasses in spring. Weeds often can be avoided for years if a good quality sod is used for establishment.

The key to weed management is to grow a thick, dense turf. Good mowing and fertility practices will reduce up to 90% of potential weed problems, especially if irrigation is supplied. Mowing stimulates hormones that encourage tillering and leaf growth. Each turf species has an optimal mowing height range to achieve vigorous growth and high turf density. Mowers should be set so that no more than one-third of the leaf tissue is removed at any one mowing to prevent scalping. Scalping opens the canopy for weed seed germination or development of new plants from existing vegetative propagules of weeds (e.g., rhizomes and stolons). Nitrogen (N) is almost always the limiting element for turf growth. High-quality turf requires 96–192 kg N per ha, applied incrementally during the growing season to achieve balanced turf growth with high density. This is approximately 1/7 to 1/4 of the N required for maximum growth. Potable water is best for irrigation to

Fig. 1 Weed management in turf is increasing due to urbanization and involves lawns, roadsides, and recreational areas. (View this art in color at www.dekker.com.)

avoid salts that may desiccate the turf. On average, turf uses about 2.5 cm water weekly through irrigation, precipitation, or soil moisture withdrawal.

Weed identification is used to select appropriate chemical controls and to diagnose underlying problems that may be corrected to prevent future weed development.^[4] Crabgrass infestation is often due to scalping in the spring. Quackgrass, ground ivy (*Glechoma hederacea*), and other weeds invade dry soil whereas many sedges prefer moist soils. Prostrate knotweed (*Polygonum aviculare* L.) indicates soil compaction, red sorrel (*Rumex acetosella* L.) indicates acidic soil, and legumes such as white clover (*Trifolium repens* L.) indicate N-deficient soil.

Biological Controls

Few if any practical biocontrol options for turf weeds exist. A bacterial wilt disease caused by *Xanthomonas campestris* showed promising results in laboratory tests but was relatively ineffective in field trials.^[5] Corn gluten meal offers promise as a preemergent herbicide but in current form the effects are ephemeral, timing and moisture are crucial, and high rates may be required.^[6]

Chemical Controls

The types and classifications of chemical controls are similar to those used in agronomic crops (Table 1); however, fewer active ingredients are available because manufacturers typically have little financial incentive to support labels for what is essentially a minor use. Homeowners have access to most of the active ingredients available to professionals, although concentrations and

formulations may differ. Preemergent herbicides are used to prevent establishment of new weeds (primarily annuals) from seed. Most weed control is performed postemergent, particularly for perennial broadleaf weeds. Relatively few contact herbicides are used because most problem weeds are perennials that require a systemic herbicide. Liquid products often are more effective than granules, although granules are often perceived as being safer for use. Many granular products are formulated as a combination of fertilizer and herbicide for either pre- or postemergent weed control.

A common perception exists that turf requires a large amount of pesticides, especially herbicides, although in fact herbicides often are used in lieu of proper cultural management practices that could reduce the need for herbicides. Golf course purchase of herbicides for 1995/96 was just over \$60 million, whereas \$130 million was spent on professional lawn care.^[7] Data on product purchases by homeowners are unavailable, but likely meet or exceed that used by professional lawn care because only about half of the 22% of home lawns treated with pesticides utilize a professional service.^[7] Adoption of integrated pest management practices has led to many of the post-emergent liquid herbicide applications used as spot treatments to individual weeds or patches rather than broadcast applications.

Another common perception is that herbicides are readily leached or lost in runoff from turf surfaces. Data from multiple research projects since the 1980s indicates that relatively little herbicide applied to dense turf

Table 1 Commonly used turf herbicides

Common name	Timing	Target weeds
Benfen	Pre-emergent	Annual grasses
Bensulide	Pre-emergent	Annual grasses
Pendimethalin	Pre-emergent	Annual grasses
Prodiamine	Pre-emergent	Annual grasses
Siduron	Pre-emergent	Annual grasses
Dithiopyr	Pre-(post)-emergent	Annual grasses
Basagran	Post-emergent	Sedges
Clopyralid	Post-emergent	Perennial broadleaves
Dicamba	Post-emergent	Perennial broadleaves
Glufosinate	Post-emergent	Herbaceous annuals
Glyphosate	Post-emergent	Herbaceous annuals and perennials
Halosulfuron	Post-emergent	Sedges
MCPA	Post-emergent	Perennial broadleaves
MCP	Post-emergent	Perennial broadleaves
2,4-D	Post-emergent	Perennial broadleaves
2,4-DP	Post-emergent	Perennial broadleaves
Triclopyr	Post-emergent	Perennial broadleaves

(<1%) is capable of leaching to groundwater.^[8] Runoff losses may be potentially higher, although less than 15% of water soluble herbicides applied to short-cut golf course fairways are likely to run off, even under worst-case scenarios.^[8] Higher mowing heights and thatch further reduce leaching and runoff due to higher runoff resistance and the pesticide-binding capacity of organic matter in the turf.^[3,9,10] Mowed turfgrasses provide a dense turf cover of 75 million to >20 billion shoots per hectare. Kentucky bluegrass (*Poa pratensis* L.), commonly used for lawns, can have up to 16,000 kg per hectare of root biomass.^[3] Soil type, soil saturation, timing of precipitation or irrigation following application, application rate, water solubility, and adsorption to organic matter can substantially affect the amount of herbicide in leachate or runoff.

THE FUTURE

A few lawn care companies have programs to meet the small but growing demand for organic lawn care. No legal definition of organic lawn care exists. Consequently, organic lawn care relies on naturally occurring fertilizers (e.g., composted sewage sludge or manure) and avoids synthetic chemicals. Because increased pesticide restrictions are limiting the development of new synthetic chemicals, the development of natural products for weed control is expected to grow.

CONCLUSION

Turf acreage is expanding as the population grows and turf maintenance has a tremendous economic impact in urbanized states. Weeds are usually the greatest pest problem in turf. Most weed problems can be managed using practices that develop a thick turf sward. Herbicides are used for weed control in all types of turf in either liquid or granular products, sometimes in combination with fertilizer.

Wheat Rusts

James A. Kolmer

United States Department of Agriculture—Agricultural Research Service and
University of Minnesota, St. Paul, Minnesota, U.S.A.

INTRODUCTION

The rusts of wheat (*Triticum aestivum* L.) are among the most common and important diseases of wheat on a worldwide basis. Wheat stem rust is caused by *Puccinia graminis* f. sp. *tritici*, leaf rust is caused by *Puccinia triticina*, and stripe rust is caused by *Puccinia striiformis* f. sp. *tritici*. When wheat cultivars are fully susceptible and the weather is ideal for repeated cycles of rust infection, wheat rusts can cause severe loss of yield, sometimes destroying whole fields of wheat. The three wheat rusts are genetically diverse, consisting of many different pathogenic races. Widespread use of wheat cultivars with specific rust resistance genes selects races of wheat rusts that have virulence to the resistance genes, resulting in rapid changes in rust races. Wheat cultivars that are resistant when initially released can lose their resistance because of the selection of these virulent rust races. Sources of partial resistance to the wheat rusts that appear to be race non-specific are available and offer long-lasting, economical control of these important diseases.

WHEAT RUST LIFE CYCLE

The rust diseases of wheat are spread over large geographical areas by means of air-borne urediniospores (Fig. 1). Urediniospores are pigmented, dikaryotic (have two haploid nuclei, $n+n$), and are the epidemic stage of the disease on wheat. Urediniospores germinate and infect wheat plants when temperatures are mild, and the leaves and stems are wet with dew or rain. The urediniospores produce specialized infection structures (appressoria, germ tube, and penetration peg) that enable the spores to penetrate the host plant stomata.^[1] After formation of a substomatal vesicle, specialized haustoria are formed, which are used to obtain nutrients from within mesophyll cells without killing them. Infectious hyphae of the fungus spread throughout the mesophyll tissue layer, resulting in the formation of additional haustoria. Rust infections on wheat leaves become visible as faint flecks within 3–4 days after the initial infection. By 8–10 days following infection, dark sporulating pustules called

uredinia (Fig. 1) erupt and break through the epidermis of the wheat plant. Each uredinium can produce from 3000 to 10,000 urediniospores per day.^[2] Freshly produced urediniospores are carried by wind to new sites on the same plant or to different plants, where each new spore has the potential to infect the host plant. The explosive nature of rust epidemics results from the exponential increase in uredinial infections in the early stages of the epidemic. As the uredinia age, teliospores are formed among the urediniospores in the uredinia.^[1] Eventually, only teliospores are formed in the uredinia. Teliospores are dark, thick-walled, and have two cells. Each cell in the teliospore is initially dikaryotic ($n+n$). Later in development, the nuclei fuse to form a diploid ($2n$) nucleus, which undergoes meiosis as the teliospore germinates. The teliospores are resting structures, which are used for overwintering, as in the case of *P. graminis*, or for oversummering, as in the case of *P. triticina*. The teliospores survive the winter or summer on wheat straw stubble, and germinate the following spring or fall. Each cell of the teliospore can produce a curved, four-celled promycelium, which produces four haploid (n) basidiospores. The basidiospores are clear and hyaline. Basidiospores are ejected from the promycelium and carried to short distances by wind to infect the alternate host. Because basidiospores are incapable of infecting wheat plants, alternate hosts must be present in the local vicinity for the wheat rusts to complete the sexual cycle. In North America, the three wheat rusts survive asexually in the uredinial stage by alternating between winter wheat and spring wheat or susceptible grasses because susceptible alternate hosts are usually not present. Each basidiospore infection on the alternate hosts produces haploid structures called pycnia, which appear as circular, yellow pustules on the upper leaf surface. The pycnia produce minute pycniospores and flexuous hypha that are haploid. Pycniospores are carried by insects or water to the flexuous hyphae present in other pycnia. The wheat rust fungi are heterothallic, with two different mating types.^[3] The transfer of nuclei from pycniospores to flexuous hyphae (plasmogamy) occurs with compatible combinations of mating type.^[1] After fertilization, aecia develop on the underside of the leaf beneath the pycnial infections, and eventually form clusters or cups that produce

Life Cycle of *Puccinia* spp. on Wheat

Fig. 1 Life of cycle of *Puccinia* spp. pathogenic to wheat. (View this art in color at www.dekker.com.)

dikaryotic aeciospores. The aeciospores are wind-dispersed and infect wheat plants in the same manner as urediniospores. Infections resulting from aeciospores give rise to the production of uredinia on the wheat plants, completing the life cycle and initiating the asexual spore stage. The origin, specificity, structure, and physiology of wheat rusts have been previously reviewed.^[4] The distribution, epidemiology, and control of the three wheat rust diseases have also been reviewed.^[5]

WHEAT STEM RUST (*P. GRAMINIS* PERS.: PERS. F. SP. *TRITICI* ERIKSS. AND HENN.)

Stem rust is potentially the most destructive rust of wheat. In North America, continent-wide epidemics occurred periodically from 1900 to 1954, which caused huge losses in wheat yields. In the state of Minnesota in the United States in 1953, 75% of the durum wheat crop was lost, and in the province of Manitoba in Canada, 40 million bushels of wheat were lost to stem rust.^[6] Stem rust is found mostly in regions with a continental climate where summer temperatures regularly reach 25–35°C. The optimum temperatures for infection and growth are

20°C and 30°C, respectively. Stem rust has been a major disease of wheat in North America, the southern cone of South America, continental Europe, the Indian subcontinent, Australia, and China.^[2] Although harmful at all times to wheat, stem rust has the potential to be very destructive late in the growing season. Crops within a few weeks of harvest can be devastated by infections of stem rust that prevent grain filling. Stem rust urediniospores are dark red (Fig. 2), and uredinial infections are found mostly on the stem, although uredinia can also form on the leaves and leaf sheaths. Host specificity in rust fungi was first demonstrated in stem rust.^[7] Different isolates of *P. graminis* f. sp. *tritici* derived from single urediniospores had different infection types of uredinia when tested on a set of wheat cultivars that differed for stem rust resistance genes. In North America, the alternate host, common barberry (*Berberis vulgaris* L.), was largely eradicated during the 1920s to the 1950s.^[8] Elimination of the sexual cycle has reduced the number of stem rust races present in North America. Stem rust has been successfully controlled throughout most of the world by cultivation of wheats that have high levels of resistance provided by stem rust resistance genes. Over 40 *Sr* (stem rust resistance) genes have been identified;^[9] however, many of the genes do not

Fig. 2 Stem rust of wheat caused by *P. graminis* f. sp. *graminis*. (From Ref. [9]. ©CSIRO Australia, 1995.) (View this art in color at www.dekker.com.)

provide resistance because races with virulence to many genes are common. Wheat cultivars with *Sr2* and *Sr31* have been resistant worldwide because stem races with virulence to these genes have only rarely been found.

WHEAT LEAF RUST (*P. TRITICINA* ERIKSS.)

Leaf rust is the most widely distributed and regularly occurring of the wheat rusts. In North America, leaf rust occurs annually almost wherever wheat is cultivated. Leaf rust is also a major disease of wheat in the southern cone of South America, western and central Europe, the Middle East, central Asia, and parts of the Indian subcontinent.^[2] Leaf rust can also be an important disease in Australia and China. *P. triticina* is also referred to as brown rust of wheat. In North America, annual losses because of leaf rust usually range from 2% to 10%. Leaf rust is most destructive in climates with fall and winter temperatures that allow the rust to infect fall-sown wheat and survive the winter as mycelial infections. Warm temperatures in the spring allow leaf rust infections to sporulate and increase while the wheat crop is breaking dormancy. This leads to heavy infections of the flag leaves before the plants have headed, resulting in severe crop loss. Leaf rust can also be severe on spring-sown wheat in regions that have summer temperatures of 20–30°C. The optimum

temperatures for infection and growth are 20°C and 25°C, respectively.^[2] Leaf rust urediniospores are dark brown red (Fig. 3), and the uredinia are found on leaves and leaf sheaths. The alternate hosts *Thalictrum speciosissimum* Loefl. and *Isopyrum fumarioides* L. are found in southern Europe and northeast Asia, respectively. However, almost all *P. triticina* populations reproduce by asexual reproduction of urediniospores because susceptible alternate hosts are usually absent. Despite the lack of a sexual cycle, *P. triticina* populations are highly diverse for virulence to leaf rust resistance genes in wheat.^[2] The wide range of adaptation of *P. triticina*, combined with the many different races that exist, has made long-lasting or durable leaf rust resistance in wheat difficult to achieve. Over 50 *Lr* genes in wheat have been described, but few condition effective resistance. However, wheats with resistance gene *Lr34*, combined with other genes, have been shown to have durable resistance to leaf rust.^[9]

WHEAT STRIPE RUST (*P. STRIIFORMIS* F. SP. *TRITICI* WESTEND.)

Stripe rust is a major disease in wheat-growing areas of the world where temperatures remain cool and moderate during the growing season. The stripe rust fungus has optimum temperatures of 11°C and 13°C, respectively,

Fig. 3 Leaf rust of wheat caused by *P. triticina*. (From Ref. [9]. ©CSIRO Australia, 1995.) (View this art in color at www.dekker.com.)

Fig. 4 Stripe rust of wheat caused by *P. striiformis*. (Courtesy of the University of Sydney, Plant Breeding Institute, Cobbitty.) (View this art in color at www.dekker.com.)

for infection and growth, which limits the distribution of the disease.^[2] Wheat stripe rust is an important disease in northwest Europe, China, parts of Central Asia, the Middle East, and the west coast of North America. *P. striiformis* f. sp. *tritici* is also referred to as yellow rust of wheat. Stripe rust occurs sporadically in the Great Plains and eastern regions of North America, the southern cone of South America, Australia, and the Indian subcontinent. Stripe urediniospores are yellow (Fig. 4), and the uredinia are found on leaves in distinct rows between the leaf veins. Wheats that are heavily infected with stripe rust can suffer severe losses. Stripe rust is also unique because an alternate host for *P. striiformis* f. sp. *tritici* has never been found. Although the stripe rust fungus lacks a sexual cycle, it is highly diverse for virulence to stripe rust resistance genes (*Yr* genes) in wheat.^[2] Mendelian inheritance of disease resistance in plants was first described with wheat stripe rust^[10] and over 30 genes have been identified for resistance.^[9] However, the variable nature of *P. striiformis* f. sp. *tritici* populations has rendered many stripe rust resistance genes ineffective. Wheats with resistance gene *Yr18*, combined with other genes, have been shown to have durable resistance to stripe rust.^[9]

CONCLUSION

Wheat rusts are challenging plant pathogens. Although stem rust has been successfully controlled by resistant wheat cultivars, epidemics of leaf and stripe rust occur regularly in many different regions of the world. Development of rust-resistant wheat cultivars and research on the biology and genetics of wheat rust fungi need to continue to reduce losses to these devastating and recurrent diseases.

Yeast Two-Hybrid Technology

Lisa Nodzon

Wen-Yuan Song

University of Florida, Gainesville, Florida, U.S.A.

INTRODUCTION

Over the past decade, protein–protein interactions have drawn broad attention because most cellular proteins function through association with other proteins, and the networks formed by protein complexes control most biological processes. To study protein–protein interactions, a number of technologies have been developed. Among them, the yeast two-hybrid system appears to be a relatively simple, yet powerful tool. This system has recently been used to detect interactions between thousands of protein pairs in the model organism yeast.

MECHANICS OF THE YEAST TWO-HYBRID SYSTEM

The two-hybrid system, performed within the yeast *Saccharomyces cerevisiae*, takes advantage of the independent domains present in many transcription factors, such as the yeast Gal4 protein. The two physically separable, functionally independent domains are a DNA-binding domain and a transcription activation domain.^[1] The DNA-binding domain targets the transcription factor to a specific promoter sequence (known as the upstream activation sequence (UAS) in yeast), whereas the activation domain recruits the transcription complex for initiation of transcription. A mutant transcription factor lacking either one of the two domains fails to activate transcription of the downstream gene driven by the promoter. The independence of the two domains was shown when early investigators revealed that a hybrid transcription factor could be reconstituted in yeast cells by fusing the Gal4 DNA-binding and the Gal4 transcription activation domains to two physically interacting proteins, respectively (Fig. 1).^[3] To demonstrate activity of the hybrid transcription factor, a reporter gene, such as the bacterial *lacZ* gene, driven by a promoter containing the UAS where the Gal4 DNA-binding domain interacts, was also introduced into the cells. The *lacZ* gene encodes the β -galactosidase enzyme that can hydrolyze the colorless substrate 5-bromo-4-chloro-3-indolyl- β -D-galac-

toside (known as X-gal) and generate a blue product. Thus, the formation of blue yeast colonies in medium containing X-gal is indicative of reconstitution of a functional transcription factor by the interaction of the two proteins that bring the Gal4 DNA-binding and activation domains into proximity. These studies led to the establishment of the yeast two-hybrid system.^[3]

The original yeast two-hybrid idea has been applied to screening of cDNA libraries to identify proteins (commonly called “prey”) that interact with a given protein (also called “bait”). The cDNAs are cloned into a Gal4 activation domain vector to generate translational fusions (prey) of the library proteins to the Gal4 activation domain. In addition to *lacZ*, a nutritional selection reporter, such as the yeast *HIS3* gene, is placed under the control of a Gal4-responsive promoter. *HIS3* encodes imidazole glycerol phosphate dehydratase, an enzyme involved in the biosynthesis of the amino acid histidine. Yeast strains with mutations in the *HIS3* gene are unable to survive on medium lacking histidine supplementation. To carry out two-hybrid screening, the prey library is transformed into the *his3*[−] mutant that expresses the bait protein and carries an engineered *HIS3* gene driven by a Gal4-responsive promoter.^[4] The transformed cells are then selected onto medium lacking histidine. The physical association between the bait and a prey activates transcription of the *HIS3* gene, allowing the transformed cells to grow and form colonies in the absence of histidine. To confirm the interaction identified by the *HIS3* reporter, the selected cells can be subjected to an assay for β -galactosidase activity using the chromogenic substrate X-gal.

USING THE YEAST TWO-HYBRID SYSTEM TO DISSECT PLANT SIGNAL TRANSDUCTION PATHWAYS

Yeast two-hybrid screens have been used to identify proteins involved in plant signal transduction pathways that regulate plant defense and development. The *Arabidopsis* protein RPM1 confers resistance to the bacterial

Fig. 1 Diagram of the yeast two-hybrid system. Interaction of the bait and prey proteins brings the DNA-binding domain (BD) and activation domain (AD) into close proximity, thus initiating transcription of the *HIS3* or *lacZ* reporter genes by the transcription complex.

pathogen *Pseudomonas syringae* expressing either of the two effectors AvrB and AvrRpm1.^[5] An *Arabidopsis* protein, RIN4 (for RPM1-interacting protein 4), was found from a two-hybrid screen using the bacterial protein AvrB as bait.^[6] RIN4 interacts with both AvrB and RPM1. Subsequent genetic analysis confirmed that RIN4 is required for accumulation of RPM1 and for RPM1-mediated disease resistance.^[6]

The *Arabidopsis* *Brassinosteroid-Insensitive 1* (*BRI1*) gene encodes a receptor kinase protein that initiates the brassinosteroid signal transduction pathway.^[7] Brassinosteroids are a class of endogenous plant hormones that regulate different physiological processes during the course of plant development.^[7] A yeast two-hybrid screen for interactors of the *BRI1* kinase domain identified a second receptorlike kinase protein, BAK1 (*BRI1* Associated receptor Kinase 1).^[8] Further biochemical and genetic studies confirmed that *BRI1* interacts with BAK1 in plants and that *BRI1* and BAK1 function together in mediating brassinosteroid signaling.^[8,9]

DETECTION OF PROTEIN–PROTEIN INTERACTIONS ON A GENOMEWIDE SCALE

The most recent application of the yeast two-hybrid system is the comprehensive study of protein–protein interactions between thousands of protein pairs. The approximately 6000 predicted open reading frames from the yeast *Saccharomyces cerevisiae* were individually expressed as Gal4 DNA-binding and transcription activation domain fusions in yeast strains of opposite mating types.^[10,11] To screen for binding between any two yeast proteins, cells expressing the Gal4 DNA-binding fusions were systematically mated with the cells expressing the Gal4 activation fusions. Diploids from the mating were then subjected to an assay for expression of the reporter genes under the control of Gal4-responsive promoters. Using this approach, more than 4000 protein–protein

interactions have been discovered.^[10,11] These studies are particularly important as a large number of genes have been predicted from genome sequencing projects, ranging from unicellular organisms, such as yeast, to multicellular organisms such as *Arabidopsis* and rice. The identification of protein–protein networks can link distinct biochemical pathways and facilitate the studies of unknown proteins whose binding partners have been characterized.

CONCLUSIONS AND PROSPECTIVES

More than 10 years have passed since the yeast two-hybrid technology was first described. Although some drawbacks, such as false–positive interactions, have been found, the system is still popular for the study of protein–protein interactions. The viability of the two-hybrid system relies on its simplicity in manipulation of libraries and sensitivity in detection of protein interactions. The only prerequisite for examining the binding of two proteins is their predicted open reading frames. Because of these features, the yeast two-hybrid system has evolved from a means to study interactions between small numbers of proteins to a powerful tool that can be used to establish a protein–protein interaction database on a genomewide scale. It is anticipated that such a global approach can be applied to investigate more complex organisms such as *Arabidopsis* and rice whose genomes have been sequenced. Information obtained from yeast two-hybrid analyses and from other sources will undoubtedly contribute to our understanding of cellular networks and to agricultural practices.
