Agricultural Origins: Old World

Taylor A. Steeves

Department of Biology, University of Saskatchewan, Saskatoon,
Saskatchewan, Canada

Abstract

The origin of agriculture began about ten thousand years ago. Seven centres of origin have been identified, four in the Old World and three in the New World. The oldest centre is in the Old World at the eastern end of the Mediterranean Sea extending through Syria, Turkey, Iraq and Iran. Two separate origins were located in China, one in the south along the Yangtze River and another in the north in the valley of the Yellow River. The fourth centre was in a band in Africa extending south of the Sahara. The transition was a gradual one in each separate case and the plants that were domesticated were distinctive of the particular region. The origin of agriculture can be looked upon as an evolutionary process in which the domesticated plants underwent substantial modifications. For the humans the transformation may also be looked upon as an evolutionary process but the changes have been largely cultural rather than physical. There is growing evidence that agricultural origins were not entirely restricted to the centres but occurred to varying degrees in other locations.

INTRODUCTION

For most of their history, humans have been hunters and gatherers and only in the past 10,000 years has agriculture become the basis of food production. Without farming, human population remained low, probably somewhere between 10 and 30 million and only the invention and spread of agriculture have allowed population to pass six billion and continue to grow. For a long time, it was widely believed that the discovery of farming techniques was a unique invention in the mountainous region east of the Mediterranean Sea. Now, however, at least six other independent centers of origin are recognized and evidence is emerging that there may be others.^[1] Four of the centers of origin are in the old world and these will be the topic of this article.

OLD WORLD CENTERS

The oldest center of origin in the old world is believed to be in the Near East in a band called the Fertile Crescent, extending from the eastern end of the Mediterranean Sea through Syria, Southern Turkey, Iraq, and Iran. The age of this center is believed to be 9000–9500 years, but there is growing support for an age of at least 10,000 years.^[2] Wheat, barley, peas, and lentils were important crops, and sheep and goats were domesticated. Sickle blades for harvesting and grinding equipment were definitely in use. During the early part of this period, the climate was warming with minor oscillations after the last Ice Age.

From here agriculture spreads along the north coast of the Mediterranean to Europe and south to the Nile valley and Mesopotamia.

The second oldest center of origin appears to have been in southern China along the Yangtze River, and the age is believed to be around 8500 years. Rice was the main crop, but various other plants were cultivated, including water caltrop and foxnut. Another center of origin in China was independently established along the Yellow River in the north, a 1000 years later, around 7500 years ago. Here the original crops were millets and only much later was rice introduced to cultivation. The fourth old world center of origin occurred much later about 4000 years ago in a band, south of the Sahara Desert. Here sorghum, millets, and a different species of rice were the major crops domesticated. Further study of the origin of agriculture has increasingly led to the conclusion that the recognized centers are important, but that there is evidence of non-centered origins including New Guinea and southeast Asia.^[3,4]

The age of organic materials found in excavations has for many years been determined by measuring the emissions of beta particles from carbon 14 formed by cosmic rays acting on nitrogen. More recently, a new method using accelerator mass spectrometry measures carbon 14 directly and can deal with very small quantities such as one seed. This technique has led to the correction of a number of dates arrived at by the older method.^[1]

THE TRANSITION TO AGRICULTURE

The transition from hunting and gathering to agriculture was a gradual one, which occurred over a long period of time and there still remain groups that have not adopted this method. The study of these people such as the Kung Bushmen in South Africa and the

aborigines in Australia has given some evidence of the preagricultural human culture. These people keep their population level down and generally do not have permanent settlements. Rather they visit a series of sites where their foods can be obtained on a regular basis. The transition to agriculture is believed to have been a gradual one, often with just one or two plants cultivated, while the remainder of the diet was collected in the wild.^[4]

There is evidence of an extended transitional or tending stage in which crops were not planted, but natural stands were protected from herbivores, cultivated and even, in some cases, provided with water by diverting natural flows. This was a kind of agroecology, and, in some cases, appears to have drastically modified the natural ecosystem. Along with this transition went storage facilities, processing equipment, and the establishment of territorial rights. There is some evidence of the response of such plants to this treatment, but they were not converted into cultivated crops.

THE ESTABLISHMENT OF AGRICULTURE

The beginning of actual cultivation has been a gradual process over an extended time period. It appears to have been a natural evolution motivated by convenience or the need for security.^[5] Some plants were preadapted to cultivation by their natural properties and may have become established on refuse heaps from discarded plant material. This process has been referred to as a revolution, but it was much more of an evolutionary phenomenon. It was in fact a coevolution of the humans and the plants that they domesticated. With the establishment of agricultural planting and harvesting, the process of human selection came into play and as the plants became domesticated, their properties changed substantially. Certain of the features of wild plants were progressively eliminated naturally by the human practice of cultivation. Wild plants tend to have a seed dormancy phenomenon in which germination is extended over a period of time, several years in some cases. This trait was eliminated automatically by agricultural practices. Wild plants tend to scatter their seed or fruits when ripe over a period of time, but cultivation selects out this trait, and the seeds and fruits tend to be retained on the plant. Many plants that were perennials in the wild were converted to annuals, and the tendency to ripen uniformly was developed. In addition, the role of deliberate human selection must have affected other qualities such as size, productivity, texture, loss of toxic or distasteful substances, and the enhancement of flavors.

On the human side, the evolutionary change was more a behavioral one than a physical one. The human pattern of existence changed, as people became dependent upon the plants that they cultivated. The introduction of cultivation increased the productivity of

the land and allowed population to grow. In time, urbanization appeared with division of labor, as food could be supplied by a portion of the population, and the remainder could develop other skills. Unlike the domesticated plants, there were few physical changes in the human population except for some dietary peculiarities that developed in certain groups.^[3]

THE DOMESTICATION OF CROPS

Many important crop plants now have widespread distribution and their actual origin has sometimes been difficult to trace. Wheat, which today is distributed around the world, had its origin in the fertile crescent at the eastern end of the Mediterranean. Wild einkorn was domesticated 9500 years ago, or even earlier, and became a cultivated crop. It is a diploid species, i.e., it has two sets of chromosomes, one from each parent and contains one kernel in each unit of the inflorescence. The other very ancient domesticated wheat is emmer, which is a tetraploid species with four sets of chromosomes. It arose as a hybrid in the wild, doubled the chromosome number, and was domesticated at about the same time as einkorn. Modern bread wheat, which is a hexaploid with six sets of chromosomes and also a hybrid, probably arose spontaneously about 8000 years ago. This wheat threshes cleanly and contains gluten, which gives it good raising properties in bread making. Today there are more than 20,000 cultivars of bread wheat alone.^[4] Barley is another cereal crop that had its origin in the Near East and has been in cultivation as long as wheat and possibly even longer. It was in fact the chief cereal of the Near East until it was supplanted by the tetraploid wheat.

Rice, which is the major cereal of southern Asia, thrives in a hot, moist climate and is usually grown in flooded paddies. Traditionally in Asia, it has been cultivated by sowing in seed beds and transplanting by hand and is also weeded and fertilized. The harvesting is also accomplished by hand labor. However the cultivation of rice can be mechanized and this has occurred in many places. Evidence indicates that it was first domesticated in the Yangtze River valley around 8000 years ago, and the wild ancestor is not entirely clear. The cultivated rice species is not known in the wild. The rice cultivated traditionally in Africa, south of the Sahara, is a different species, although the Asian variety has now been introduced. More than 16,000 varieties of cultivated rice have been identified around the world and these are mostly diploid.^[3] The independent origin of agriculture in the Yellow River valley in North China occurred around 7500 years ago, a 1000 years later than its occurrence in South China, and was based on millets. Rice was introduced only later after contact with South China was established.^[3]

Although agriculture spreads widely from the Near Eastern center of origin, it did not apparently spread across Africa, south of the Sahara Desert. Here agriculture was based on sorghum, which is a relative of maize, species of millets, and a type of rice entirely different from the Asiatic species. Agriculture arose in a broad sub-Saharan band about 4000 years ago.^[3]

In addition to the cereals, which were domesticated, legumes or members of the pea family have been of great importance, because they provide excellent sources of protein, which is deficient in cereals. The unripe pods or the mature seeds contribute protein to the diet. They are valuable also because their roots contain nodules in which symbiotic bacteria fix nitrogen from the atmosphere, which is released into the plant cells and converted into nitrogenous compounds. Among the important associated plants of the old world are lentils, one of the oldest cultivated plants from the Near East, and peas, which are found in the same sites. The broad bean or faba bean is a plant of the Mediterranean region, which was cultivated at least 4000 years ago and possibly much longer. Also from the Near East is the chick pea or garbanzo, which was cultivated by the ancient Egyptians, Greeks, and Israelites, but today 80% of the crop is produced in India. Another legume of ancient use in Asia is the soybean, which originated in central China. Its use goes back 3000–5000 years in time. This plant is still of significant importance in China, but the major production has now shifted to U.S.A. and South America. It is an excellent food source but also has many industrial uses.^[4]

CONCLUSIONS

As further investigation continues, there may be other centers of origin of agriculture in the old world and in fact there is already evidence suggesting this fact. The independent origin in a number of separate locations widely spaced in time suggests that the process was a natural development of human needs and intellectual capacity. This origin had a profound effect on human history and the present population of the earth could not exist without this foundation underlying it. It is an interesting question to consider how long human population growth can continue on this planet, with agriculture as the chief basis of its food supply.

Agriculture and Biodiversity

A

Deborah Stinner

Ohio State University, Wooster, Ohio, U.S.A.

INTRODUCTION

No other human activity has greater impact on the earth's biodiversity than agriculture. From its origins some 12,000 years ago, the goal of agriculturists has been to enhance production of desired species over competing species. Expansion of human agricultural activity around the globe historically has resulted in significant impacts on global biodiversity in four major ways: 1) loss of wild biodiversity and species shifts resulting from conversion of native ecosystems by agroecosystems; 2) influence of agroecosystems' structure and function on agrobiodiversity; 3) off-site impacts of agricultural practices; and 4) loss of genetic diversity among and within agricultural species.^[1] Although agriculture and biodiversity often are inversely related, biodiversity enhancement can be a key organizing principle in sustainable agroecosystems.^[2-4]

AGRICULTURE'S IMPACT ON WILD BIODIVERSITY GLOBALLY

Historically, the earliest subsistence farmers and pastoralists had low population densities and limited technology and their small-scale patchworks of fields, pastures, and home gardens had little net effect on global biodiversity.^[2] In some ecosystems, agricultural activity may have actually increased biodiversity because more diverse habitats and ecotones were created—a pattern that may still exist in some areas.^[2] However, as surplus agricultural production allowed human populations to increase and with the development of civilizations, the impacts of agriculture on wild biodiversity increased, even to the point that biodiversity loss may have contributed to the decline of some ancient civilizations.^[2] Since 1650, there has been at least a 600% increase in the worldwide deforestation of native ecosystems for agriculture and wood extraction that have resulted in radical changes to wild biodiversity globally.^[2]

Wild biodiversity is more threatened now than at any time since the extinction of the dinosaurs, with nearly 24% of all mammals, 12% of birds, and almost 14% of plants threatened with extinction.^[2] If current trends continue, it is estimated that at least 25% of the earth's species could become extinct or drastically reduced by the middle of this

century.^[2] Conversion of natural ecosystems to agroecosystems is a primary cause of these alarming trends.^[2,4,5]

At least 28% of the earth's land area currently is devoted to agriculture to some degree.^[1] Intensive agriculture dominates 10% of the earth's total land area and is part of the landscape mosaic on another 17%, while extensive grazing covers an additional 10%–20%.^[2] Nearly half of the global temperate broadleaf and mixed-forest and tropical and subtropical dry and monsoon broadleaf forest ecosystems are converted to agricultural use (45.8% and 43.4%, respectively).^[1,2] However, agriculture's greatest impact has been on grassland ecosystems, including temperate grasslands, savannas, and shrublands (34.2%); flooded grasslands and savannas (20.2%); and montane grasslands and shrublands (9.8%).^[1] Combined, 64.2% of the earth's grassland ecosystems have been converted to agriculture, primarily for production of cereal grasses—maize, rice, and wheat.^[1,2] In the past 20 years, net expansion of agricultural land has claimed approximately 130,000 km²/yr globally, mostly at the expense of forest and grassland ecosystems, but also from wetlands and deserts.^[1]

The native ecosystems that agriculture has replaced typically had high biodiversity. A hectare of tropical rain forest may contain over 100 species of trees and at least 10 to 30 animal species for every plant species, leading to estimates of 200,000 or more total species.^[6] In contrast, the world's agroecosystems are dominated by some 12 species of grains, 23 vegetable crops, and about 35 fruit and nut crop species.^[1] Furthermore, conversion of native ecosystems to agriculture causes dramatic shifts in ecosystem structure and function that affect ecosystem processes above and below ground including energy flow, nutrient cycling, water cycling, food web dynamics, and biodiversity at all trophic levels.^[7] The amount of wild biodiversity loss depends on the degree of fragmentation of the native landscape. Whereas some species require vast continuous areas of native habitat, many can survive as long as the appropriate size and number of patches with connecting corridors of native habitat are left intact and provided that barriers to species movement—such as road and irrigation networks—are limited. However, when conversion leads to critical levels of native landscape fragmentation, chain reactions of biodiversity loss have been observed as interdependent species lose the resources they need to survive.^[2] Loss of wild biodiversity

at this level leads to loss of numerous ecosystem benefits that are essential to agriculture, e.g., 1) drought and flood mitigation; 2) soil erosion control and soil quality regeneration; 3) pollination of crops and natural vegetation; 4) nutrient cycling; and 5) control of most agricultural pests.^[5]

STRUCTURE AND FUNCTION OF AGROECOSYSTEMS AND BIODIVERSITY

The structure and function of agroecosystems are largely determined by local context, including interaction of ecological conditions (including bio-, geo-, and chemical) with social factors, including farmers' economic needs, cultural and spiritual values, and social structure and technology. Two types of agrobiodiversity have been defined:^[8] Planned biodiversity is the specific crops and/or livestock that are planted and managed; associated biodiversity is nonagricultural species that find the environment created by the production system compatible (e.g., weeds, insect and disease pests, predators and parasites of pest organisms, and symbiotic and mutualistic species).^[8] Planned and associated biodiversity can enhance stability and predictability of agroecosystems.^[5] Traditional forms of agriculture—such as home gardens and shade coffee farms in the New and Old World tropics^[4,6,8] and traditional Amish dairy farms in North America^[9]—have a complex and diverse spatial and vertical structure and high planned and associated biodiversity. For example, traditional neotropical agroforestry systems commonly contain over 100 annual and perennial plant species per field.^[4] Traditional agroecosystems create landscape patterns of small-scale diverse patches with many edges, habitat patches, and corridors for wild biodiversity.

In contrast to traditional agroecosystems, the vertical and horizontal structure of modern industrial agroecosystems is simplified into monocultures on a large scale that create landscape patterns of widespread extreme genetic uniformity with few edges, habitat patches, and corridors for dispersal.^[2] For example, in the United States 60–70% of the total soybean area is planted with 2–3 varieties, 72% of the potato area with four varieties, and 53% of the cotton area with three varieties.^[6] The structure and function of industrial livestock agriculture impose similar negative impacts on biodiversity worldwide.^[10] Livestock operations for all major species—particularly swine, poultry, beef, and dairy—are becoming increasingly concentrated, with feed produced in monocultures and brought to the animals in feedlots. Even in more extensive grazing operations, although good management can increase plant biodiversity,^[3,10] these systems replace native forests and/or grasslands that once supported highly diverse com-

plexes of coadapted plants and migratory grazing and browsing ungulates and their predators.^[10]

OFFSITE IMPACTS OF AGRICULTURAL ACTIVITIES

The third major way that agriculture impacts global biodiversity is through the direct and indirect off-site effects of the various managements used to maintain their structure and function. Growing annual species in large monocultures goes against ecological forces of plant community succession; therefore, a great deal of intervention is required to maintain high levels of production. Fertilizers applied to maximize production of crop plants create favorable habitat for other plant species that are adapted to nutrient enriched conditions, including alien invasive species. Tillage, herbicides, and genetic engineering may prevent competition between crop plants and annual and perennial weeds. Widespread monocultures of nutrient enriched plants create an easily exploited resource for insect pests and disease organisms. Insecticides, fungicides, and genetic engineering may protect crops from these competitors. Furthermore, conventional cropping agroecosystems are notoriously leaky (i.e., the sheer volume of external inputs being applied in combination with soil disturbance and decreased soil quality often exceeds the capacity of the agroecosystem to absorb and process the inputs).^[1] Concentrated livestock agriculture also can be a major source of chemical and biological pollution. As a result of these many factors, sediment, excess fertilizer, manure, and pesticides run off into streams and down into groundwater. Hydrological alterations to land and natural streams in combination with chemical and biological pollution cause considerable reductions in aquatic biodiversity that can extend throughout whole watershed systems.^[2] The Hypoxia in the Gulf of Mexico is a dead zone that covers 18,000 km² where aquatic biodiversity has been drastically reduced by impacts of agriculture in the Mississippi River watershed.^[2] A new concern regarding off-site impacts of modern agriculture on biodiversity is the genetic pollution that can result as genetically modified crops expand worldwide.^[1] Possible transfer of genes for resistance to weeds, insects, fungi, and viruses could overwhelm wild populations and communities.^[2]

LOSS OF DIVERSITY WITHIN AGRICULTURAL SPECIES

Of 7000 crop species, less than 2% are currently important, only 30 of which provide an estimated 90% of the world's calorie intake—with wheat, rice, and maize alone providing more than half of plant-derived calories.^[1]

Some 30–40 animal species have been used extensively for agriculture worldwide, but fewer than 14 account for over 90% of global livestock production, whereas some 30% of international domesticated breeds are threatened with extinction.^[1] There are additional trends of decreased varietal and landrace diversity within crop species as more farmers adopt modern high-yielding varieties.^[1,4] These alarming trends have prompted government policy recommendations whose purpose is to: 1) ensure that current agricultural genetic diversity in plants is preserved in seed banks and plant and germplasm collections (*ex situ*) or as growing crops (*in situ*), particularly wild relatives of major crops and livestock breeds in their centers of origin; and 2) ensure that wild crop and livestock relatives are conserved in carefully identified natural systems.^[5]

CONCLUSION

Biodiversity as a Principle of Agroecosystem Management

Although industrial agriculture is generally inversely related to biodiversity, there are promising examples of alternative agroecosystems that protect and enhance biodiversity and are also highly productive.^[2–4] Some of these include: 1) organic agriculture; 2) sustainable agriculture; 3) permaculture; 4) natural system agriculture; 5) holistic management; and 6) ecoagriculture.^[2,3] These models are based on ecological principles and the assumption that biodiversity can contribute significantly to

sustainable agricultural production. Within ecoagriculture, the following strategies are proposed to protect and enhance wild biodiversity: 1) create biodiversity reserves that also benefit local farming communities; 2) develop habitat networks in nonfarmed areas; 3) reduce (or reverse) conversion of wild lands to agriculture by increasing farm productivity; 4) minimize agricultural pollution; 5) modify management of soil, water, and vegetation resources; and 6) modify farming systems to mimic natural ecosystems.^[2] Examples of specific management practices that sustain or enhance biodiversity include: 1) hedgerows; 2) dykes with wild herbage; 3) polyculture; 4) agroforestry; 5) rotation with legumes; 6) dead and living mulches; 7) strip crops, ribbon cropping, and alley cropping; 8) minimum tillage, no-tillage, and ridge tillage; 9) mosaic landscape porosity; 10) organic farming; 11) biological pest control and integrated pest management; 12) plant resistance; and 13) germplasm diversity.^[11] New research, particularly if conducted in a participatory mode with farmers, should lead to many more ways to protect and enhance biodiversity, including: rotational grazing of high-diversity grasslands for dairy and beef cattle production, timber and pulp production systems that use perennial plants, high-diversity mixtures of single annual crops and/or rotational diversity, and precision agriculture that closely matches small-scale soil conditions with optimal crop genotypes.^[5] Although specific management practices are helpful, also needed are whole-farm planning approaches and decision-making processes that encompass farmers' values and economic needs, in addition to environmental concerns for biodiversity^[2] (e.g., holistic management).^[3] More

research and education and policies that encourage farmers and consumers to appreciate the ecological, economic, and quality-of-life values of biodiversity are needed to thwart current threats to global biodiversity and agrobiodiversity, and to address the many challenges and opportunities of global sustainable food security.^[4]

Agriculture: Why and How Did It Begin?

David R. Harris

University College London, London, U.K.

INTRODUCTION

Today the world's population exceeds 6000 million people, almost all of whom depend on agriculture for their survival, and yet growing crops and raising domestic animals is a very recent development in the history of humanity. Anatomically modern humans—*Homo sapiens*—began to colonize the continents as foraging hunter-fisher-gatherers some 100,000 years ago, but it was not until about 12,000 years ago that farming began to replace foraging as the main mode of human subsistence. It did so first, and very gradually, in the so-called Fertile Crescent of Southwest Asia. In other regions of the world, such as central China, northern tropical Africa, and Mesoamerica, primary (independent) transitions from foraging to farming also occurred, even later than in Southwest Asia, but by 1500 A.D., when Europeans were beginning to expand overseas, most of the world's population (estimated at 350 million) had become dependent on agriculture.

From today's perspective, this late emergence and very gradual development of agriculture may seem surprising. It prompts the question, why did it not occur much earlier, or, conversely, why did humans remain dependent on hunting, fishing, and gathering for so long? This response stems from a deeply embedded and still prevalent assumption that the transition to agriculture was an inevitable stage in human progress. However, in the long perspective of humanity's foraging past the question that demands an answer is not why did agriculture not develop sooner, but why did it develop at all?

Before pursuing that question, we need to consider what precisely is meant by "agriculture," because failure to define it, and other related terms such as cultivation and domestication, has led to confusion in attempts to explain why and how agriculture arose. Here, cultivation is defined as the sowing or planting, tending, and harvesting of useful domesticated *or* wild plants, which may or may not involve tilling the soil. Domestication is defined as the genetic, physiological, and/or morphological alteration of wild plants that results from deliberate or inadvertent cultural selection and leads to the plants' dependence on humans for their long-term survival. Agriculture is defined as the growing of domesticated crops by methods of cultivation that usually but not always involve systematic tillage of the soil. The distinction between cultivation and

agriculture is particularly important because it enables us to differentiate between systems of crop production practiced by farmers and systems of wild-plant production practiced by foragers. Having clarified this distinction, we need next to consider how foragers have cultivated wild plants to enhance their productivity.

PLANT CULTIVATION BY FORAGERS

Many historical and ethnographic accounts of "hunter-gatherers" show that they not only gathered wild plants but often increased the productivity of selected taxa by such methods as controlled burning; vegetation clearance and weeding; harvesting, storing, sowing, and planting seeds, tubers, cuttings, and other propagules; and tilling, draining, and irrigating the soil.^[1] Such practices can be regarded as forms of cultivation, but, although they are sometimes described as "protoagricultural,"^[2] they do not amount to agriculture (as here defined) because they rarely include fully domesticated crops. This distinction is not just semantic, because the ethnographic, historical, and more limited archaeological evidence we have indicates that cultivation by foragers was usually only a minor activity in their hunting-fishing-gathering systems of subsistence.

Although many forager groups engaged in small-scale cultivation, it did not normally, and certainly not inevitably, lead to full plant domestication and the development of agriculture. However, that this did occasionally occur is undeniable, for if it had not, agriculture would never have arisen. So we must next ask what factors may have caused particular forager groups to invest more time and effort in cultivation and to become progressively more dependent for food and other products on suites of plants that underwent domestication and were transformed into agricultural crops, thus initiating primary transitions from foraging to farming.

FACTORS THAT MAY HAVE PROMOTED PRIMARY TRANSITIONS TO AGRICULTURE

Many factors, singly or in combination, have been proposed as causal agents that could have promoted crop

domestication and the rise of systems of agricultural production. They range from factors external to the human groups concerned, such as natural climatic and vegetational changes, to social-behavioral ones such as reductions in seasonal mobility associated with year-round, long-term occupation of settlements (sedentism) and the elaboration of storage techniques; population pressure; competition for scarce resources; differential access to food and other products associated with the development of social ranking; exchange and trade; and technological innovation.

Underlying the discussion of the relative importance of such factors is the more general question of whether the earliest foragers to develop agriculture were pressured into doing so by factors that induced subsistence stress or whether the process was a more random one by which some groups “drifted” voluntarily into progressively greater dependence on a narrower range of plants, some of which were domesticated. It is impossible to resolve such a general question conclusively by appeal to direct archaeological evidence of forager and early agricultural subsistence (which is in any case very meager), but the ethnographic and historical record strongly suggests that agriculture is more demanding of time and energy, and generally more risky, than foraging, even when the latter includes an element of cultivation. It therefore seems unlikely that foragers would have voluntarily and progressively become dependent on agriculture for their main food supply unless they were subjected to some form(s) of subsistence stress.

There is ethnohistorical evidence that some foragers did select and sufficiently modify particular plants that became largely dependent on their cultivation for survival, and can be said to have been at least semi-domesticated,^a but what most foragers did not do was focus their energy on the cultivation, and domestication, of selected crops to such an extent that they became farmers. This evolutionary pathway appears to have been followed only by a few forager groups in the past whose livelihood came under sustained stress. Such stress could have been generated by several of the factors already mentioned, such as climatic and vegetation changes, population growth, and competition between groups for scarce resources. Very probably, it was when several factors combined in particular situations to exert sustained stress on the subsistence practices of forager groups that transitions to agriculture took place. So we

need next to ask in what contexts is this likely to have occurred.

THE CONTEXTS OF TRANSITIONS TO AGRICULTURE

There is little direct archaeological evidence that allows us to trace primary transitions from foraging to farming. Although it is possible to distinguish from their wild progenitors the remains of many domestic plants and animals recovered from sites of early agriculture, there are very few known sites that span and reveal such transitions. One that does is the Levantine site of Tell Abu Hureyra on the Euphrates River in Syria, where large assemblages of charred plant remains of Late Palaeolithic and Neolithic age have been recovered and analyzed. Changes in the composition of the assemblages indicate a transition from the exploitation of the seeds of a wide range of wild plants, including grasses and herbaceous legumes, during the second half of the Late Palaeolithic (Epipalaeolithic) occupation c. 13,000–10,000 years ago, to the cultivation, by the Pre-Pottery Neolithic period at the site c. 9400–7300 years ago, of a small number of domesticated crops, including barley, wheat (einkorn, emmer, and bread wheat), lentil, pea, and faba bean.^[4,5]

The evidence suggests that by the Epipalaeolithic period Abu Hureyra was occupied year round and that the inhabitants regularly harvested the seeds of the wild cereals and legumes. They probably began to cultivate them in response to an abrupt change to colder and drier conditions that began about 11,000 years ago and lasted until about 10,000 years ago (the Younger Dryas climatic interval) and progressively reduced stands of the wild plants from the least to the most drought-tolerant species. Toward the end of the Younger Dryas, there is archaeobotanical evidence of increases in weeds typical of dryland cultivation, and through the succeeding Pre-Pottery Neolithic period (c. 10,300–7500 years ago) in the Levant as a whole the number and size of settlements increased in response to population growth, and the remains of the “founder crops” of Southwest Asian agriculture^[6] appear at an increasing number of sites.^[7] By the end of the period, grain farming (and the herding of domestic goats and sheep) had become the mainstay of the human population of the Fertile Crescent and the new agro-pastoral, village-based way of life had begun to spread outward, toward Europe, North Africa, and Central and South Asia.^[8,9]

The Southwest Asian Fertile Crescent currently provides a uniquely detailed archaeological record of a primary transition from foraging to farming. It highlights

^aFor evidence of semi-domestication of plants by foragers see Ref. [3].

the importance of the interaction of several factors in the process: climatic and vegetational change, sedentism and associated population growth, increased competition for declining food resources, and technological innovation (e.g., in the manufacture of sickles and grindstones). We do not have equivalently comprehensive evidence for primary transitions to agriculture—as opposed to the spread of already established agricultural systems—in other regions of the world where distinctive combinations of plants (and in some cases also animals) were domesticated, such as China, southern India, New Guinea, northern tropical Africa, Mesoamerica, the Andean highlands, Amazonia, and eastern North America. (For more detailed discussion of crop domestication in most of these regions, and in Southwest Asia, see the articles in this volume by Bar-Yosef, Delgado-Salinas et al., Asch and Hart, Lu, Pasquet, and Paz). It is not yet possible to determine with confidence what factors may have interacted to induce foragers to become farmers in these regions, but there is some tentative evidence from central China that may implicate the Younger Dryas climatic interval in the transition from the harvesting of wild rice to its cultivation and domestication in the Late Palaeolithic and the widespread establishment of rice agriculture in the Neolithic.^[10,11]

In Mexico and Central and South America, however, there is little evidence of the Younger Dryas. Factors such as the establishment of sedentary settlements associated with population growth and social differentiation, resulting in more intensive exploitation of local wild foods, may have led to greater dependence on the cultivation of particularly productive plants, such as squash, maize, and beans, that ultimately became staple crops. In northern tropical Africa and eastern North America on the other hand, it is possible that short-term changes of climate (more recent than the Younger Dryas) may have stimulated the transitions to agriculture that occurred there later in the Early Holocene.^[12,13]

CONCLUSION

It appears that climatic change (to colder and drier conditions) was a key factor in the earliest known transition to agriculture in Southwest Asia. Such changes, in combination with increased sedentism, population growth, and other social factors, may have played an important part in transitions elsewhere. Progress toward a more complete understanding of the process requires the recovery, identification, and accurate dating of plant (and animal) remains from archaeological sites that span periods of transition from foraging to farming. Very few such sites are

known and even fewer have been investigated using modern techniques of excavation, dating, and analysis. Until more such research is accomplished, conclusive answers to the questions of why and how agriculture began will remain elusive.

Air Pollutant Interactions with Pests and Pathogens

Andreas von Tiedemann

University of Göttingen, Göttingen, Germany

INTRODUCTION

The exponential economic growth in developed countries since the mid-nineteenth century has been accompanied by an increase in the concentrations of various tropospheric trace gases. Among the gaseous pollutants most studied during the past decades are carbon dioxide (CO₂) with a global distribution, ozone and peroxyacetylnitrate (PAN) with a more regional dimension, and others such as sulfur dioxide (SO₂), nitrogen oxide (NO₂), and hydrogen fluoride (HF), which are associated with emissions from local sources. Besides their potential to influence the global climate and their direct effects on plant growth and yield, their effects on plant-pathogen or plant-insect relations may already be, or could become, an important factor affecting plant health. However, evaluation of these effects is difficult because of the diverse temporal/spatial distribution and differences in the chemical behavior and because of the complex interactions between the effects of the trace gases and agronomic factors relevant for plant resistance to diseases and insect pests, including fertilizer and pesticide use, crop variety, soil management, water supply, etc. Also, direct effects of gaseous pollutants on the pathogen or insect cannot easily be separated from indirect effects on the host plants through changes in physiological processes. Experiments under controlled conditions can only reveal a limited picture of the multitude of possible effects that may occur in the field. Despite these limitations, a number of studies mainly carried out between 1970 and 2000 have resulted in a significant amount of data describing specific effects of the main trace gases on the incidence of plant diseases and insect pests. These can be compiled and used to formulate some generalizations.

EFFECTS OF AIR POLLUTANTS AND ELEVATED CO₂ ON PLANT DISEASES

Among the photooxidants, ozone has been the prevalent compound studied for its effects on both plants and plant diseases. Because its photochemical production is favored under conditions of high irradiance, direct effects of ozone on fungal or bacterial pathogens are less likely, as these only grow actively on plant surfaces during wet

and cloudy periods. The same applies to soilborne pathogens. Therefore, the main pathway for ozone effects on diseases occurs indirectly via changes in the physiology of the plant. A number of physiological changes induced by ozone are important with respect to plant disease resistance. Numerous physiological effects of ozone may impair the conditions for growth of pathogens, particularly of biotrophs, such as accelerated ageing/premature senescence, degradation of membrane lipids accompanied with increased cellular leakage, reduced net photosynthesis, increased protein degradation, or enhanced ethylene production, in combination with changes in factors directly affecting resistance. These include elevated antioxidant levels, reinforcement of cell walls (lignin, callose, extensins), induction of phytoalexins, or expression of PR-proteins.^[1] Although these effects may occur in most plant species, they can lead to contrasting effects on the pathogens, according to their parasitic nature. On one hand, ozone stress can cause a reduction in the growth of bacteria and biotrophic fungi such as powdery mildew and rusts, while on the other hand increased infection by necrotrophic parasites can result from ozone predisposing the plants.^[2] It has often been observed that the effect of ozone on a particular pathogen is similar to the effect of ageing and senescence. The profile of ozone exposure and the dose of ozone are important because the exposure may or may not cause visible injury prior to infection. For instance, grey mold induced by *Botrytis cinerea* was enhanced on ozone-injured leaves through the delivery of entry ports, while the disease was restricted on uninjured leaves after exposure to chronic ozone doses. In the latter case, triggering of plant resistance factors may have been involved in increased resistance against fungal invasion. As visible injury is less frequent in the field, the latter situation may be of practical importance.

A few studies have addressed interactions of virus diseases with ozone. These studies consistently looked at changes in ozone sensitivity in virus-infected plants, and they showed that virus infections can protect plants from ozone injury.^[2,3]

Most soil fungi can tolerate more than a 10- to 100-fold increase in atmospheric carbon dioxide concentrations. Some pathogenic aerial or soilborne fungi and bacteria were found to be inhibited only at CO₂ concentrations exceeding 3–5%, and others were unaffected or even

stimulated in growth and/or sporulation under these conditions. This suggests that an increase in atmospheric CO₂ from 0.03–0.07% over the next 50 years will probably not have a direct effect on fungal and bacterial plant pathogens but that it may act indirectly via alterations in plant growth, physiology, and metabolic state. Elevated CO₂ can have profound effects on plants, ranging from increased photosynthesis rates to enhanced growth, elevated leaf carbohydrate contents, altered stomata regulation, etc. These changes may favor the growth of biotrophic pathogens, while increased plant growth leading to a denser canopy structure favors foliar pathogens because of more humid microclimatic conditions favoring infection. Increased biomass production will lead to larger amounts of plant litter, which, in turn, has the potential to favor the survival of necrotrophic pathogens during periods with adverse conditions.

Co-occurrence of ozone stress and elevated CO₂ may partly counteract inhibitory or stimulating effects of the two trace gases on plants. This has been demonstrated in studies of combined effects of the two gases on photosynthesis, growth, and yield. However, while CO₂ may offset deleterious effects of ozone on plant growth, the

impact of ozone on plant resistance to pathogens seems to be less affected by elevated CO₂.^[2]

With the advancement of clean-air technologies in many of the developed countries, the importance of the point-source-related pollutant gases such as sulfur dioxide and hydrogen fluoride has decreased, but in less developed regions, negative effects may still be of great importance. Effects of SO₂ were studied intensively in relation to the occurrence of pathogens associated with forest trees and agricultural crops. In some cases, trees weakened by this pollutant were found to be predisposed to infection, whereas in other cases they were not. Conflicting observations were also made with respect to SO₂ effects on cereal pathogens. The inconsistencies may be related to whether or not injury is caused by the pollutant prior to infection. Exposure to atmospheric hydrogen fluoride (HF) leads to an accumulation of fluoride in plant foliage to levels much higher than those present in the atmosphere. Similarly, fluoride accumulation may occur in plants growing on contaminated soils. At high concentrations, fluoride impairs the growth of some representative plant pathogens, both *in vitro* and *in vivo*.^[3,4]

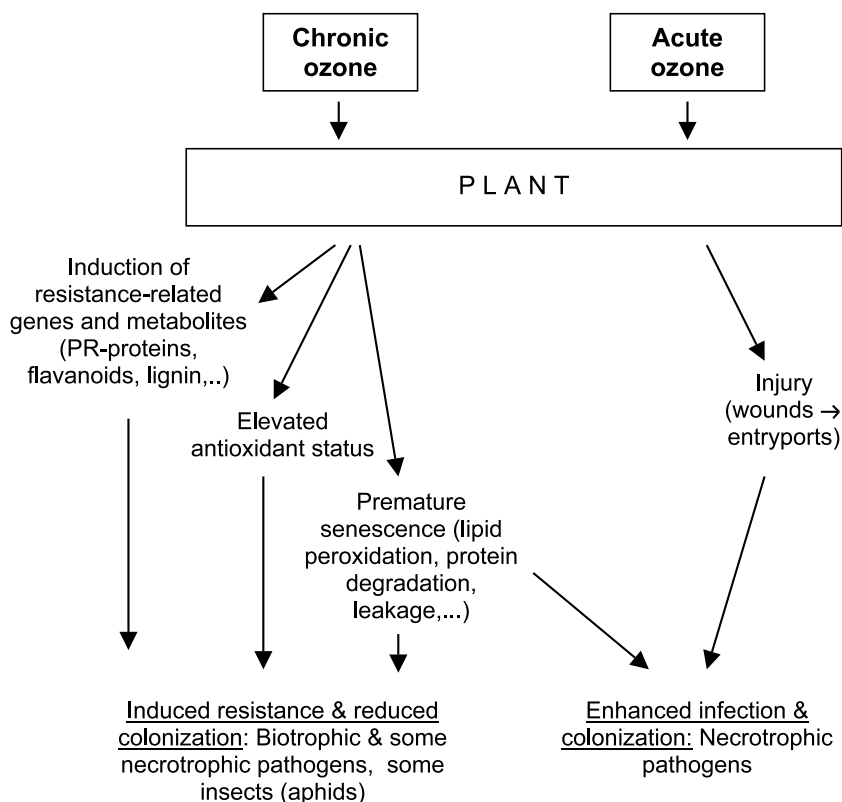

Fig. 1 Summary of the main effects of ozone stress on diseases and pests, mediated by the plant.

EFFECTS OF AIR POLLUTANTS AND ELEVATED CO₂ ON INSECT PESTS

Among the herbivorous insects, aphids attracted the most research interest, much more than, for instance, beetles, moths, and butterflies. Earlier field observations along pollution gradients in the vicinity of industrial plants, urban areas, or motorways and more recent experimental investigations using insect suction traps, filtration systems in urban air, open-top chambers, or field fumigation systems have consistently demonstrated that the growth of herbivorous insect populations in terms of their mean relative growth rate is favored by moderate levels of pollution but inhibited in more polluted environments. This general finding mainly refers to effects of SO₂ and NO₂ in the vicinity of point sources or alongside motorways. In particular, various important aphid species on crop plants such as wheat, barley, broad bean, pea, lupin, and brussels sprout or on tree species including apple, beech, pines, and spruces have consistently performed better in atmospheres with moderate levels of the two pollutants,^[3,5-7] both in the field and in closed fumigation chambers. It is generally believed that an increase in

available amino acids in polluted plants leads to the stimulation of the growth of aphid populations.

Direct effects of SO₂, NO₂, or O₃ on insects have been less studied, but the available evidence suggests that insects can largely tolerate these air pollutants at realistic levels when exposed either during feeding on artificial diets or on plants. This has been demonstrated when the host plants were exposed prior to or after the transfer of insects. Consequently, by far the most important effects of air pollutants on herbivorous insect populations are mediated through changes in the host plant.

Effects of ozone have been mostly studied in closed chambers, and results have been far more complex than those of SO₂ or NO₂. While many experiments have demonstrated increased growth of aphids under ozone stress, this effect was reversed or abolished either at higher temperatures or when applying ozone continuously instead of episodically. Since, in ambient air, peaks in ozone concentrations typically occur episodically, it remains unclear how both the presence of higher temperatures and a diurnal cycle acting in combination would modulate ozone effects on insect pests in the field. Ozone effects on free amino acid content in plants have been

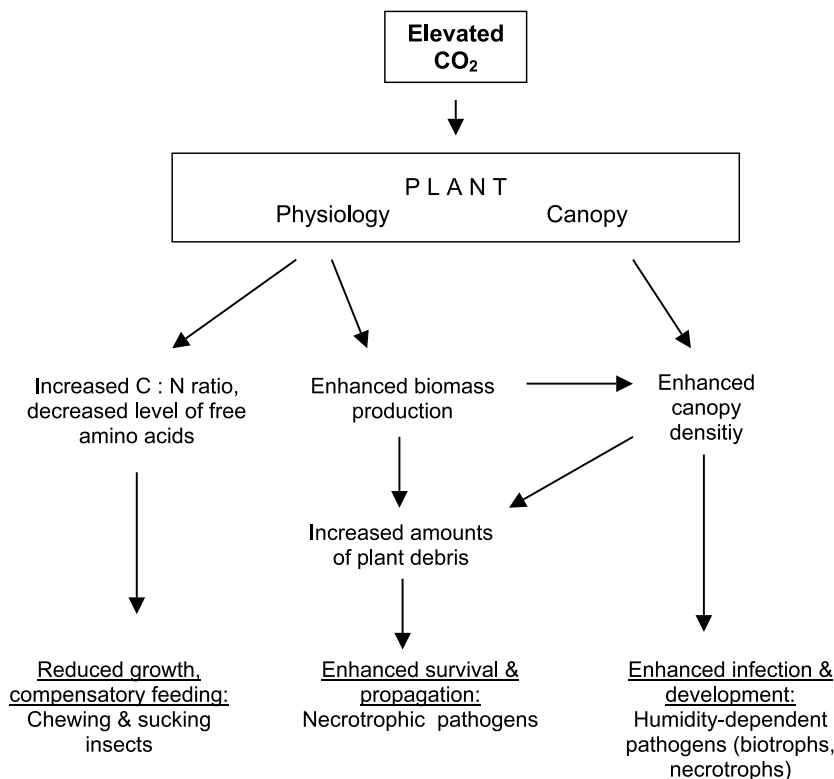

Fig. 2 Summary of important effects of elevated carbon dioxide on diseases and pests, mediated by the altered plant physiology and canopy structure.

found to vary among plant species, pollutant doses, or environmental conditions. Thus, factors other than nutritive traits may be involved in the mediation of ozone effects—for instance, changes in the feeding stimuli on the plant surface.

Limited data on effects of elevated CO₂ demonstrate that insect herbivores, in particular chewing and sucking insects, grow and develop more slowly but consume more plant material. This effect can be attributed to the increased C/N ratio and the reduction in the content of free amino acids in plants grown at elevated CO₂.^[7,8] While CO₂ effects on population growth may be negative or not detectable, enhanced compensatory feeding of chewing insects appears to be a consistent phenomenon and may aggravate the damage to plants. Elevated CO₂, a significant growth factor, affects not only the chemical plant composition but also the physical structure and density of the plant canopy, leading to altered microclimatic conditions in the field. Therefore, the combination effects of CO₂, temperature, humidity, nutrient supply, and interactions with other pollutants such as ozone determine the outcome of plant-insect relationships, but present knowledge of these complex interactions is limited.

GENERAL RISK CONSIDERATIONS

Figs. 1 and 2 summarize important effects of ozone and elevated CO₂ on plant diseases and insect pests. However, a general evaluation of the risk for enhanced plant diseases caused by air pollution is difficult because effects vary among different plant-pathogen relationships. Moreover, ozone in combination with elevated CO₂ is less effective as compared to its effects as a single gas. It seems certain, though, that effects of pollutants on diseases and insect pests occur preferentially through alterations in the host plants. However, plants can acclimate to rising CO₂, leading to long-term effects that are different from those observed in controlled short-term experiments. Interacting effects from antagonists, predators, parasitoids, and environmental factors further complicate the evaluation of risks under field conditions. Therefore, a general risk assessment of enhanced diseases and pests caused by ozone stress and/or elevated CO₂ is not possible. Specific risks may exist for some insect infestations in the presence of episodic ozone stress and moderate temperatures. Importantly, SO₂ and NO₂ play a major role in regions of the developing world that, at the

same time, suffer from insufficient agricultural production, and an elevated risk caused by insect pests under the prevailing climatic conditions seems likely. Hence, these regions may be most threatened by air pollutant effects on insect pests in the future.

Air Pollutants: Effects of Ozone on Crop Yield and Quality

Håkan Pleijel

Göteborg University, Göteborg, Sweden

INTRODUCTION

Air pollutants have been known for more than one hundred years to affect both yield and quality of agricultural crops. This is true for a wide range of pollutants including sulfur dioxide, fluorides, and nitrogen-containing pollutants such as nitrogen oxides (NO, NO₂) and ammonia (NH₃). Today, the main focus is on effects of the regional occurrence of elevated tropospheric ozone (O₃). In North America and Europe, where emissions of sulfur dioxide and fluorides have declined, the problem of ozone pollution has received most attention. In contrast, in many developing countries emissions of a number of pollutants are increasing and there are strong indications of adverse effects on crops. However, these effects have been studied to a much lesser extent than in Europe, North America, Japan, and Australia.

DISCOVERY OF OZONE EFFECTS ON CROPS

Systematic studies of ozone effects on crop yield and quality started around 1950 in California, U.S.A.,^[1] where the problems caused by ozone and other photochemical oxidants were first discovered. At that time, the studies were mainly of an observational nature, and they were based on visible injury appearing on the plant leaves. Controlled experiments in the laboratory began later; however, initially these yielded largely qualitative data which were not suitable as a basis to estimate the magnitude of potential effects in the field.

But, it should be noted here that in certain crops, such as spinach and tobacco, leaf injury is of large economic importance, apart from potential reductions in absolute yield. In some crops visible leaf injury, expressed as necrotic spots on the leaves, is the most pronounced effect by ozone and other pollutants, while in others a reduction in the leaf life span, the so-called premature senescence, is most important, as it reduces the length of the growth period. The latter occurs in wheat, in which characteristic leaf injury at moderate ozone exposure is generally lacking, while early senescence in response to ozone is pronounced.^[2]

OPEN-TOP CHAMBERS

With the introduction of the open-top chamber (OTC) as an exposure system,^[3] which permits semicontrolled exposure of plants to gaseous pollutants under ecologically realistic conditions in the field, an important step was taken towards a quantitative understanding of impacts of ozone and other pollutants. An OTC is a transparent plastic cylinder through which air (ambient air, filtered air, or air enriched with various levels of pollutant gases) is ventilated using a fan. OTCs can be mounted in plots of a field-grown crop and kept in place throughout the growing season. Although the system alters the microclimate of the plants to a certain extent,^[4] the ecological realism is much larger than in a closed chamber system in the laboratory.

CROP LOSS ASSESSMENT PROGRAMS

In the U.S.A., a large experimental program, the NCLAN (National Crop Loss Assessment Network), involving the use of OTCs of crops, was executed during the 1980s. The NCLAN results showed that ambient levels of ozone had the potential to reduce the yield of a number of crops, including soy bean, wheat, and alfalfa.^[5] In addition, economic estimates of crop losses for the U.S.A. indicated an annual loss for the farmers in the range of a few billion U.S. dollars.

A similar program, the European Open-Top Chamber Programme (EOTC), was organized in Western Europe beginning in the second half of the 1980s until the early 1990s. Negative effects of ozone levels typical of wide areas of Europe were observed in beans and spring wheat.^[6] In some, but not all, experiments with pastures the main effect of ozone was on the species composition, with clover being replaced by grasses. This effect acts to reduce the protein content and thus the fodder quality of the yield. Towards the end of the 1990s a European research program, Changing Climate and Potential Impacts on Potato Yield and Quality (CHIP), studied the effects of ozone on potato. It was concluded that current ozone levels in Europe can cause significant effects on potato, but that the sensitivity is less than in wheat.

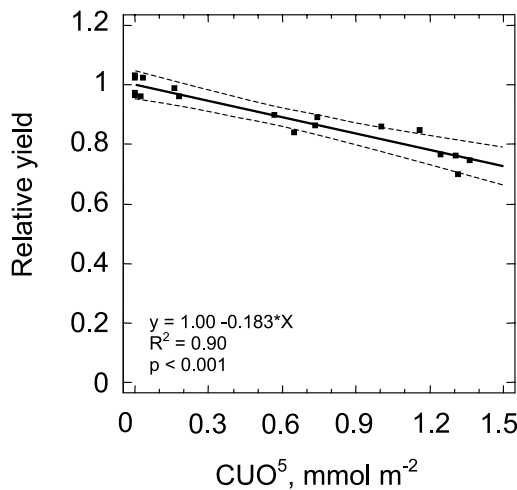

Fig. 1 Relationship between the relative yield of field-grown spring wheat and the cumulative ozone uptake (CUO) by the flag leaves based on stomatal conductance modeling. An ozone uptake rate threshold of $5 \text{ nmol m}^{-2} \text{ s}^{-1}$ was used, since this threshold resulted in the best correlation between relative yield and ozone uptake. Five open-top chamber experiments performed in Sweden were included. (From Ref. 8.)

Based on the experiences of both research programs in North America and Europe, it can be concluded that soybean, wheat, tomato, pulses, and watermelon can be classified as highly sensitive to ozone. Barley and certain fruits are rather insensitive, while potato, rapeseed, sugar beet, maize, and rice are intermediate with respect to ozone sensitivity. There exists a certain degree of intra-specific variation in ozone sensitivity, such as in different bean varieties, but a recent European study resulted in a rather uniform ozone response pattern for different cultivars of wheat.

“CRITICAL LEVELS” OF OZONE

The relationship between grain yield and ozone exposure was most consistent in spring wheat across cultivars and experimental sites, and, considering the pronounced sensitivity observed for this crop, the combined data were used as a basis to derive critical levels for ozone effects under the Convention on Long-Range Transboundary Air Pollution of the United Nations Economic Commission

Fig. 2 Relationship between grain protein concentration and grain yield in field-grown spring wheat based on data from open-top chamber experiments performed in Sweden, Finland, Denmark, and Switzerland. The experiments included ozone treatments, carbon dioxide treatments, and a few irrigation treatments. Relative scales were used for both axes: The effects were related to the open-top chamber treatment with non-filtered air (NF) without extra ozone or carbon dioxide fumigation in each of the sixteen experiments included. (From Ref. 9.)

for Europe (UNECE). For this purpose, the ozone exposure index AOT40 (the accumulated exposure over a concentration threshold of 40 nmol mol^{-1} ozone based on hourly averages) was used.^[7]

OZONE UPTAKE

An important recent development in the field of crop loss assessments is the consideration of ozone uptake by the plant leaves, in place of a statistical index to characterize the concentration of ozone in the air surrounding the plants, such as the AOT40 exposure index. Key to this method is the quantification of ozone diffusion through the stomata of leaves.

The stomatal conductance of the plant leaves varies with a number of factors, such as soil and air moisture contents, temperature, solar radiation, phenology, and the levels of other pollutants, including carbon dioxide. Stomatal conductance models can now be used to establish relationships between yield loss and ozone uptake. An example is given in Fig. 1 showing the relationship between relative yield in two Swedish wheat

cultivars and the calculated, cumulated uptake of ozone by flag leaves, taking into account an uptake rate threshold of $5 \text{ nmol m}^{-2} \text{ s}^{-1}$ (CUO^5).^[8] This threshold provided the best correlation between effect and exposure, and it may represent the biochemical defense capacity of the plants. However, it remains to be shown that the two thresholds are directly related to each other.

EFFECTS OF OZONE ON PROTEIN CONTENTS

Much less attention has been paid to the influences of ozone on crop quality as compared to efforts made to understand the relationship with yield. The most discussed quality aspect has been the protein concentration or content, for instance, of wheat grains. The combined results of sixteen open-top chamber experiments performed in four different European countries (Finland, Sweden, Denmark, and Switzerland) were used to show the relationship between grain yield and grain quality (Fig. 2), and grain yield and the off-take of grain protein per unit ground area (Fig. 3), at different ozone or carbon

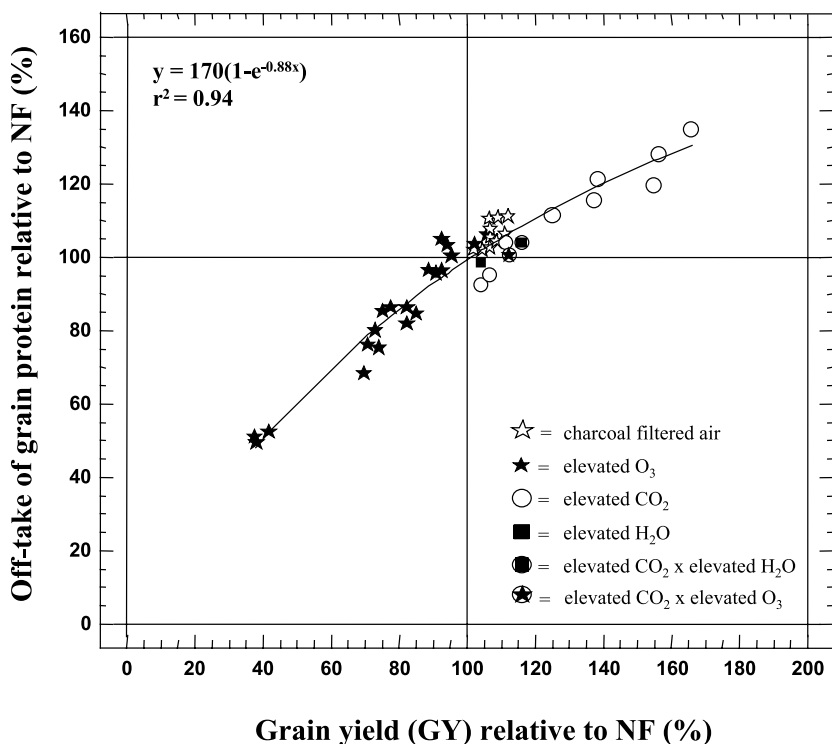

Fig. 3 Relationship between grain protein off-take per unit ground area and grain yield in field-grown spring wheat based on data from open-top chamber experiments performed in Sweden, Finland, Denmark, and Switzerland. The experiments included ozone treatments, carbon dioxide treatments, and a few irrigation treatments. Relative scales were used for both axes: The effects were related to the open-top chamber treatment with non-filtered air (NF) without ozone or carbon dioxide fumigation in each of the sixteen experiments included. (From Ref. 9.)

dioxide levels.^[9] From Fig. 2, it can be inferred that, relative to control (always the open-top chamber treatment with non-filtered air), the grain concentration of protein was higher and yield was lower in elevated ozone, which is the opposite result of situations with elevated carbon dioxide or in chambers where the ozone had been reduced by using charcoal filters. This situation could be attributed to a so-called growth dilution effect by elevated carbon dioxide and air filtration stimulating the carbohydrate accumulation relatively more than the uptake of nitrogen at a given nitrogen fertilizer application rate, while in situations of elevated ozone, carbohydrate accumulation was negatively affected more strongly than protein accumulation.

However, Fig. 3 shows that the protein yield per unit ground area was negatively affected by ozone and enhanced by elevated carbon dioxide, although the latter effect tended to saturate at a level determined by the availability of nitrogen in the soil.

CONCLUSION

There is strong evidence that current ozone concentrations over large areas in the industrialized world are high enough to cause yield loss in several important agricultural crops, but it remains a challenge to quantify these effects exactly. New approaches based on the uptake of the pollutant by plants, rather than the concentration in the air surrounding the plant, are promising.

The protein concentration of the yield tends to increase with increasing ozone in some crops in connection with declining yield. On the other hand, the protein yield per unit ground area tends to decrease. In future research, the understanding of additional quality effects of air pollutant exposure should be given more attention.

In the developing world, such as many countries in Asia, there is a great risk for crop losses due to a number of air pollutants for which emission rates are increasing dramatically.^[10] A loss in food production in these countries represents a much larger problem than in the industrialized world. More research should be devoted to this problem in the decades to come.

Air Pollutants: Interactions with Elevated Carbon Dioxide

Hans-Joachim Weigel

Institute of Agroecology, Bundesallee, Braunschweig, Germany

INTRODUCTION

The concentrations of various compounds in the atmosphere have undergone significant changes during the last century, and they continue to change. Many of these compounds interact with the terrestrial biosphere. Depending on the concentration in the atmosphere, gases such as SO₂ or NO₂ may be beneficial to natural and agricultural ecosystems or they may act as air pollutants affecting these systems in a negative or adverse manner. In contrast, carbon dioxide (CO₂) is the basic plant nutrient and has positive and growth stimulating effects on vegetation. Because of their co-occurrence, the assessments of potential effects of atmospheric changes on vegetation have to consider these contrasting impacts and the interactions between effects of air pollutants and elevated CO₂.

ATMOSPHERIC CHANGE: CONCENTRATIONS AND TRENDS

Anthropogenic activities have changed the concentrations of a wide variety of gaseous and particulate compounds in the atmosphere, including carbon dioxide (CO₂), nitrogen monoxide (NO) and nitrogen dioxide (NO₂), sulphur dioxide (SO₂), ozone (O₃), ammonia (NH₃), heavy metals, and volatile organic compounds (VOC).^[1] Prominent examples of global importance are CO₂ and tropospheric O₃. Since the beginning of the 19th century, the concentration of CO₂ [CO₂] has increased globally to current values of about 360 ppmv (parts-per-million by volume). It is expected that [CO₂] will continue to increase even more rapidly and may reach about 550–650 ppmv between 2050 and 2100.^[2] As CO₂ is the substrate for plant photosynthesis, this increase in [CO₂] will have far reaching consequences for most types of vegetation.^[3,4]

Parallel to the increase in [CO₂], ground-level O₃ concentrations ([O₃]) in most industrialized countries have nearly doubled during the last 100 years. Current mean [O₃] in nonurban areas is between 40–75 ppbv (parts-per-billion by volume) during the growing season and 20–35 ppbv as an annual mean.^[1] Today, O₃ pollution has also become a major environmental problem in many developing countries. Predictions for the future development of [O₃] are uncertain; in the case that the emission of

the precursor compounds nitrogen oxides and volatile organic compounds remain high or continue to increase, [O₃] will follow these emission trends. [O₃] varies considerably in time and space and shows annual and diurnal patterns. In contrast to CO₂, elevated [O₃] is phytotoxic and affects plants negatively.^[4,5] However, quantification of the effects of O₃ is difficult due to the large variability of exposure concentrations.

EFFECTS OF CO₂ AND O₃ ALONE

As current atmospheric [CO₂] limits photosynthesis in most C₃ plants, any increase in [CO₂] results in a stimulation of plant physiological and growth processes.^[3] The most frequently observed effects of elevated [CO₂] include a stimulation of photosynthesis, enhanced concentrations of soluble carbohydrates, an increase in growth rates and leaf area, and stimulated biomass production and yield. Transpiration rate (per unit leaf area) and stomatal conductance, as well as tissue element concentrations (particularly nitrogen), usually decline. Yield enhancements of up to 25–35% as compared to ambient [CO₂] have been observed when plants were exposed to 550–750 ppmv CO₂.^[3,6] The initial stimulation of photosynthesis often decreases under long-term exposure to elevated [CO₂], leading to smaller growth and yield enhancements than expected from the short-term photosynthetic responses. Plant species differ widely in their response to high [CO₂].^[6]

By contrast, O₃ is currently regarded as the most important phytotoxic pollutant in the atmosphere.^[5] Primary O₃ effects include subtle biochemical and ultrastructural changes, which may result in impaired photosynthesis, alterations of carbon allocation patterns, symptoms of visible injury, enhanced senescence, reduced growth and economic yield, altered resistance to other abiotic and biotic stresses, reduced flowering and seed production, loss of competitive abilities of plant species in communities, and shifts in biodiversity. Current ambient [O₃] in many industrialized areas are high enough to suppress crop yields of sensitive species and to retard growth and development of trees and other plant species of the non-woody (semi-)natural vegetation. As with CO₂, there is large inter- and intraspecific variability in the O₃ susceptibility of plants.^[4,5]

INTERACTIVE EFFECTS OF CO₂ AND AIR POLLUTANTS

While single exposures to elevated [CO₂] or air pollutants may have contrasting effects on plant performance, it is of particular interest to understand how the individual changes in atmospheric constituents may interfere with each other in order to predict the likelihood of combined effects of atmospheric changes on terrestrial ecosystems.^[4,7-9]

CO₂ and O₃

A great number of studies on the combined effects of the two gases have shown that high [CO₂] either partially or totally compensate for adverse O₃ effects.^[4,7] This has been demonstrated, for example, for some crop species including soybean, wheat, and corn. However, summarized over the total available database with different plant species and cultivars (Table 1), the information is not entirely consistent, as several studies revealed that ele-

vated [CO₂] may not always protect plants from the adverse effects of O₃.^[7]

The proposed mechanisms to explain the protective effect of elevated [CO₂] against the phytotoxic effects of O₃ include 1) reduced uptake or flux of O₃ through the stomata due to a CO₂-induced stomatal closure, 2) improved supply of carbon skeletons supporting the synthesis of antioxidants involved in the destruction of O₃ and its toxic products, 3) protection of the Rubisco protein from O₃-induced degradation and 4) CO₂-induced changes in the cell surface/volume ratio.^[4,7,8] However, it has been shown that in spite of decreased stomatal conductance under elevated [CO₂], adverse effects of O₃ may still occur. As CO₂ effects on stomatal conductance may be species-specific, it is not yet possible to support a general concept of a CO₂-induced reduction in the flux of O₃ into the plant. Moreover, in a given plant species, protection by high [CO₂] from a particular adverse effect is not necessarily associated with the protection against another adverse effect. For instance, in wheat plants an elevated [CO₂] provided full protection from effects of O₃

Table 1 Selected examples of the effects of elevated [O₃] and [CO₂], singly or in combination, on plant metabolic and growth responses (examples with significant adverse effects of O₃ only)

Species	O ₃ Effect	CO ₂ Effect	O ₃ /CO ₂ Effect
Potato (cv. Bintje)	Decreased chlorophyll content; visible foliar leaf injury	n.e.	Adverse effect of O ₃ on chlorophyll content unchanged; reduced degree of visible O ₃ -induced leaf injury
Wheat	Visible leaf injury (30%)	n.e.	Reduced degree of visible O ₃ -induced leaf injury (5%)
Wheat (cv. Minaret)	Loss of Rubisco protein; decline in flag leaf CO ₂ assimilation rate	Loss of Rubisco protein; increase in CO ₂ assimilation rate	Amelioration of O ₃ effects
Wheat (cv. Cocker 9904)	reduced seed yield	Slightly increased seed yield	Amelioration of O ₃ -induced yield loss
Wheat (cv. Minaret)	Reduced flag leaf photosynthesis	Increased flag leaf photosynthesis	Amelioration of negative O ₃ effects
Wheat (cv. Hanno)	Reduced plant relative growth rate; reduced plant biomass	Slight increase in relative growth rate; increased plant biomass	Amelioration of negative O ₃ effects
Soybean (cv. Essex)	Reduced seed yield (40%)	Insignificant increase of seed yield	Amelioration of yield suppression
Cotton (cv. Deltapine 51)	Reduced leaf area per mass; reduced starch contents	Increased leaf area per mass and starch contents	Prevention of adverse effects of O ₃ by CO ₂
Norway spruce	visible leaf injury (chlorotic mottling)	n.e.	No effect of CO ₂ on the degree of O ₃ -induced leaf injury
Trembling aspen (different O ₃ -sensitive and -tolerant clones)	Reduced tree growth parameters (height, diameter, volume)	Enhancement of growth parameters	No effect of CO ₂ on the degree of O ₃ -induced growth reductions

Compiled from Refs. 4,7-9; n.e. = no effect.

on total plant biomass, but not on grain yield. Hence, the available data are still too limited to allow for a unified view of how these two gases might interact.^[7]

CO₂ and Other Air Pollutants

Hardly any studies have addressed the combined effects of elevated [CO₂] and of other air pollutants. Studies of the combined effects of elevated [CO₂] and nitrogen oxides (NO, NO₂) are confined to commercial greenhouses under conditions of horticultural crop production and are not considered here. SO₂ has been found to adversely affect agricultural crops and forest plants in a large number of studies.^[8,9] Reduced photosynthesis, altered water relations, growth retardations, yield losses and altered susceptibilities to other stresses are common plant responses observed under SO₂ stress.

It was shown for a range of plant species under various exposure conditions that elevated [CO₂] reduced the sensitivity of the plants to SO₂ injury or protected them from negative effects of SO₂ on growth and yield.^[9] With the combined exposure of crop species to both gases, the yield increments were sometimes even larger when compared to the stimulation observed with exposure to elevated [CO₂] alone, suggesting that the plants were able to use the airborne sulphur more effectively under the conditions of enhanced carbon availability. It must be kept in mind that low to moderate SO₂ concentrations may confer a nutritional benefit to plants, particularly under conditions of low sulphur availability in the soil.

CONCLUSION

Rising atmospheric concentrations of CO₂ and air pollutants can have interactive effects on agricultural and wild plant species. Existing evidence on potential interactions is almost exclusively restricted to CO₂ and tropospheric O₃, the concentrations of which are increasing globally. While high CO₂ levels are beneficial to plants, current ambient [O₃] is high enough to impair plants in many regions of the world. There is ambiguous information in the literature concerning the protective effect of elevated [CO₂] from adverse effects of O₃, but it has been demonstrated to occur in many experimental studies. The mechanisms by which elevated [CO₂] and O₃ interact at the physiological and metabolic level remain uncertain. There is also some evidence that rising [CO₂] may protect plants against phytotoxic SO₂ concentrations. Overall the existing database on air pollutant/CO₂ interactions lacks a general conceptual model of the potential modes of interactions. Additional long-term field experiments will be necessary, combined with a better understanding of how other plant and environmental variables, such as plant

genotype, soil water deficit, nutrient availability, or temperature, may modify the interaction.

Air Pollutants: Mode of Action

Robert L. Heath

Department of Botany and Plant Sciences, University of California, Riverside, California, U.S.A.

INTRODUCTION

Air pollutants are volatiles that are not found in high concentrations in natural atmospheres and are often produced in urban settings. These pollutants can cause injury to plants, distorting their metabolism, altering their appearance, and lowering their agricultural productivity. As these pollutants move into rural areas, they generate the same problems that, in the total ecosystem, alter plant and animal interactions and distributions. There are many types of pollutants, but the most common include sulfur dioxide, fluoride, oxides of nitrogen, and oxidative species, such as ozone. All pollutants generate their effects by different mechanisms but most must enter the tissues via the stomata to cause their specific injuries. The injuries are best described by the visible injury or tissue damage symptoms but also plant metabolism tends to be shifted away from the more productivity state. Ozone creates more of the most troublesome conditions by inhibiting and disrupting many photosynthetic processes. Air pollutants can be controlled and their concentrations lowered, but that requires political and economic motivations.

Alteration of the atmospheric environment existed as long as Earth has existed. The question of how far the atmosphere can deviate from the norm and still support life will be argued, but in the modern era that question is more defined. In the United States, acceptable alternations to the urban atmosphere is defined politically as to be small enough not to cause harm primarily to humans and secondarily to plants. The balance between protection of life and the lack of economic disruption is continuously being argued in the scientific halls, political chambers, and the courtrooms. For each pollutant a balance must be struck in governmental discussions of the scientific issues.^[1] The pollutants that are understood as to their modes of action are shown in [Table 1](#). To be sure, there are many others that are formed by commercial activities but are deemed to be in such low concentrations or are so poorly understood that they are not regulated. As our ability to detect smaller concentrations of these unusual compounds continues to increase, the pressure to regulate those other compounds will grow, especially if they are found to cause problems with human health or to injury, normal growth, development, and productivity of plants.

Presently, as we understand how plants respond to the environment, there is a band of adaptability of the individual to any environmental condition. Each individual integrates its response to the total environment and that generates a general response of the species within that environment—some individuals will perish but the majority will survive if that species is to continue within that particular ecosystem. Our problem is to manage the total ecosystem to maintain diversity (at least as defined by our society) and to generate a concept of risk assessment—that is, what band of adaptability is acceptable to us? For the most part, the appearance of visible injury on the surface of the leaf is the test of varied air pollutants. There is an older book^[2] that has a fine collection of pictures of varied injuries that develops upon leaves due to a variety of pollutants. Unfortunately, there is a variation between species as well as other atmospheric conditions, which influence the production of visible injury. Yet, it is still the method of choice to monitor in the field what air pollutants are present and how much. Plants respond to air pollutants similarly to other stresses on several levels: exclusion, tolerance, and repair. The response mechanism depends upon the concentration of the air pollutant, environmental conditions, and the developmental and metabolic state of the plant. Any response is detrimental to plant productivity because it costs the plant metabolic resources. For example, the stomata can close under the pollutant exposure to exclude the pollutant from the interior of the plant, thus preventing damage. However, stomata closure lowers photosynthetic CO₂ fixation and plant productivity will suffer.

FLUORIDE, SULFUR DIOXIDE, AND AMMONIA

In [Table 1](#), the first three pollutants (fluoride, sulfur dioxide, and ammonia) can be controlled, generally at the source of the pollutants (smelter plants and livestock paddocks). While they have been historical problems, their modes of action are generally understood and their levels are now well controlled.^[3] Yet they have an interesting mode of action that revolves about their charge under different pHs and their ease of entry into the cell. The change in charge is best shown for

Table 1 Types of inorganic air pollutants. This table shows the more common types of air pollutants and gives a summary of the species and possible mechanism of plant toxicity. Suggested mechanisms regarding how the plants deal with the species (either by detoxification or neutralization) are also listed

Compound	Chemical species	Putative mechanism	Countermeasure
Fluoride	F ⁻	Metabolic poison; alteration of soil chemistry	Physical elimination from cells; chemical binding within soil
Sulfur dioxide	Sulfite/sulfate ions	Osmotic load of sulfate; SO ₃ ²⁻ , metabolic poison	Faster metabolism; elimination of SO ₃ ²⁻ by oxidation
Ammonia	NH ₃	Metabolic poison; overload of ammonia and disruption of pH within cells	Conversion to more oxidized form of nitrogen
<i>Urban oxidants</i>			
Acid rain	H ⁺ (with varied anions)	Soil nutrient alterations; mobilization of Al	Buffering power
Oxides of nitrogen	NO _x	Excess nitrogen; altered ammonia in tissues; disruption of pH within cells	Faster metabolism
Nitric oxide	NO	Possible signal transducer	Elimination by oxidation
Nitrogen dioxide	NO ₂	Excess nitrogen	Faster metabolism
Nitric acid	HNO ₃	Acidic reactions of cuticle; leaching of ions	Strong pH buffers
PAN	(CH ₃) ₂ O-O-NO ₂	Membrane injury	Antioxidants
Hydrogen peroxide (activated oxygen)	H ₂ O ₂	Unknown, but probably false signal transducer	Antioxidants
Ozone	O ₃	Membrane injury	Antioxidants

NH₃ and for fluoride in Fig. 1. The charged moiety does not typically enter the cell, but rather it is the uncharged species that can penetrate the membrane. Thus, pH outside the cell plays a critical role in the dose of the pollutant, which actually reaches the interior of the cell. Within the cell both species can re-equilibrate with the cell's pH and so generate other possible species (for sulfur oxides in Fig. 1). Fluoride is a well-known metabolic poison, which is active in the cell's main line of metabolism (e.g., ATP production). Ammonia is required by the cell for normal metabolism but in excess can injure metabolism presumably by acting as a pH shifter (by taking up H⁺) and by causing water imbalances through osmotic forces.

SO₂ presents a slightly different problem in that it first must enter the water solution surrounding the cell (as does F⁻ and NH₃) and then is hydrated. The hydrated form can undergo a series of oxidations to form diverse oxides of sulfur. Some of species are cellular poisons while others are osmotically active

species. While sulfate is present in all cells and can be tolerated in relatively high concentrations, sulfite is a metabolic poison and interferes with photosynthetic processes at the electron transport level.

NITROGEN OXIDES AND OZONE

Again the oxides of nitrogen have the same type of responses as does SO₂. It was thought that they can add excess nitrogen (N) to the plant, which is similar to a fertilizer. Unfortunately, in a typically N-poor ecological setting, this shift in N can cause an alteration in the dominant plants. In southern California, native plants seem to be overwhelmed by grasses, brought in by humans, and fertilized by the atmospheric NO_x. While a problem, the mode of action of NO_x was deemed to be understood.^[4] However, recently it has been suggested strongly that NO could be involved in signal transduction and so extra NO

Fig. 1 Diagram of species penetration into plant cells. As these compounds are formed with a water solution and then ionize, some of the species are charged and do not move into cells, while others being uncharged easily penetrate the cell membranes. Each of the processes has different ionization constants and thus the concentration of each species is very dependent upon the pH of the wall, cell, and organelles.

from the atmosphere could shift normal metabolism. NO_x compounds include HNO_3 and that acid seems to erode the leaf cuticle leading to excess water loss.

The depletion of stratospheric ozone is currently a principle concern of humankind; the depletion can lead to high levels of biologically damaging UV reaching the Earth's surface. However, the production of tropospheric ozone is different but likewise has a serious impact upon life. The combustion of gasoline produces varied forms of NO_x (multiple forms of oxides of nitrogen), which cannot be totally diluted by large masses of clean air. One of the principle forms of NO_x is NO_2 . As shown by the Fig. 2, NO_2 (being dark brown) absorbs light and decomposes into NO and $[\text{O}]$ (atomic oxygen), which reacts vigorously with O_2 to produce O_3 . As the O_3 builds up, it can react with NO to produce NO_2 (and O_2) leading to an equilibrium of $\text{NO}/\text{NO}_2/\text{O}_3$, which is shifted toward excess ozone

Fig. 2 The oxides of nitrogen/ozone cycle occurring within urban atmospheres. The generation of ozone relies upon light during the day and the presence of oxides of nitrogen. Nitrogen dioxide absorbs visible light, which acts to disassociate the NO_2 species into NO and atomic oxygen. Atomic oxygen is very unstable and reacts immediately with oxygen to produce ozone. NO can react with ozone to produce nitrogen dioxide again. During the day the equilibrium is toward higher levels of ozone while at night the equilibrium shifts to “mop up” ozone and produce more NO_2 . The ozone level at night actually drops to near zero in urban settings.

during the day. This series of reactions lead to the production of the ozone that badly impacts our cities' atmospheres.

Ozone induces visible injury to the surface of leaves and a loss of productivity of plants; both have been used to monitor ozone's presence and reactions. Generally, the visible injury patterns—such as “water-logging,” lower surface “bronzing,” upper surface “silvering”—can be used to assess injury by persons who are well versed in their identification. Yet there are three sequential processes that combine to trigger ozone stress from the movement of gases from the atmosphere into the sites of action within the leaf.^[5]

Process 1. Entry of the pollutant into the leaf. The entry of gases into a leaf is a well-defined path,^[6] which includes gaseous diffusion through the leaf boundary layer and stomata into the substomata cavity approximately following a linear flux law of:

$$j = g(C_o - C_i)$$

in which the flux (j) into the internal space of a leaf is related to the conductance (g) through the boundary layer and stomata, and the gradient of concentration (C) of gas from the outside (C_o) to the inside (C_i). For both water and CO_2 , this formulation has been used for years. For ozone, internal concentration has been found to be very close to zero, most probably because ozone is extremely reactive with cellular biochemicals. Thus, the effective delivery rate is ($g \times C_o$) with stomata conductance being the major regulatory control. The flow of gaseous pollutants is from the substomata cavity within the leaf into the cell, through the wall, where varied charges can influence its rate of decomposition and the products formed. An equilibrium between the gas and aqueous phase occurs at the interface where the gaseous species dissolve into the water, according to Henry's Law.

Process 2. Biochemical reactions of the gases with the cell. Many reactions of the gas in the water phase at the cell's surface and the reaction of each species thus generated generates diverse components within the wall region of the cell (some are shown in Table 2). These chemical reactions are poorly understood although there are some data suggesting that free radicals and oxygen species do form.^[6] Ozone does react with organic molecules at double bonds (such as ethylene and unsaturated fatty acids) to form carbonyl groups and, under certain circumstances, peroxides. Sulfhydryls are particularly easy targets, with the formation of disulfide bridges or sulfones. In water, the reactions become more confusing, but some oxidative products that can be linked to metabolic changes are hydrogen peroxide (H_2O_2), hydroxyl

Table 2 Mechanisms of toxic product production by ozone within the cellular space*Possible ozone reactions^a**Detoxification of radicals^b*

Superoxide dismutase

Catalase

Ascorbate peroxidase

Glutathione peroxidase

Peroxidase

^aPossible ozone reactions within the wall and cytoplasmic space of a plant cell are listed. These reactions have been observed within chemical and some biochemical systems but have not yet been detected within the plant or its cells. These reactions are consistent with metabolic changes observed within the plant and the detection of free radical signals after ozone exposure.

^bThese are the varied antioxidants and their reactions, which have been postulated and observed to interfere with ozone induced injury to plants.

radical (HO^\bullet), and superoxide (O_2^-). Effective detoxification reactions can occur within the wall and inside the cell via antioxidant metabolites and enzymes, such as ascorbate, glutathione, and superoxide dismutase, if they are present at high enough concentrations (see Table 2). Certainly chemical modification of wall-specific biochemicals is possible, such as ascorbate, glucan synthase, peroxidases, and diamine oxidase.^[6,7]

Process 3. Movement of reaction product(s) and their enzymatic or chemical transformations within the cell. Currently, there are several major theories of how ozone or its toxic products alter varied processes within the cell.

- *Membrane dysfunction.* The membrane is altered by ozone, principally via protein changes not involving the lipid portions of the membrane (except at extremely high levels of ozone where the fatty acids of lipids are involved). These alterations involve increased permeability with less selectivity, decline in active transport, and changes in the trigger mechanisms of signal transduction pathways such that the signals are no longer the correct state of the cell. Changes in the cellular pools of $\text{Ca}^{2+}/\text{K}^+/\text{H}^+$ are the primary suspects.^[6]
- *Antioxidant protectants.* The varied antioxidants (both as metabolites and enzyme systems) can eliminate the oxidant or its products, if present at time of fumigation and in high abundance. Too rapid entry of the oxidant can overwhelm the antioxidant response.^[8]
- *Stress ethylene interactions.* Visible injury is caused by the interaction of ozone with stress-induced ethylene, either by direct chemical transformation

of ethylene to a toxic product or by alteration of the biochemical relations at the ethylene binding and sensing sites.

- *Impairment of photosynthesis.* At least two distinct processes inhibit photosynthesis. Some product of ozone entry causes a decline in the m-RNA for the primary CO_2 fixing enzyme, Ribulose 1,5-bisphosphate carboxylase/oxygenase (Rubisco) such that the level of Rubisco slowly declines within the chloroplast, leading to a lowered rate of CO_2 fixation and lowered productivity. This process appears to be early senescence and may be linked to general senescence. Also, ozone alters the normal ionic and water relations of guard cells and subsidiary cells, such that the stomata close and so limits CO_2 fixation.^[9] Thus, the response of the stomata to the current environment is incorrect for efficient photosynthesis.
- *Translocation disruption.* One of the most sensitive biochemical systems to ozone exposure seems to be the translocation of sugars, such that even a mild exposure will lower the ability to transform and move carbohydrate within the plant and cause the loss of sugar transport out of the cell to sinks necessary for efficient growth and productivity.
- *General impairment/disruption of varied pathways of metabolism.* A seemingly wide range of impairment of metabolism was noted in early work on ozone injury, including disruption of metabolic pools and changes in enzymatic activity. These results lead to the vaguest concept of how ozone alters metabolism; it is based upon earlier work in which enzymes and metabolites, which could be assayed, were measured. This concept was based

upon what could be done rather than a testing of any coherent hypothesis or following interactions of genes and enzymes.

In the early days of pollution studies the pathological observations far outstripped the physiological understanding of the basic mechanism of why those observations occurred. During the past decade understanding of the physiology of plants, including the genetics and basic biochemical interactions and foundations, has caught up with the observations and in many cases is now ahead of those past observations. The older pathologies have not proven to be incorrect but with understanding of mechanisms, remediation and preventions now is more possible. This means that reviewing the older literature is highly useful to re-learn those older pathologies and observations. While the older described mechanism were very insightful, modern theories can give a better picture of exactly how the pollutants alter normal physiology (for a summary see Refs.^[5,10]).

CONCLUSIONS

In conclusion, the pollutants generated in the urban areas remain the most problematical ecological abuse since they are linked to economic productivity and growth. Aside from human health many of these pollutants have been shown to lower plant productivity, induce a visible injury, generate conditions of early senescence, and disrupt many normal metabolic pathways. For these reasons pollutants must be carefully regulated to prevent occurrence of high levels in urban air basins.

Air Pollutants: Responses of Plant Communities

Andreas Fangmeier

University of Hohenheim, Stuttgart, Germany

INTRODUCTION

Responses of plant communities to air pollutants have been investigated much less than those of individual plants or single plant species. From studies comparing individuals of different species, it is clear that the sensitivity varies considerably among species. However, because of interactions between species, such as competition and facilitation, individual species responses do not represent the responses of the same individuals growing in communities. From the existing knowledge, it is difficult to draw a generalized picture of community responses. Rather, different communities tend to show individualistic responses.

AIR POLLUTANTS: NUTRIENTS AND/OR TOXIC AGENTS

Atmospheric pollutants can roughly be divided into three groups: 1) phytotoxic compounds that cause only adverse or toxic effects, such as ozone (O₃); 2) essential macro- and micronutrients that can act as fertilizers at low deposition rates but may have adverse effects at high deposition rates,^[1] such as sulphur dioxide (SO₂) or nitrogen compounds (NO_x, NH_y); 3) pollutants that in most cases represent an essential resource, such as carbon dioxide (CO₂). In the case of pollutants causing adverse or toxic effects, it can be expected that a species that exhibits high sensitivity to the air pollutants when grown in monoculture will suffer even more when grown in competition with a less sensitive species. In the case of air pollutants that act as potential macro- and micronutrients, the situation is more complex because both the beneficial effects, including growth promotion due to the additional nutrient supply, and the adverse effects, such as lowered stress resistance,^[2] must be taken into account on top of any plant–plant interactions.

SCALING FROM SINGLE SPECIES TO PLANT COMMUNITIES

The current knowledge of the responses of plant communities to changes in atmospheric quality is based on a

much smaller data base than knowledge of the responses of single species grown in isolation. Roughly less than 1% of the experimental studies with air pollutants, such as O₃, SO₂, NO_x, NH_y, or elevated CO₂, have involved plant communities. The vast majority of experiments have used single plants or monocultures of a species grown under conditions that are not representative of their natural environment. This is mainly because field experimentation with plant communities is demanding and requires exposure experiments with large plot sizes, replicate numbers, and long durations in order to account for the biological variation found in natural habitats.

Sensitivity and responsiveness of plants to air pollutants differ considerably among species, and a sensitive species may be even more affected when grown together with a less responsive species because of the competitive advantages of the latter. Besides competition, other forms of interactions exist between different species, leading to a disadvantage, an advantage (e.g., facilitation), or no effect on either of the partners. Any alteration of the environmental conditions, such as a change in atmospheric quality, may affect these interactions and, hence, the specific responses to the change. Therefore, community reactions cannot easily be predicted from results of exposure experiments with single species. Some studies with communities have shown surprising results, e.g., the success of one particular species, which could never be expected from exposures with the same species grown in isolation. Hence, pollutant effects on plants are modified by the environment and by the presence of other species (Fig. 1). Nevertheless, some basic response patterns have emerged, and examples of illustrative studies are given below.

CASE STUDIES

Tropospheric Ozone—Phytotoxicity Overestimated?

Tropospheric ozone is regarded as the most important and most widespread gaseous air pollutant in many industrialized regions of the world. Its background concentrations have at least doubled over the past century.^[3] Recent approaches to define thresholds above which exposures do

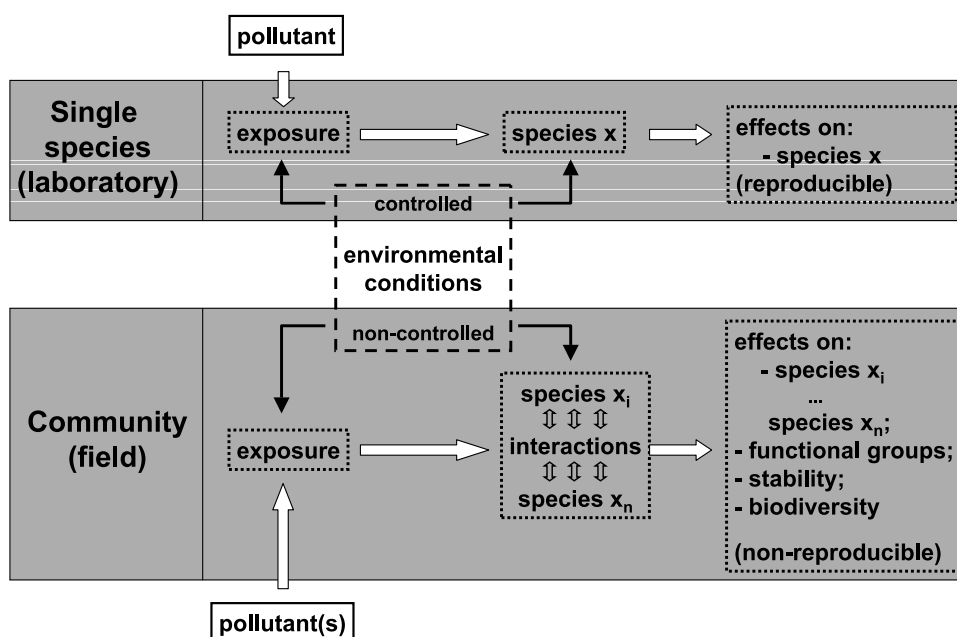

Fig. 1 Scheme of the differences in pollution effects on single species and on plant communities due to species interactions and the degree of variability in environmental conditions. For a better illustration of the problem, two extreme cases are compared: single species exposure under controlled laboratory condition and multispecies exposure in the field.

not harm sensitive vegetation have been based on the Critical Levels concept, which uses the exposure index AOT 40, i.e., the sum of all hourly ozone concentrations exceeding a baseline of 40 ppb during hours when global radiation levels exceed 50 W m^{-2} . For instance, an AOT 40 of 3000 $\text{ppb}\cdot\text{h}$ calculated over a three-month growing period is currently assumed to protect agricultural crops from negative effects of O_3 on yield^[4] and to prevent damage to natural vegetation.

However, from the few experimental field studies with ozone involving plant communities, such thresholds cannot be confirmed. Significant effects on plant species diversity due to ozone in an early successional community were observed when twice ambient ozone concentrations were applied with an AOT 40 reaching 38,000 and 48,000 $\text{ppb}\cdot\text{h}$ in two consecutive experimental seasons, respectively, but not at lower exposure levels.^[5] In an ongoing long-term study with a species-rich meadow, minimal effects of elevated O_3 on the plant community composition could be observed, although the AOT 40 values largely exceeded 3000 $\text{ppb}\cdot\text{h}$ in each year (P. Bungener, pers. comm.) Thus, it is not clear at present whether O_3 affects the composition of established plant communities, as it was expected from short-term exposure studies with monocultures. Further studies involving herbaceous seminatural ecosystems may give additional insight into the responses of plant

communities to tropospheric O_3 by involving modeling based on either mechanistic or plant functional-type principles.^[6]

Changes in Plant Communities Exposed to Sulphur Dioxide

Responses of plant communities to SO_2 are known either from field studies around point sources of emission or from fumigation experiments. The general picture emerging from these studies is that of a strong impact of SO_2 leading to different zones of vegetation corresponding to the severity of the pollutant exposure. Acute concentrations may inhibit plant growth completely and even lead to soil erosion because of the high load of acidity and the complete absence of vegetation. An example from a temperate forest region^[7] showed that further away from the emission source a zone existed with a low-density cover formed by resistant grasses, herbs, and dwarf shrubs. With increasing distance and decreasing exposure, the herb cover increased and tree species of poor habitats could survive, thus providing the picture of a tree-line "ecotone" (the so-called "Kampfzone"). Symptoms of forest decline could be observed over longer distances from the emission source, and only at exposure levels close to the background concentrations did the upper tree

canopy, which is most prone to adverse SO₂ effects, regain its natural shape and performance.

Nitrogen Deposition—An Unwanted Fertilizer

Nitrogen (N), like sulphur (S), is a macronutrient. However, the demand of vegetation for nitrogen is much higher than for sulphur. Typically, N:S ratios in plant tissues approximate 10:1 to 15:1. Therefore, sulphur becomes toxic at much lower rates of deposition compared with nitrogen, and current loads of nitrogen often lead to enhanced growth and productivity rather than to injury. However, eutrophication of ecosystems due to excess nitrogen inputs may also have adverse effects: Nutrient-poor stands that carry some of the most diverse plant communities may be lost, and ecosystems may become more susceptible to different forms of additional stresses.

Most plant species from natural habitats are adapted to nutrient-poor conditions and, because they have a low competitive ability against nitrophilous species, they can only compete successfully in systems with low nitrogen input. Consequently, changes in species composition caused by high nitrogen loads, often associated with a loss of biodiversity, have been observed in several ecosystems. Over the past decades, the forest floor vegetation at many locations in western, central, and northern Europe has seen an increase in nitrophilous species. In heathlands, which represent seminatural ecosystems in most of their area of distribution in western Europe, a transition to grasslands has occurred. Apparently, the equilibrium between nutrient output by periodic removal due to grazing and sod removal and nutrient input by mineralization in these heathlands has been disturbed. This is due to not only the absence of management (e.g., less or no sheep grazing, abandonment of sod removal), but also excess nitrogen deposition from the atmosphere.^[8] Somewhat similar effects have been observed in nutrient-poor grasslands, in particular in calcareous grasslands. Because of the soil conditions or as a result of management leading to removal of nutrients by grazing or hay making, these grasslands remain nutrient-poor and carry a high species diversity with many endangered plant and animal species present, and, therefore, they have been set aside as nature reserves. Excess nitrogen deposition to calcareous grasslands strongly stimulates the growth of *Brachypodium pinnatum*, leading to the formation of a dense cover that reduces the light quantity and quality in the lower parts of the canopy, which, in turn, causes a drastic reduction in species diversity.^[9]

Besides these effects, nitrogen deposition has been shown to reduce stress resistance. Coniferous trees and heathland shrubs such as *Calluna vulgaris* exhibited

lower tolerance to drought and frost after moderate exposure to ammonia (NH₃), and the attack on *C. vulgaris* by an insect herbivore, the heather beetle (*Lochmaea suturalis*), was more severe under conditions of excess nitrogen.^[8]

CO₂ Enrichment: The Planet Might Get Greener, But Is This All?

In general, CO₂ enrichment promotes vegetation growth and productivity and makes plants more efficient in their use of resources. Irrespective of the type of the CO₂ fixation pathway (C₃, C₄, or CAM) of a particular species, higher plants profit from CO₂ enrichment by increased water-use efficiency. In addition, plants with C₃-photosynthesis show higher nitrogen-use efficiency when grown at elevated CO₂ levels.

At present, the ambient atmospheric CO₂ concentration limits plant growth in species involving the C₃ fixation pathway. In contrast, C₄ plants possess an efficient CO₂ pre-fixation mechanism, and their photosynthesis is CO₂-saturated at the present atmospheric CO₂ concentration. Therefore, C₃ plants are expected to profit more from CO₂ enrichment than C₄ plants in terms of growth and productivity. This expectation has been confirmed in some, but not all, experimental field studies with plant communities. In a salt marsh under long-term CO₂ enrichment, the C₃ sedge gained competitive advantages over the C₄ grasses.^[10] In a tallgrass prairie ecosystem composed of tall warm-season perennial C₄ grasses and smaller cool-season perennial C₃ grasses plus C₃ forbs and C₃ *Cyperaceae* members, eight years of exposure to CO₂ enrichment had little effect on the C₄ grasses but caused a decline in cool-season C₃ grasses and an increase in C₃ forbs and C₃ *Cyperaceae*.^[11] In a calcareous grassland composed of C₃ species belonging to different functional groups (graminoids, nonleguminous forbs, and legumes), the legumes were most responsive to CO₂ enrichment in one year, and the forbs in the following year.^[12] At the species level, the biomass response ranged from a decrease in several *Trifolium* species to an increase by 271% in *Lotus corniculatus* and by 249% in *Carex flacca*. These examples illustrate the current difficulty in predicting any general responses to CO₂ enrichment across different plant communities.

CONCLUSION

Responses of plant communities to air pollutants may be much more subtle and therefore more difficult to detect

than effects on single species or individual plants. Unfortunately, knowledge is restricted to a limited number of experimental exposures with artificial mixtures of species and to an even more limited number of field exposures involving natural plant communities. Thus, at this stage it is difficult to draw general conclusions from limited data. Some general patterns emerge from studies either of the effects of SO₂ pollution, with climax tree species being most susceptible, or of excess nitrogen deposition, e.g., loss of species adapted to nitrogen-poor habitats, whereas no general picture is available concerning effects of O₃ or elevated CO₂. This is due to the lack of data and the fact that individual communities show specific responses. Furthermore, hardly any knowledge exists about the resilience of plant communities in response to air pollutants. From long-term studies on SO₂ effects, it can be concluded that communities and ecosystems are able to regain their structure and function upon termination of the air pollution stress. It may well be possible that complex plant communities can react flexibly to air pollutants, and, consequently, effects are less than expected. Conversely, it seems possible that any pollution level above the natural background could have subtle adverse effects—e.g., in terms of losses in biodiversity, stability, or other ecosystem services—and thus should not be tolerated. Furthermore, it should be noted that effects of combinations of air pollutants on plant communities have rarely been investigated. Therefore, the current approach to protect vegetation and ecosystems from adverse effects of pollutants by means of the Critical Levels and Critical Loads concept must be reevaluated regularly and critically as new information on air pollution effects at the community level becomes available.

Alternative Feedstocks for Bioprocessing

Joseph J. Bozell

National Renewable Energy Laboratory, Golden, Colorado, U.S.A.

INTRODUCTION

Bioprocessing is an inexact term often incorrectly limited to the single context of combining a fermentable sugar with an organism for the purpose of making a chemical. This is a common misconception, and one that must be dispelled, because bioprocessing includes all aspects of the use of renewable and sustainable materials for the production of chemical products, fuels, and power. Alternative feedstocks is a term more easily understood, and for the purposes of this discussion, will mean biomass-derived raw materials and building blocks, i.e., renewables. Bioprocessing deals with three primary issues: supply, separation, and conversion.

DISCUSSION

Supply issues are primarily associated with the growing and collection of the biomass feedstock. Bioprocessing deals with the source of the starting feedstock, its availability, the best geographic location for production, its supply and sustainability, collection, densification, and processing.

In a direct analogy to crude oil, biomass feedstocks are complex mixtures of different materials that must be separated to obtain the primary raw materials for conversion into other products. Bioprocessing involves developing the best methods for separation and isolation of these renewable building blocks, such as lignocellulosic components (cellulose, hemicellulose, lignin), oils (soy oil, canola, etc.), protein, extractives, and higher-value chemicals.

Once isolated, renewable building blocks must be converted into chemical intermediates and final products. Bioprocessing investigates development of the best technology to carry out these transformations. The very limited view of bioprocessing being only a sugar interacting with an organism more correctly fits as a subset of conversion. It is important to realize that bioprocessing does not *require* biotechnology. Bioprocessing also includes the use of conventional chemical technology to carry out transformations on renewable building blocks, as well as hybrid transformations such as combining nonrenewable building blocks with biochem-

ical technology. Lichtenthaler has written extensively about the use of conventional chemical technology to convert carbohydrates to new products.^[1]

A comparison between a bioprocessing industry (the “biorefinery”) and the existing petrochemical industry is appropriate because each faces the three primary issues. For the most part, issues of supply and separation are generally understood for both bioprocessing and petrochemical refining. However, conversion processes are not as well understood for bioprocessing as they are for petrochemical processing. The primary difference between the two industries is *technology development*. The petrochemical industry has gained amazing transformational control over the behavior of their many crude oil derived building blocks.^[2] In contrast, the analogous use of renewables suffers from a much narrower range of discrete building blocks, fewer methods to convert those building blocks to other materials, and a lack of information about the properties and performance available from those products. We are faced with the puzzle of possessing an almost limitless source of raw material in the United States, while being unable to effectively convert it to a wide range of useful products.

This discussion cannot cover all the specifics surrounding these three very broad areas. Accordingly, this brief overview will describe only the major concepts involving bioprocessing and alternative feedstocks for the production of new chemical intermediates and products.

THE CASE FOR RENEWABLES

Well into the 20th century, bioprocessing of renewable feedstocks supplied a significant portion of the United States’ chemical needs. The chemurgy movement of the 1930s, led by such notables as William Hale and Henry Ford, promoted the use of farm products as a source of chemicals, with the belief that “anything that can be made from a hydrocarbon could be made from a carbohydrate.”^{[3,4]a} It is only in the period of time

^aInterestingly, the chemurgical movement was not initiated as a result of a shortage of other feedstocks, but rather as a way to use farm surpluses.

between 1920 and 1950 that we have witnessed the transition to a nonrenewables-based economy.^[5]

A vast amount of renewable carbon is produced in the biosphere. About 77×10^9 tons is fixed annually, an amount that could supply almost all domestic organic chemical needs, currently about 7–8% of our total nonrenewables consumption.^[6–8] When measured in energy terms, the amount of carbon synthesized is equivalent to about ten times the world consumption.^[9] Cellulose, the most abundant organic chemical on Earth, has an annual production of about 100×10^9 tons.

Yet our chemical feedstock supply is overwhelmingly dominated by nonrenewable carbon. Only about 2% comes from renewable sources,^[10] thus, relatively few examples of large scale industrial bioprocessing exist. Two notable exceptions are the pulp and paper and the corn wet milling industries. Both convert huge amounts of renewable feedstocks into market products. The corn industry alone produces $8\text{--}10 \times 10^9$ bushels of corn/yr. Each bushel contains 33 lb of renewable carbon as glucose, and a corn harvest of 10×10^9 bushels is equivalent to 500×10^6 barrels of crude oil.^[11] Over 1×10^9 bushels of this supply is converted to ethanol (EtOH) and high fructose corn syrup. The pulp and paper industry consumes over 100×10^6 metric tons/yr of wood.^[12] Specialty dissolving-grade celluloses are used for the production of over 1.4×10^6 metric tons/yr of cellulose esters, ethers, and related materials. Lignin production by the pulp and paper industry is $30\text{--}50 \times 10^6$ metric tons/yr.^[13] The experience of these industries would seem to indicate that renewables hold considerable promise as feedstocks, complementary to those used by the chemical industry. However, the pulp and paper industry devotes only a small part of its production to chemicals, while the corn wet milling industry is focused largely on starch and its commercial derivatives, ethanol and corn syrup.

Several advantages are frequently associated with bioprocessing of alternative feedstocks:

- The use of biomass has been suggested as a way to mitigate the buildup of greenhouse CO₂ in the atmosphere.^[14] Because biomass uses CO₂ for growth through photosynthesis, the use of biomass as a feedstock results in no net increase in atmospheric CO₂ content when the products break down in the environment.^{[15]b}

^bThis statement presumes that the CO₂ contained in standing trees, debris, and soil is not released and that consumed biomass is replaced by fresh plantings, i.e., the system must be sustainable.

- It is generally acknowledged that increased use of biomass would extend the lifetime of the available crude oil supplies.^{[16,17]c}
- A chemical industry incorporating a significant percentage of renewable materials is more secure because the feedstock supplies are domestic, leading to a lessened dependence on international “hot spots.”
- Biomass is a more flexible feedstock than is crude oil. For example, the advent of genetic engineering has allowed the tailoring of certain plants to produce high levels of specific chemicals.

Moreover, increased use of renewable feedstocks could address broader issues:

- **Global Feedstock Needs:** Recent work has attempted to model when world oil production will peak and has concluded that a decline will begin sometime in the next 5–10 years.^[18] Demand will not decrease in line with production. United States energy consumption has increased by more than 28% (about 21 quadrillion btu) during the last 25 years, but more than half of the overall energy growth of the last 25 years (about 11 quadrillion btu) has occurred during the last 6 years.^[19]
- **Domestic Energy Consumption:** The United States annually consumes about 94 quads of energy.^[19] Of this, 35 quads are used by industry in general, almost 8 quads of which are used in the production of chemicals and paper. This is a significant energy target, and one that could be addressed by a greater use of renewables.

ECONOMICS OF BIOPROCESSING

Economic issues do not appear to present a major hurdle to the use of bioprocessing. The costs of a number of polymeric and monomeric materials compete favorably with nonrenewables (Table 1).^[20–22] Other evaluations show that two of the most basic renewable feedstocks, corn and cellulose, are competitive with several fossil feedstocks on both a mass and an energy basis (Table 2).^[23] The breakeven price for oil when compared to cellulosic

^cThe concept of “diminishing supplies” is subjective. During the oil crises of the 1970s, projections concluded that oil prices would be about \$100/barrel by the late 20th century. In contrast to expectations, crude oil is still relatively inexpensive. A projection by the International Energy Authority predicts that the price of oil (in 1993 dollars) will rise only to \$28/barrel by 2050.

Table 1 Costs of some selected renewable feedstocks

Material	US\$/kg	US\$/lb	Cost type	Source
<i>Polymers</i>

biomass at \$40/ton is \$12.7/barrel on an energy basis and \$6/barrel on a mass basis.

TECHNOLOGY FOR BIOPROCESSING

Primary examples of bioprocessing in the chemical industry are represented in two major areas:

- **Conventional Processing:** Renewable feedstocks can be converted to marketplace chemicals using conventional chemical transformations. This approach was frequently used in the early part of the 20th century. It offers the advantage of using the vast knowledge possessed by today's chemical industry for the conversion of a new feedstock source to products. However,

the technology development issues described earlier have hindered greater use of these kinds of approaches.

- **Biocatalysis:** Biocatalysis offers the benefits of proceeding under very mild conditions, frequently in aqueous reaction media, and the use of readily available renewable feedstocks as starting materials. However, issues of separation, expense, productivity, maintenance of organisms, and new capital investment have so far limited the use of bioprocesses in the chemical industry, except where no other alternatives are available.^[24]

Significantly absent from the standard tools available for bioprocessing is the use of nonbiological catalysis. Catalysis is proving to be a powerful technology for the petrochemical-based chemical industry, with 80–90% of all chemical processes involving at least one catalytic

Table 2 Comparative raw material costs^a

	Oil	Natural gas	Coal	Corn	Lignocellulosics
\$/dry tonne	129 (\$17.5/barrel) 94 (\$12.7/barrel) 44 (\$6/barrel)	122 (\$2.50/1000 scf)	33	98 (kernels, \$2.50/bushel) 19 (stover)	44 (poplar, switchgrass)

step.^[25] Catalysis will also see increasing use as a tool for bioprocessing.^[26–29]

EXAMPLES OF BIOPROCESSING IN THE PRODUCTION OF CHEMICALS

Conventional Processing

Conventional transformation of renewable feedstocks to products is not common in the chemical industry. In many cases, the products are those that can be isolated from existing renewable resources without further structural transformation. Examples include extractives from the pulp and paper industry used in the production of turpentine, tall oils, and rosins,^[30] the production of oils from corn or other oil crops,^[31] or starch-based polymers.^[32] Other products are made by simple derivatization of the materials found naturally occurring in biomass. The pulp and paper industry produces a number of chemicals, including a wide range of cellulose derivatives such as cellulose esters and ethers, rayons, cellophane, etc. A few well-known routes exist for the conversion of renewables to low-molecular-weight monomeric products. Glucose is converted to sorbitol by catalytic hydrogenation, and to gluconic acid by oxidation. Furfural is manufactured by the acidic dehydration of corn byproducts.^[33] Xylitol is also produced from xylose by hydrogenation.^[34] Vanillin^[35] and DMSO have been commercially produced from lignin.

Some renewables-based materials under development have promise, but their production is not yet commercialized. These products include levulinic acid^[36] and its derivatives;^[37,38] methyltetrahydrofuran, an automobile fuel extender;^[37,38] δ -aminolevulinic acid, a broad spectrum biodegradable herbicide, insecticide, and cancer treatment;^[39–43] and diphenolic acid, a material for the production of polymers and other materials.^[44] Levoglucosan and levoglucosenone are products of sugar pyrolysis. Hydroxymethylfurfural is made by acid treatment of sugars.^[45–47]

Lignin has also been investigated as a chemical feedstock (for example, in the production of quinones.^[48]) and has been widely suggested as a component in graft copolymers or polymer blends.^[49]

Biocatalysis

The most successful route so far for introducing renewables to the chemical industry has been through biotechnology, although its use for the production of large-volume chemicals is only starting to be realized. Most examples of the use of organisms or enzymatic steps in the

Table 3 Commercial uses of biotechnology

Compound	1000 tons/yr	US\$/ton
Glucose	15,000	600
EtOH	13,000	400
Fructose	1,000	800
Citric acid	800	1,700
Monosodium glutamate	800	1,900
L-lysine	350	2,200
L-lactic acid	70	2,100
L-ascorbic acid	60	1,000
Gluconic acid	40	1,700
Xanthan	30	8,000
Penicillin G	25	20,000
Aspartame	15	40,000

production of chemicals have been limited to low-volume, high-value fine chemicals and pharmaceuticals such as oligosaccharides, amino acids, purines, vitamins, nicotine, or indigo.^[50–53] This is a sensible first application, given the strict structural requirements of many of these specialty materials. Biocatalysts are generally unchallenged in their ability to provide the stereo-, regio-, and enantioselectivity required by these specialty products. The development of more robust biological systems that can operate in extreme conditions (temperature, low water levels, in organic solvents, under high hydrostatic pressure) will also broaden their applicability.^[54–57] An important new example of industrial biotechnology is the Mitsubishi Rayon process for acrylamide, currently operating on a 3×10^4 metric ton/yr basis by the treatment of nonrenewable acrylonitrile with nitrile hydratase.^[58,59]

Several examples of large-scale biotechnological processes are known (Table 3).^[60] Some operations have been used for many years because there is no equivalent nonbiological route. Ethanol and lactic acid are of particular interest, because they represent chemicals whose original nonbiological production has been almost totally replaced by biochemical manufacture. In addition, the pulp and paper industry has started to incorporate enzyme treatments into their pulping and bleaching sequences,^[61] and low-lactose milk (up to 250,000 liters daily) is produced by treating milk with β -galactosidase.^[62]

CONCLUSION

The United States possesses sufficient renewable resources to supply all domestic organic chemical needs without sacrificing traditional applications of renewables

in the production of food, feed, and fiber.^[63] Bioprocessing of renewables will play an important role in the future evolution of the chemical industry. Progress in the use of conventional chemical processing and catalysis for the conversion of renewables to products will see significant growth as nonrenewable crude oil feedstocks diminish and the world turns its attention to new carbon sources.

Amino Acid and Protein Metabolism

Estela M. Valle

Facultad de Ciencias Bioquímicas y Farmacéuticas, Rosario, Argentina

INTRODUCTION

Amino acid metabolism is one of the most important biochemical processes in plants; similar to other topics in biochemistry, it has been affected by the tremendous developments in science. Following are four actively studied aspects in the field of amino acid metabolism: 1) the identification of new transporters of amino acids and other N-forms like nitrate and ammonium; 2) the characterization of factors controlling the metabolism *in situ* in distinct cells or subcellular compartments; 3) the regulation of the multiple isoenzymes of amino acid metabolism in the context of a single plant; and 4) the role of amino acids as signaling molecules.

Studies on protein metabolism, on the other hand, have focused on the processes of protein synthesis. The complex regulation of protein degradation is today attracting more attention, particularly because proteolysis is involved in cellular processes such as programmed cell death, circadian rhythm, and the defense response in plants. This chapter summarizes the latest insights in the studies of amino acid metabolism and protein degradation.

The focus of this review is to examine the regulation of amino acid metabolism and protein processing in the context of a single plant. Particular emphasis is given to the enzymes involved in NH_4^+ assimilation, which are often oligomers located in different subcellular compartments. The mechanism operating in oxidative protein cleavage is also discussed.

AMINO ACID METABOLISM

Ammonium is the inorganic N-form to be incorporated into carbon skeletons for the production of amino acids. Several transporters have been identified for NO_3^- , NH_4^+ , and amino acids that contribute to a wide array of physiological activities.^[1] N-forms assimilated into glutamine or glutamate disseminate into plant metabolism because they are N-donors to other amino acids, nucleotides, chlorophylls, polyamines, and alkaloids.^[2] Amino acids are well known as building blocks of proteins, and they are essential in both primary and secondary plant metabolism. Various amino acids also perform other important roles, as signalling

molecules or precursors of stress-related compounds under adverse environmental conditions,^[3] in particular glutamate, which is found in the intersection of several metabolic pathways. In the chloroplast, one net glutamate molecule is produced by the concerted action of glutamine synthetase (GS) and ferredoxin-dependent glutamate synthase (Fd-GOGAT), which form the GS-GOGAT cycle, responsible for the prevalent NH_4^+ assimilation in plants.^[3] Additionally, two molecules of glutamate are generated as the end product of lysine catabolism by the saccharopine pathway in seeds of cereals and dicots.^[4] This pathway may be involved in the transient synthesis of glutamate, which then functions as messenger between cells during organ development or in response to environmental changes.^[4] In fact, glutamate could be converted into γ -aminobutyric acid, a stress-related signalling molecule; proline, an osmolyte providing drought-tolerance under water stress; and arginine, a precursor of polyamines and nitric oxide generated during stress.^[3,4]

In the era of functional genomics and metabolic engineering, new experimental approaches are appearing that help us understand the regulation of amino acid metabolism. Among the analytical methods, nuclear magnetic resonance (NMR) spectroscopy is a promising technique yield insight into the integration and regulation of plant metabolism through nondestructive and noninvasive measurements.^[5] Through *in vivo* NMR methods and under certain experimental conditions, it was possible to differentiate amino acid pools from cytosolic or vacuolar compartments. Certainly, by inducing alkalization in sycamore cells and leaves of Kerguelen cabbage, it was demonstrated that the concentration of amino acids in the cytosol was much higher than in the vacuole, and that proline accumulated to a concentration 2–3 times greater in the cytosol than in the vacuole.^[5]

The enzymes involved in NH_4^+ assimilation are generally isoenzymes of different oligomeric arrangements, which are often located in particular subcellular compartments or within different organs and tissues.^[3] Whether these enzymes play overlapping (redundant) or distinct (nonredundant) roles, the factors controlling this process during plant growth and development are still a matter of discussion. The strategies used to study these topics are the production of either mutant plants defective in a particular isoenzyme or transgenic

plants overexpressing one gene member of a small gene family regulated differentially during the life span of the cells. To illustrate the application of these technologies, studies were selected showing the role of enzymes involved in the glutamate metabolism.

All plants contained two types of GOGAT, an NADH-dependent enzyme and a Fd-GOGAT, unique to photosynthetic organisms.^[3] Thus, while Fd-GOGAT accounts for 96% of the total GOGAT activity in leaves, NADH-GOGAT constitutes the predominant isoenzyme in roots. To assess the *in vivo* role of GOGAT in primary nitrogen assimilation and in photorespiration, an Arabidopsis mutant deficient in Fd-GOGAT was studied.^[3] Gene expression combined with Fd-GOGAT-deficient mutant analyses demonstrated that Arabidopsis contains two expressed genes (*GLU1* and *GLU2*) encoding two distinct Fd-GOGAT isoforms. *GLU1* gene product plays a major role in photorespiration as well as in primary nitrogen assimilation in leaves. The Fd-GOGAT isoenzyme encoded by *GLU2* is proposed to be involved in primary nitrogen assimilation in roots.^[3] These contrasting patterns of gene expression suggest nonoverlapping roles for *GLU1* and *GLU2*.

As an example of the second approach is the constitutive overexpression of the cytosolic GS in alfalfa.^[6] GS isoenzymes can be localized in the chloroplast (GS₂) or in the cytosol (GS₁), and they have distinct *in vivo* functions.^[7] Plants appear to possess a single nuclear gene encoding GS₂ and multiple GS₁ genes, which are members of small gene families and differentially regulated.^[7] In this study, a GS₁ gene was constitutively expressed in all cell types of alfalfa driven by the cauliflower mosaic virus promoter to bypass the transcriptional regulation component.^[6] The GS₁ gene was transcribed in these transgenic plants, but GS₁ was unstable and did not accumulate. The results suggested that GS is regulated at multiple steps, besides being regulated at the transcriptional level. One step of regulation is at mRNA stability and may be controlled by the glutamine/glutamate ratio, the ATP/ADP ratio, or the redox balance. Another level of regulation would be protein turnover, and would involve the inactivation of GS by oxygen radicals generated by redox reaction.^[6,8]

PROTEIN DEGRADATION

Protein degradation is an important aspect of the cell cycle that occurs in the normal life of the plant. A process of protein selection occurs to specifically degrade proteins; some proteins are degraded when they become damaged. The proteases found in plants can be identified as matrix metalloproteases, processing proteases, and proteases

involved in mobilization of storage-protein reserves. Proteolysis also takes place during photoinhibition in the chloroplast, programmed cell death, and photomorphogenesis in the developing seedling involving several subcellular compartments.^[9] In the chloroplast, for example, and due to its endosymbiotic origin, each protease is related to a bacterial counterpart. The FtsH1 protein, which is involved in the D1 protein degradation, is related to *Escherichia coli* FtsH1 protein, a metalloprotease and chaperone. Another example is the ClpP, which is responsible for the regulated degradation of the cytochrome b₆f complex.^[9] Among the mechanisms operating in protein degradation, the conjugation of proteins by ubiquitin has been implicated. A protein with a chain of at least four ubiquitin subunits is recognized by the proteasome and degraded. The ubiquitin subunits are removed from the substrate by an ubiquitin-specific protease and recycled.^[9]

Protein structures are also affected by the state of oxidation of some amino acid residues, which may be the principal parameter affecting the *in vivo* and *in vitro* stability of proteins.^[10] Transition metals, ozone, nitric oxides, and metal ions are involved in these oxidative modifications of proteins and free amino acids. Protein oxidation was rigorously tested and verified in *E. coli* GS.^[10] In plants, GS₂ is extremely prone to oxidative cleavage, and reduced transition metals—presumably resulting from the destruction of iron–sulfur clusters during photoinhibition—play a crucial role in the degradation process.^[8] In this process, proteolytic enzymes may not be involved because protease inhibitors provide little or no protection to the light-induced GS degradation.^[8]

CONCLUSION

In the past few years the study of amino acid and protein metabolism has diverged enormously, due to the advances of emerging tools in genomics. Understanding this complex regulated network requires the identification of the factors controlling gene expression in response to changes in N status. Data are now emerging to provide evidence that NO₃⁻, NH₄⁺, or amino acid may also serve as signaling molecules in plants, aside from their role as building blocks. There is also increasing evidence that glutamate may function in a manner that is analogous to its signaling function in the animal nervous system. Several N-metabolizing enzymes have been at least partially characterized and much more information is emerging regarding the organization and control of the genes encoding these enzymes, as well as the modulation of the activity of the enzymes themselves once synthesized. These studies will bring new

A

perspectives to improve the level of essential amino acids in plant seeds.

Regarding protein metabolism, our focus will change in the future to the study of the complex regulation of protein degradation, which still needs more attention.

Aneuploid Mapping in Diploids

P. K. Gupta

Ch. Charan Singh University, Meerut, India

INTRODUCTION

Genetic mapping in crop plants (both diploids and polyploids) initially involved the use of recombination frequencies that were treated to be in proportion with genetic distances and, therefore, could be converted into centiMorgan units with the help of a mapping function (Kosambi's mapping function has generally been used). These genetic maps each had a number of linkage groups that generally equaled the haploid chromosome number of the organism concerned. Later, the individual linkage groups could be assigned to specific chromosomes using aneuploids, which are organisms that have a somatic chromosome number that is not an exact multiple of a basic chromosome number. The aneuploids that have been used for mapping differed in diploid and polyploid crops. While trisomics have been used in a large number of diploids such as barley and tomato, monosomics have been more frequently used in polyploids such as bread wheat, cotton, and tobacco. In the case of maize, which was treated earlier as a diploid and is now known to be an archeo-tetraploid, both trisomics and monosomics have been used. Such genetic mapping of chromosomes makes use of abnormal segregation ratios that are obtained in aneuploids, relative to normal diploids, if the gene of interest is located on the chromosome that is involved in aneuploidy. A variety of these aneuploids have been utilized for mapping in diploids. Because much literature is available on the subject, only a summary will be presented in this section.

Only a brief account of the different types of trisomics, their methods of production, and their use in chromosome mapping (both genetic and physical) is given here. Detailed information is available elsewhere.^[1,2]

TYPES OF TRISOMICS AND THE TERMINOLOGY

The term trisomic originally referred to a condition in an organism where a particular chromosome is present in three doses, in contrast to each of the other chromosomes being present as a pair.^[3] These trisomics were later described as simple primary trisomics to distinguish them from complex primary trisomics (where the extra chro-

mosome is normal, but the remaining constitution is not), and also from the type of trisomics where the extra chromosome is not normal (e.g., secondary, tertiary, telo-, and compensating trisomics). A number of other trisomic types have also been produced and used for mapping. For instance, a complete set of telotrisomics in rice, a variety of compensating trisomics and haplo-triplo disomics in tomato, and a number of acrotrisomics and metatrisomics in barley have been produced and used (discussed later). Balanced tertiary trisomics have also been produced in crops such as barley and utilized for hybrid seed production,^[4] but they have rarely been used for mapping.^[2]

PRODUCTION OF TRISOMICS IN DIPLOIDS

Methods for the production of trisomics differ depending upon the type of trisomics desired. However, in most diploids, the simple primary trisomics have generally been produced using triploids, often derived from a tetraploid \times diploid cross. These triploids, when selfed or crossed (as female parent) with diploids, yield a fairly large number of trisomic plants that can be assembled into a complete set of trisomics and are always equal to the haploid number of chromosomes in the species concerned. Other types of trisomics, including secondary trisomics, telotrisomics and compensating trisomics, often have been obtained in the progeny of simple primary trisomics. Tertiary trisomics, however, have been obtained in the progeny of interchange heterozygotes, due to rare 3:1 meiotic disjunction of interchange quadrivalent, which is characteristic of a translocation heterozygote.

CHARACTERIZATION AND IDENTIFICATION OF TRISOMICS

Simple primary trisomics and other trisomic types have been characterized using one or more of the following criteria: 1) morphological deviations from the normal diploids; 2) karyotype alterations; 3) crosses with known interchange testers; and 4) crosses with the genetic stocks carrying known markers (including molecular markers). However, the most important criterion has been morphological deviation. Meiotic behavior also has been used to

Table 1 Expected gametes and their ratios for a gene present in trisomic condition^a

Genotype	Gametes		Gametic ratio (A:a) (AA+Aa+A):(aa+a)
	(x+1)	(x)	
AAa	1AA:2Aa	2A:1a	5A:1a
Aaa	2Aa:1aa	1A:2a	1A:1a

^aAssuming 1:1 ratio of the two types of gametes.

distinguish the different types of trisomics (e.g., primary, secondary, tertiary, and compensating trisomics).

USE OF TRISOMICS FOR CHROMOSOME MAPPING

Due to the presence of three homologous chromosomes instead of two, a trisomic can have two heterozygous genotypes (AAa, Aaa), which give segregation ratios (described as trisomic ratios) that are different from those obtained in normal diploids (disomic ratios) and thus facilitate chromosome mapping.

Trisomic Genotypes and Segregation Ratios

If the gene to be mapped occurs on the chromosome that is present in an extra dose in a trisomic, and a cross is made between this trisomic and the normal diploid, the resulting F₁ trisomic can be duplex (AAa) or simplex (Aaa) depending upon whether the trisomic carries a dominant or a recessive allele. The segregation ratio for this gene in F₂ deviates from the expected Mendelian ratio in a normal diploid. The ratios that are expected in two types of trisomics have been established (Table 1; Fig. 1). These ratio deviations have been used for assigning genes to specific chromosomes.

Assigning Linkage Groups to Specific Chromosomes

Linkage groups already established in a species through conventional linkage analysis can be assigned to specific chromosomes when at least one marker from each linkage group gives abnormal segregation in one of the trisomics in the F₂ generation. Multiple genetic marker stocks (having markers from more than one linkage group) could be used and would reduce the work involved. This method has been used successfully in a number of crops, including maize, tomato, and barley.

Assigning Genes to Specific Arms of Chromosomes

Once a gene is already assigned to a specific chromosome, secondary, tertiary, and telotrisomics can be used to map this gene to either the short or the long arm of this chromosome. If the dominant allele is present on the arm involved in the extra chromosome of a secondary, tertiary, or telotrisomic, all trisomic progeny in an F₂ population derived from a cross of this trisomic with a recessive genetic stock will exhibit the dominant character (A:a=all:0), thus indicating that the gene is present on this arm. Segregation for this character will suggest that the gene is present on the other arm, which can be confirmed by using telotrisomic for that chromosome arm.

Location of Centromere and Orientation of Linkage Groups

If the linear order of three or more closely linked genes located on two different arms of a chromosome is known, the position of the centromere and the orientation of the chromosome map can be determined. For example, if out of three linked genes a-b-c, a is on the short arm and b

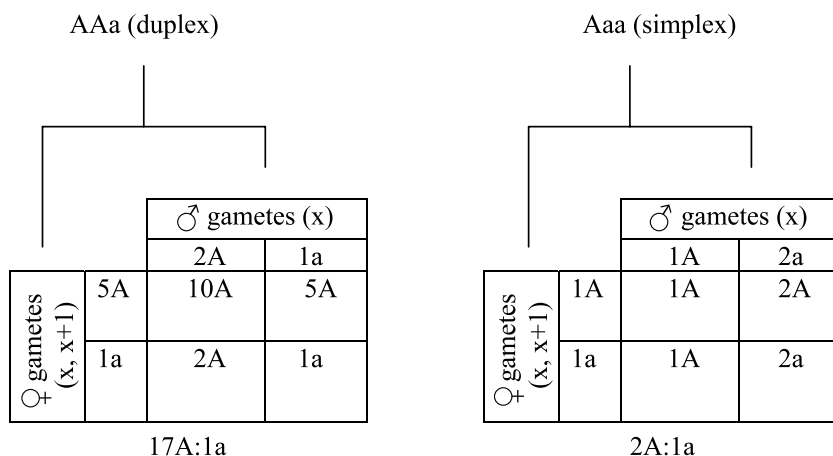

Fig. 1 Formation of gametes and derivation of F₂ phenotypic ratios in a trisomic with AAa (duplex) and with Aaa (simplex) genotype.

and c are on the long arm, the orientation would be a-b-c. In the reverse situation (if a is on long arm and b and c are on the short arm), the orientation would be c-b-a, the centromere being between a and b in both the cases (the genes are read from the end of the short arm to the end of the long arm).

Physical Mapping Using Acro- or Metatrismics

Physical mapping of genes on chromosomes in diploid crops such as maize and tomato has been accomplished by studying structural changes in chromosomes at pachytene. However, in barley, acrotrismics (the extra chromosome has one complete arm and a small segment of the other arm) and metatrismics (having terminal deficiencies in both arms of the extra chromosome) have been produced and used successfully to map individual genes physically on chromosomes. When genes are already assigned to a specific chromosome arm, and acrotrismics and metatrismics with segmental deficiencies for this arm are used, they can be mapped physically due to the absence of a trisomic ratio if the gene is present in the deficient region of the extra chromosome.^[5]

ALIEN ADDITION LINES FOR MAPPING IN DIPLOIDS

Individual alien chromosome-addition lines have been produced for a number of diploid crops by adding an individual chromosome from the diploid crop to a related polyploid that could tolerate the addition of an extra chromosome. In some cases, telocentric additions have also been successfully produced.^[6] Chromosomes of a number of diploid species including rye and barley have been added to tetraploid and hexaploid wheat, and individual maize chromosomes have been added to the oat genome for the purpose of mapping.^[7] Alien chromosome additions have also been obtained in rice, Brassica, sugar beet, and cotton. Addition lines have been utilized for mapping molecular markers using barley and rye additions to wheat and maize additions to oat. Deletions produced in the alien chromosomes in these addition lines can also be used for physical mapping.

PRODUCTION AND USE OF MONOSOMICS FOR MAPPING

Monosomics in diploid crops have been produced only sparingly, because loss of a chromosome has a more drastic effect in a diploid than in a polyploid. However, monosomics for some chromosomes in tomato and for all the 10 chromosomes in maize have been successfully

produced and used for mapping. For instance, at least three primary monosomics and 25 tertiary monosomics were produced in tomato, and some of them were used for mapping.^[8] Similarly, in maize, a complete set of monosomics has been produced using either the B-chromosome system to cause elimination of chromosomes^[9] or an *r-xi* deficiency. These monosomics have been used to map genes and molecular markers.^[10]

TRANSLOCATION STOCKS FOR MAPPING

Translocation stocks in maize and barley have also been used for mapping. In maize, the linkage between a gene and semisterility due to translocation was observed and facilitated mapping of genes with respect to the translocation breakpoint. B–A translocations (translocation between B-chromosomes and autosomes) were also used for mapping.^[11] More recently, translocation stocks were used for physical mapping of restriction fragment length polymorphism (RFLP) markers in relation to the translocation breakpoints in barley. Individual microdissected translocation chromosomes were used for (PCR) driven by primers designed from RFLP markers, so that the positions of translocation breakpoints could be located by identification of closely linked markers (already mapped genetically) that were found to be present on two different chromosomes involved in a translocation.^[12]

CONCLUSION

In diploid plants, hyperaneuploids such as trisomics have generally been used for the preparation of genetic and physical maps of chromosomes, although in tomato and maize, monosomics have also been produced and successfully used for mapping. The presence of genes on chromosomes or chromosome arms that are in three doses in a trisomic and a single dose in a monosomic, in contrast to a double dose in a normal diploid, leads to segregation ratios that deviate from normal Mendelian ratios, thus facilitating the assignment of genes to specific chromosomes or chromosome arms.

Aneuploid Mapping in Polyploids

David M. Stelly

Texas A&M University, College Station, Texas, U.S.A.

INTRODUCTION

Aneuploidy denotes the condition of having extra or missing chromosomes. For specific aneuploid states that are not overly debilitating, the altered genetic constitution enables gross genome mapping through the localization of genes and sequences to specific genomic, subgenomic, chromosomal, and subchromosomal regions. The information from these analyses lends itself to divide-and-conquer strategies that expedite mapping and other forms of genome analysis that impact efficacy of research, cloning, genetic engineering, interspecific germplasm introgression, marker-assisted selection, and other aspects of breeding.

Plant genomes range about 2500-fold in size, from about 50 Mbp to 125,000 Mbp, with chromosome numbers ranging about 300-fold, from 2 to close to 600. The process of mapping eukaryotic genomes is biologically and technically complex. All mapping methods suffer from technical, statistical, and human limitations. To create robust maps, several orthogonal mapping methods must be extensively integrated, e.g., segregation analysis, aneuploid analysis, molecular cytogenetics, radiation hybrids, contig assembly, and sequencing. Only then is it possible to harness the synergistic benefits from their complementary strengths and weaknesses.

The integration of aneuploid-based mapping with linkage mapping and other orthogonal approaches is especially beneficial and applicable to disomic polyploid plant species, genomes of which are larger and involve many more gene and sequence duplications than diploid related taxa. Aneuploid-based mapping provides a means to establish a sound biological footing to the maps and reduce complexity of the target. Polyploid genomes are more tolerant of the various genic imbalances associated with aneuploidy, and therefore more amenable to aneuploid-based mapping.

ANEUPLOIDY

The most common types of aneuploids are presented diagrammatically in Fig. 1. They can be broadly categorized by whether they have increased or decreased chromosomal (genetic) content, though some involve both. Hypoaneuploids have chromosomal deficiencies, e.g., $2x - 1$,

whereas hyperaneuploids have chromosomal excesses, e.g., $2x + 1$. Hypoaneuploids (deficient for chromosomes or chromosome segments) are generally preferred to hyperaneuploids, because they offer greater efficacy for mapping, as well as for chromosome substitution-mediated germplasm introgression.

Irrespective of ploidy, individuals with chromosomally imbalanced sets are called aneuploids. This imbalance may arise from deviations that affect whole chromosomes, chromosome arms, and/or chromosome segments.^[2] Certain terms denote changes in chromosome number by indicating the abnormal content remaining, e.g., monosomy for $2n - 1$ and trisomy $2n + 1$. Modifiers indicate content of the affected chromosome, e.g., primary for an intact chromosome and tertiary for a translocated chromosome.^[3] Segmental aneuploids may or may not have a normal chromosome number, but all are genetically imbalanced because of abnormal dosage of one or more specific segment(s). Telosomes lack essentially an entire chromosome arm. Other segmental aneuploids have an excess/deficiency of specific chromosome segment(s), due directly to deletion or duplication, or derived indirectly from ancestral heterozygosity for translocations or other rearrangements.

The size and type of each chromosomal abnormality is important to mapping because it determines not only the physical scope of localization, but also what kinds of genes or markers are most amenable to analysis, the method of analysis, and the difficulty and time-requirements of the analysis. Some give immediate results, while others require follow-up analysis, e.g., progeny testing and/or segregation analysis. Where segregation data are gathered, their statistical efficacy can also differ markedly according to the type of analysis and map distances involved.

COMMON ANEUPLOID-BASED MAPPING APPLICATIONS

Aneuploids are commonly applied to five kinds of mapping objectives:

1. Localization of individual mutants or small numbers of loci, e.g., a specific marker, or simple or oligogenic trait.

COMMON ANEUPLOIDS

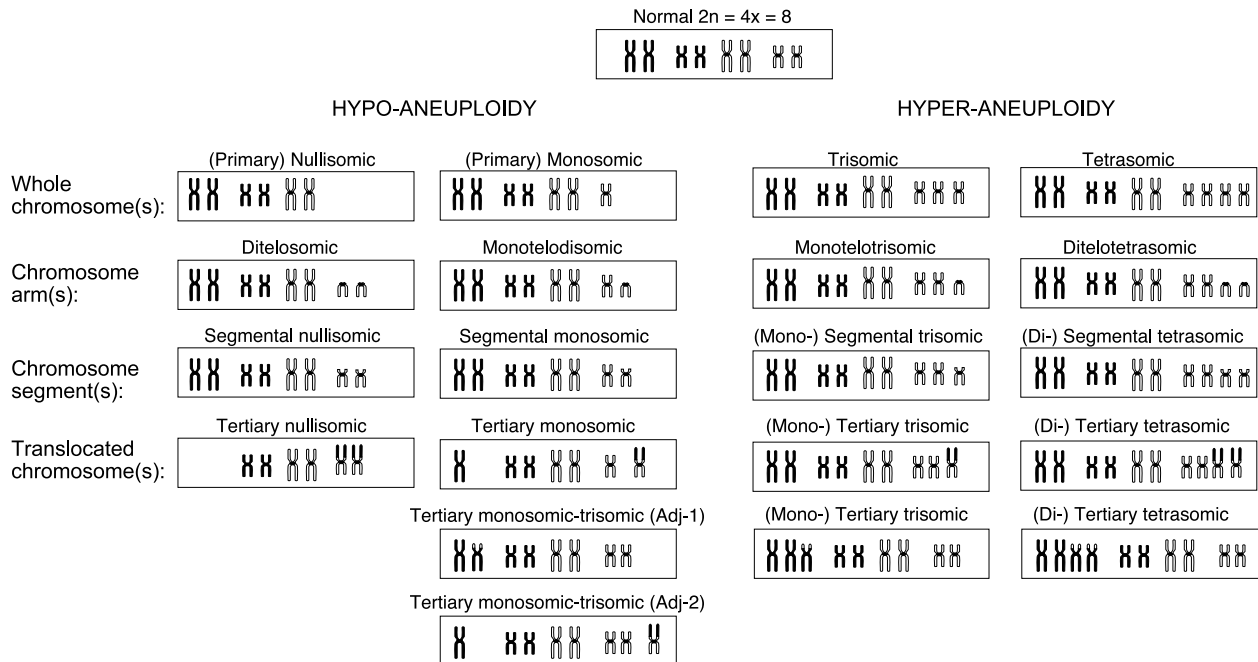

Fig. 1 Common types of aneuploids are depicted for a hypothetical disomic tetraploid species ($2n = 4x = 8$), illustrating differences between hypo- versus hyperaneuploidy, as well as differences with respect to coverage at the chromosome level. The types shown are not exhaustive but illustrate most of the types commonly used for mapping.

2. Genomics and other large-scale genetic endeavors to localize many loci and/or gene products.
3. Centromere mapping.
4. Broad surveys for major chromosome- or segment-specific effects on one or more complex traits, through development of chromosome substitutions or chromosome additions.
5. Development of chromosome-specific mapping populations for genetic dissection of alien germplasm for effects on complex traits, through development of phenotypically characterized mapping populations from chromosome substitutions.

The various types of aneuploids, e.g., whole-chromosome versus telosome aneuploids, differ in their effectiveness for specific mapping goals (Fig. 2).^[4,5] The localization of molecular markers and linkage groups to specific chromosomes establishes a biological, cytological, and macromolecular foundation, and enables a logical basis for development of a common nomenclature for linkage groups among research laboratories. Intra-chromosomal analyses with telosomes enable placement of centromeres on linkage maps. Telosomes and other segmental aneuploids can be used to establish the

orientations of linkage groups with respect to the two arms of each chromosome. Through the accumulation of many segmental aneuploids, the mapping process can be extended to small subchromosomal regions, as in wheat.^[6]

PRINCIPLES OF ANEUPLOID-BASED MAPPING

The methods of aneuploid mapping rely on cytogenetic types that are deficient for one or both copies of a locus (hypoaneuploid), or have extra copies (hyperaneuploid). The procedures used for aneuploid-based mapping are determined partly by the type of gene action or marker detection and by the type of aneuploid (Fig. 3). Deletion mapping entails the removal of a locus or allele, the use of which is most efficient when the subject allele or marker is dominant or co-dominant, and not obscured by allele(s) at other loci. Under these circumstances, both the nulli- and the hemizygous states are directly informative about the absence or presence of the particular DNA sequence.

All types of aneuploids: Any comprehensive LG can be localized to the aneuploidy-affected chromosome.

Comprehensive but anonymous LGs

Mutant genes
Molecular markers
Anonymous linkage groups

Aneuploidy associates marker(s) from LG with specific chromosome.

E.g., LG-I associated with B2 by absence of several dominant LG-I marker(s) from plant monosomic for B2 or a B2 segment.

Full-chromosome aneuploids: Telomere-to-telomere detection of all loci or linkage groups whether independent or linked.

All LGs and markers associated with the chromosome are detected.

One telosome: Orientate linkage group with respect to chromosome arms; localize loci to arm p.

Both telosomes: Delimit centromere to segment; plus confirm orientation of LG on chromosome.

Segmental aneuploids: Integratively relate physical positions on chromosomes and linkage group loci.

Fig. 2 Common strategies and goals used in aneuploid-based mapping. All sorts of aneuploids enable localization of a comprehensive linkage groups to specific chromosomes. Full-chromosome aneuploids enable detection of all loci and linkage groups. Telosomes are often used to orient linkage groups and delimit the location of the centromeres where the latter activity is to be accomplished with opposing telosomes. Segmental aneuploids enable similar localization and mapping at subchromosomal levels. Tertiary chromosomes enable mapping to segments of two chromosomes at once.

DIRECT DETECTION					
Gene or marker on affected chromosome	Hyperaneuploid (increased dosage)		Euploid (heterozygote)	Hypoaneuploid (deletion or decreased dosage)	
	Tetrasomic	Trisomic	Disomic	Monosomic	Nullisomic
Dominant	Trait or marker visible			Trait or marker will be absent	
Co-dominant	Proportionate strengthening of trait or marker, subject to potential masking effects of orthologous and paralogous alleles.		Trait or marker visible	Proportionate loss of trait or marker strength, subject to potential masking effects of orthologous and paralogous alleles.	
Recessive or null	Trait or marker not visible				

INDIRECT DETECTION					
Gene or marker on affected chromosome	Hyperaneuploid (increased dosage)		Euploid (heterozygote)	Hypoaneuploid (deletion or decreased dosage)	
	Tetrasomic	Trisomic	Disomic	Monosomic	Nullisomic
Dominant	Traits or markers can be associated with polysomic segment by segregation ratio testing.		Disomic inheritance ratios	Traits or markers can be associated with polysomic segment by segregation ratio testing.	
Co-dominant					
Recessive or null					

Fig. 3 Effectiveness of direct versus indirect detection systems for mapping by hyper- and hypoaneuploid conditions, according to type of aneuploidy and type of gene or locus “action.” Hypoaneuploids that are lacking or deficient for a segment offer the most widely effective means of mapping; elimination allows for direct manifestation of dominant and co-dominant alleles, but not recessive alleles (progeny testing required). In general, hyperaneuploids do not allow for direct mapping in most instances, and must be augmented by progeny testing for polysomic versus disomic inheritance to be effective. Co-dominant alleles and markers are relatively amenable to analysis with both classes of aneuploids.

When the deleted allele or marker is recessive or null, hypoaneuploid deficiency mapping requires progeny testing, because there is no change in phenotype or marker status in the hypoaneuploid. Progeny testing and segregation analysis are generally required for hyperaneuploids, unless 1) new alleles are introduced on the extra chromatin, e.g., as for alien chromosomes or segments from a related species, or 2) sufficiently accurate

dosage analysis is possible. Progeny tests can also be used to confirm deletion mapping results from dominant and co-dominant alleles and, thus, bolster reliability of results. In rare instances, recessive traits must be homozygous to be expressed, i.e., they will not be expressed when hemizygous, as when the dominant allele is deleted through monosomy. In these cases, too, deletion mapping alone is insufficient, and progeny testing is required. When

a marker is obscured by other similar alleles at the same or different loci, further analysis is often difficult. However, if the marker is readily quantified and present at levels proportional to dosage, then it may be possible to localize the marker by quantitative analysis.

Hypoaneuploids: Nullisomics and Other Deficiency Homozygotes

Where available, nullisomics, ditelosomics, and homozygous deletions are often the tools of choice, because they eliminate a locus or gene. Thus, all molecular markers unique to a nullisomic region are completely absent. For dominant and co-dominant genes and markers, the absence is directly detectable. Deletions of null mutants and recessive alleles are not directly detectable, but can be ascertained by progeny testing. Although nullisomics can be derived in bread wheat, a disomic hexaploid species, they are not available for most plants due to severe effects on viability and fertility. Maintenance across sexual generations requires viability and function of nullihaploid micro- and mega-gametophytes.

Hypoaneuploids: Monosomics and Other Deficiency Hemizygotes

Less severe effects result from monosomy, monotelodisomy, and heterozygosity for segmental deletions. The affected loci are hemizygous, not heterozygous or homozygous. For large-scale mapping applications, the most useful approach has often been to screen for hemizygosity among hypoaneuploids recovered after wide-cross hybridization. For example, a set of different monosomic plants would be mated as female with a divergent genotype, e.g., a different biotype, race, or closely related species. Each hypoaneuploid F_1 hybrid would be highly heterozygous, except for the respective hypoaneuploid chromosome, arm, or segment(s), which must be hemizygous for all loci in it. Differential absence of maternal dominant and co-dominant markers and alleles from a hypoaneuploid but not euploid F_1 hybrids indicates that the locus is associated with the respective chromosome. Progeny tests can be used to confirm results for dominant and co-dominant markers and to detect deletion of cryptic alleles, e.g., null alleles. Highly distorted self and testcross progeny ratios often result due to reduction or absence of sexual transmission, especially through pollen.

Hyperaneuploids

For crops in which hypoaneuploids are not available, hyperaneuploids can usually be obtained. Their use typically entails progeny-segregation analysis to discern between disomic and polysomic inheritance. For example, consider tests of recessive allele "a" across a series of trisomics; if closely linked with the centromere, segregation from the respective A-bearing trisomic will be about 8:1 (A-phenotype : a-phenotype), versus just 3:1 for the euploid and the other trisomics.

Hyperaneuploids may also result from interspecific introgression. If the alien genome does not recombine with the genome of the recurrent parent, monosomic addition lines may be obtainable by iterative backcrossing, and, if transmissible through both gametophytes, disomic additions may be derived from selfing the monosomic additions. These aneuploids and similar segmental derivatives offer high rates of polymorphism relative to the host genome, and thus present an effective tool for direct analysis of the alien genome, and by way of comparative mapping, of the host genome, too.

SOURCES OF ANEUPLOIDS

Because the occurrence of specific aneuploids is typically an unusual or rare event, collections of aneuploid stocks have been developed systematically for a number of organisms, e.g., arabidopsis, corn, cotton, potato, soybean, rice, tomato, and wheat. In some cases, these have been maintained either independently or as part of public genetic or germplasm collections for a number of organisms. Collections may be maintained in plant, seed, vegetative, and/or DNA form. Otherwise, the aneuploids must be generated anew, distinguished, and identified. Typical sources include 1) crosses with an odd-ploid genotype, 2) mutations affecting chromosome or chromatid disjunction in meiosis or mitosis, and treatments with 3) physical mutagens (e.g., X-rays or gamma-rays) or 4) chemicals, e.g., certain mutagens or spindle inhibitors.

SEARCH ENGINE

A panel of aneuploids is useful as a search engine, e.g., to localize grossly one gene, hundreds of genes, or thousands of genes to specific chromosomes or regions. If the panel includes all chromosomes, the search will be comprehensive. Because genomes of most plants contain 5–26 chromosomes per genome, each chromosome represents a

significant proportion of a genome, e.g., from 2–20% for most chromosomes. Given a tentative estimate that the basic angiosperm genome contains approximately 30,000 genes, a typical angiosperm chromosome must contain 600–6,000 genes. Thus, aneuploid-based methods are very efficient for large-scale mapping of genes, and yield a “big picture,” whereas complementary methods are typically used to provide higher resolution and detail.

Abstract

The response of plants to anaerobiosis is characterized by a dramatic change in gene expression. The availability of molecular tools for genome-wide analyses of *Arabidopsis thaliana* seedlings transcriptome opens new opportunities for the study of plant responses to anoxia. Anoxia exerts a dramatic effect on the transcriptome. In this article we analyse the results obtained by transcript profiling of *Arabidopsis* seedlings under anoxia and discuss the results in relation to the existing literature on the anaerobic response of higher plants.

INTRODUCTION

Plants are aerobic organisms requiring oxygen for their life. However, plants can experience a lower oxygen availability (hypoxia) or total absence of oxygen (anoxia) owing to flooding of the soil or as a consequence of the anatomical structure of some tissues. Plants cannot survive for long periods of time under hypoxia or anoxia, but some species can avoid or withstand anaerobiosis.

The physiological mechanism(s) allowing some plant species to survive in oxygen-deprived environments are still largely unknown. In this review, we describe some classical aspects of the physiology of plants under limited oxygen availability, highlighting new evidences of gene modulation by anoxia arising from recent microarray experiments using *Arabidopsis* seedlings.^[1]

ANOXIA REPRESSES LIPID METABOLISM, ENHANCES SUCROSE SYNTHASES-DRIVEN SUCROSE UTILIZATION, AND ACTIVATES ALCOHOLIC FERMENTATION

Genes coding for enzymes of the lipid degradation pathway are repressed by anoxia, mostly at the level of lipases, while the genes encoding β -oxidation and the glyoxylate cycle genes are unaffected or moderately induced by anoxia.^[1] Repression of lipases may avoid the buildup of fatty acids, which cannot be metabolized because of the inactivity of β -oxidation in the absence of molecular oxygen.

The microarray results^[1] highlight the strong induction of two sucrose synthase genes (*At3g43190*; *At5g20830*), which, together with the repression of a neutral invertase (*At1g35580*) and the activation of

an invertase inhibitor (*At1g47960*), suggest that a sucrose-synthase pathway predominates for sucrose utilization under anoxia, as previously proposed for rice seedlings.^[2] The effects of anoxia on starch synthesis genes are limited,^[1] and the pathway of starch degradation is not induced under anoxia in *Arabidopsis thaliana*.

Several glycolytic genes are strongly induced by anoxia. Among these genes we find those involved in alcoholic fermentation such as alcohol dehydrogenase (*At1g77120*), pyruvate decarboxylase1 (*At4g33070*), and pyruvate decarboxylase2 (*At5g54960*).

The concerted action of pyruvate decarboxylases and alcohol dehydrogenase may be unable to consume the pyruvate accumulating as a consequence of the inactivity of the Krebs cycle. The induction of an alanine aminotransferase (*At1g17290*) allows the conversion of the excess pyruvate to alanine. The production of alanine is indeed relevant in rice roots, reaching up to 1.2% of the dry weight after 24 hr under anoxia.^[3]

REDOX GENES: ANOXIA INDUCES STRONGLY A NON-SYMBIOTIC HEMOGLOBIN AND ACTIVATES THE ASCORBATE–GLUTATHIONE CYCLE

Although the activation of the alcoholic fermentation will likely mitigate the excessive buildup of Nicotinamide adenine dinucleotide reduced (NADH), activation of other genes able to compensate for the redox imbalance could be of importance. Non-symbiotic hemoglobin (*Ahb1*, *At2g16060*) is the most induced gene in the group of redox genes, while a class 2 non-symbiotic hemoglobin (*At3g10520*) is repressed.^[1] Although the role of *Ahb1* in the physiology of plants

is still largely unknown, it has been proposed that *Ahb1* may be functioning as a NADH-dependent nitric oxide (NO) oxidizing factor, producing nitrate that is in turn converted back to NO by nitrate reductase.^[4] Remarkably, nitrate reductase1 (*NR1*, *At1g77760*) is induced by anoxia.^[1] Beside the important role of the fermentative metabolism, the Ahb/NR1-dependent NADH utilization can be useful to regenerate nicotinamide adenine dinucleotide (NAD) under anoxia.

Hypoxia, as well as reoxygenation, affects the production of reactive oxygen species (ROS), and the production of antioxidant molecules is likely of importance for survival.^[5] The ascorbate–glutathione cycle (Halliwell-Asada pathway) may operate to reduce hydrogen peroxide (H₂O₂).^[5] The genes involved in this pathway are modulated by anoxia, with induction of ascorbate peroxidase (*At4g35000*), monodehydroascorbate reductase (*At3g09940*), dehydroascorbate reductase (*At1g19570*), and glutathione reductase (*At3g24170*).^[1]

LACK OF OXYGEN AFFECTS HORMONE SYNTHESIS AND SIGNALING

A low-oxygen environment induces the production of ethylene in several plant species, where it plays a role in petiole/internodes elongation and/or in aerenchyma and adventitious root formation.^[6] Ethylene production under anoxia is prevented by the lack of oxygen, required for the conversion of 1-aminocyclopropane-1-carboxylic acid (ACC) to ethylene, while production of this hormone is observed under hypoxia. Loreti et al.^[1] show that none of the 11 genes coding for 1-aminocyclopropane-1-carboxylic acid synthase (ACS) or ACS-like proteins are induced by anoxia in *Arabidopsis*. On the contrary, a gene coding for an ACC oxidase (*Aco*, *At2g19590*) is induced by anoxia. Remarkably, a number of genes involved in ethylene sensing and signal transduction are induced by anoxia. Flooding induces an *AtEtr1* homologue in *Rumex*,^[7] and our results show that the *Etr2* (*At3g23150*) gene is induced by anoxia. Induction of *Etr2* by hypoxia in *Arabidopsis* root cultures has also been reported by Klok et al.^[8] Eight genes coding for putative ethylene responsive elements are also induced by anoxia.^[1] Induction of these genes by anoxia, when ethylene cannot be synthesized, rules out the possible induction by hypoxia-triggered ethylene synthesis. As outlined by Vriezen et al.^[7], induction of elements involved in the synthesis, perception, and/or signaling pathway may enhance the response to ethylene, produced during flooding or after flooding, when oxygen is available and may drive a burst of ethylene production during postanoxia.

Anoxia plays a negative role on the physiology of auxin.^[1] Among the repressed genes, there are four genes

coding for proteins involved in auxin transport (*At1g70940*, *At1g23080*, *At1g77690*, and *At2g01420*). Repression of auxin transport is indeed of importance for flooding-dependent adventitious root formation, as proposed by Visser et al.^[9] A large group of genes encoding auxin-regulated proteins is downregulated by anoxia.

Abscisic acid (ABA) signaling appears to be activated under anoxia.^[1] ABA level increases in flooded tomato plants, although no increase in ABA levels was detected in *Arabidopsis* under hypoxia (De Bruxelles et al.^[10]). It has been proposed that ABA may contribute to the induction of alcohol dehydrogenase (ADH) and, indeed, exogenous ABA does increase the *Adh* transcript level. However, ADH induction by hypoxia is retained in ABA-insensitive mutants, suggesting that distinct signaling pathways control the induction of ADH by ABA and hypoxia.^[10] ADH is also induced by cold stress, and the cold and ABA-inducible protein Kin1 (*At5g15960*) is induced under anoxia.^[1]

Gibberellins may play a role in petiole elongation under anoxia, as proposed by Rijnders et al.^[11] in *Rumex* species. The impact of anoxia on the physiology of gibberellins in *Arabidopsis* seedlings appears however to be limited.^[1] Cytokinins (CK) may play a role in flooding tolerance. Transgenic *Arabidopsis* plants expressing an *Agrobacterium* CK biosynthetic gene controlled by the senescence-specific SAG12 promoter tolerate flooding and submergence better than wild-type plants.^[12] The SAG12 promoter is activated in *Arabidopsis* leaves from flooded plants,^[12] but the 6 hr anoxia treatment we used did not affect its expression, indicating that SAG12 is activated as a consequence of the flooding-induced senescence rather than by oxygen absence. A limited number of genes involved in CK physiology are modulated under anoxia.^[1]

A small number of genes involved in brassinosteroids, jasmonate, and salicylate physiology are induced by anoxia. Involvement of these signaling molecules under anoxia has not been reported before, with the exception of the microarray study by Klok et al.,^[8] showing the induction of jasmonate and brassinosteroid-related genes.

Signaling

Calcium signals play a central role in the molecular responses of plants to anaerobiosis.^[13] The most induced genes in this cluster^[1] include two putative calmodulin coding genes (*At1g76640* and *At1g76650*), and the Ca²⁺-binding protein RD20 (*At2g33380*), both induced by anoxia. Interestingly, the RD20 transcript accumulates rapidly in response to dry, NaCl and ABA,^[14] suggesting that RD20 plays a role in an ABA-related signaling pathway. In this respect, the activation

of the ABA signaling by anoxia (see above), together with the activation of ABA-modulated proteins (RD20 and KIN1), indicates that ABA plays a role in response to anoxia, although the pathway appears to share common elements with other stress-signaling processes. Changes in cytosolic calcium levels originate from influx through the plasma membrane as well as from intracellular stores. The *Cax1* transcript (*At2g38170*), coding for a vacuolar calcium exchanger is repressed by anaerobic conditions.^[1]

CONCLUSIONS

We reported an overview of the effects of anoxia on the Arabidopsis transcriptome. Some results, as expected, confirm the available knowledge about the anaerobic response of plants, with a clear induction of previously identified anaerobic proteins such as sucrose synthases and genes involved in alcoholic fermentation. Besides the classical view of anoxic metabolism through fermentation, it has to be emphasized that a large number of genes not related to this pathway are remarkably affected by anoxia. However, most of these genes encode proteins of unknown function, and an effort to identify the function of these genes will hopefully lead to a more complete understanding of plant responses to anaerobiosis.

Universität Hamburg, Hamburg, Germany

INTRODUCTION

Haploid and double haploid plants attract the interest of geneticists, plant embryologists, physiologists, and breeders. Their genetic characteristics make them an elegant experimental system for genetic studies as well as an integral part of breeding programs, especially in generating pure lines. Haploid plants can be induced from male as well as female gametophytes. This article focuses on haploid plants derived from the male gametophyte, i.e., anther and microspore cultures, concisely discussing the origin of haploid plants and techniques applied to their production, after a historical overview.

HAPLOIDS

The development and viability of pollen play a key role in the fertility of plants. Besides its importance in sexual reproduction, pollen can be used for haploid plant production. Haploid plants are genetically characterized as plants containing only one set of chromosomes. The haploid state occurs due to the reduction of zygotic (diploid) chromosome number to gametic (haploid) number during meiosis. In nature haploid plants appear via abnormal fertilization, i.e., chromosome elimination or mispairing during the *crossing-over*. Haploid plants are sterile and therefore doubling of the chromosome set is required to produce fertile plants, which are called double haploids (DHs) or homozygous diploids. Two basic genetic features make DHs distinct for genetic studies and breeding.^[1] They are

1. The full complement of haploid genome is expressed in the phenotype. For example,
 - A. Recessive characters are not suppressed by dominant ones.
 - B. Lethal mutations or any gene defects lead to the elimination of undesirable genotypes.
2. The production of homozygous diploids is possible in one generation via chromosome doubling of haploid plants.

The best known application of haploids is the F1 hybrid system for the production of homogeneous hybrid varieties. The DH lines are also used for targeted genetic manipulation, mutant breeding and selection, which considerably reduces the time required for the production of new cultivars.

Historical Overview

In 1922, Blakeslee and co-workers first discovered the appearance of natural haploid embryos and plants, which were derived from gametophytic cells of *Datura stramonium*.^[2] To date, naturally occurring haploid plants are described in about 100 species of angiosperms.^[3] In 1954, Tulecke, for the first time, observed that mature pollen grains of a gymnosperm *Ginkgo biloba* can be induced to proliferate in culture to form haploid callus,^[4] but direct formation of embryolike haploid structures from anther culture of *Datura innoxia* was first reported by Guha and Maheswari in 1964. Their experiments clearly demonstrated the feasibility of induction of haploid structures from anther tissues. In 1967, Bourgin and Nitsch succeeded in producing the first haploid plants from cultured anthers of *Nicotiana sylvestris* and *Nicotiana tabacum*. Later in 1974, the first description of microspore culture was also made by Nitsch.^[4] Since then, the techniques of microspore and anther culture were optimized for a wide range of economically important dicotyledonous and monocotyledonous plants.^[4]

Origin of Haploids: Androgenesis

Two basic strategies are applied to the induction of haploids from higher plants: in vivo and in vitro induction by various physical, chemical, or biological stimulants. The first method for haploid production, developed by Kasha and Kao in 1970, is based on chromosome elimination in hybrid embryos.^[4] This methodology exploits the fact that when two unrelated plant species are crossed, the chromosome sets of both parents fail to pair during the crossover stage of meiosis. For example, with crosses between common barley (*Hordeum vulgare*) and its wild ancestor (*Hordeum bulbosum*), the chromosomes of *H. bulbosum* are eliminated with the embryo possessing only

one set of *H. vulgare* chromosomes. The developing haploid embryo is then cultivated on nutrition medium and gives rise to a haploid plant. This technique is known as the *bulbosum* technique and is restricted to a limited number of genotypes.

Anther and pollen culture represent the major techniques for in vitro induction of haploid plants. The development of haploid plants can be induced from pollen via embryogenesis. The formation of embryos from the androgenic (male) tissues is called androgenesis. In this case, the microspores are switched from their normal gametophytic fate to sporophytic development.^[5] Different physical and chemical stimuli have been studied for the induction of androgenesis. The most efficient and widely applied techniques include 1) cold pretreatment of spikes (4°C, 4 weeks); 2) starvation—a cultivation of dissected anthers in media without carbon source (20–25°C, 1–4 days); and 3) incubation under higher temperatures (32–36°C, 1–3 days).

Genotype, physiological state of donor plants, stage of microspore development, culture media, and culture conditions are also important determinants of androgenesis.^[1,4,6] The anthers containing microspores in mid- or late-uninucleate stage are most suitable for the induction of androgenesis.^[2,6] Of the different media components, the carbon source, its concentration, and the ratio of nitrate and ammonium ions (NH⁴⁺) are important in achieving embryogenesis and the development of green plants from microspores.^[7,8] Based on these findings several basal media were developed for androgenic cultures. Phytohormones, especially the content of cytokinins and auxin; aeration and permanent supply of fresh, well-buffered medium; increased osmotic pressure; and temperature are all critical for successful establishment of androgenic cultures. Regeneration of haploid plantlets from androgenic cultures can be achieved by direct embryogenesis from microspores or via organogenesis.^[4]

The doubling of chromosomes in androgenic cultures has been reported to occur spontaneously in culture via endomitosis.^[4] It happens at high frequency in wheat (20–50%), rice (72%), and barley (87%).^[6] Chromosome doubling can be induced using chemicals such as colchicine.^[4] In many plant species, the frequency of spontaneous chromosome doubling in in vitro culture is high enough to produce a significant number of haploid plants.

ANTHER CULTURE

The technique of anther culture is relatively simple and efficient and requires minimal facilities^[4,5] (Fig. 1). The androgenesis can be induced by pretreating whole inflorescences (cold pretreatment) or by pretreating dissected anthers (high temperature, starvation). Anthers are cul-

tured on a solid or in a liquid medium on a rotary shaker at 50–60 rpm. The cultures are kept at 24–27°C. First, anthers are cultured on the callus induction medium for about 2 weeks in darkness and subsequently transferred to a regeneration medium containing phytohormones and organic substances at 16-hour photoperiods (2000–8000 lux) for shoot regeneration. Developing plantlets are then transferred to a rooting medium containing lower concentration of carbohydrates and other nutrients. The regeneration frequency of androgenic cultures is usually very high. In barley it ranges from 4.8 to 50 green plants per single anther.^[6]

Plant breeding companies routinely use anther culture for the production of haploid plants. The only disadvantage of this technique is the regeneration of plants with different ploidy due to the presence of both gametophytic and sporophytic cells in the culture.

MICROSPORE CULTURE

The technique of microspore (pollen) culture was developed more recently than anther culture. In this technique, pollen grains are separated from the anther tissues and cultured in a liquid medium (Fig. 1). Microspores provide haploid single cells that can be utilized for various biological studies.^[2]

Different techniques are applied for the isolation of microspores.^[6] The most efficient is the technique of microblending, in which small pieces of inflorescence are put in a blender and quickly cut to release microspores into the isolation solution. The crude preparation is filtered through a sieve and the microspore suspension centrifuged to separate microspores. The plating density (the number of viable microspores per volume of medium) is an important factor in the induction of androgenesis. The optimal population density depends on the genotype, the quality of donor material, and the isolation technique. The induction of androgenesis occurs either while they are still inside the spikes (cold pretreatment) or directly after the isolation (high temperatures, starvation). Microspores are cultured in a liquid induction medium on a rotary shaker. They are kept in the dark at 24–27°C for 3–4 weeks. The emerging calli of visible size are transferred to a solidified medium. Further cultivation of microspore-derived cultures is similar to those derived from the dissected anthers.

The isolated microspore culture offers the possibility of combining selection procedures with the advantages of a haploid system. The nutritional requirements of the isolated microspores are much more complex than those of dissected anthers. The use of isolated microspore culture finds wide application in different fundamental studies and provides greater opportunities for cell

Fig. 1 Methods of haploid production: microspore and anther culture. (Modified from Ref. 9.)

manipulation than does anther culture.^[6] Because of their unicellular nature, isolated microspores represent a very promising target for genetic manipulation. Haploid and dihaploid plants with resistance to environmental stress or pathogens can be produced by in vitro cell selection procedures or by transfer of foreign genes within one generation.

In spite of the great potential for haploid plant production, anther and pollen culture methods have two major limitations. Both methods are strongly genotype-dependent and produce a high percentage of albino plants with no practical utility.^[6] The percentage of albino plants could reach up to 80% in cultures of monocotyledonous plants.^[6]

CONCLUSION

Pollen (microspore) and anther culture can be used for the production of haploid and dihaploid plants. Haploid plants are valuable material for breeding new varieties and biotechnological applications. Fertile dihaploid plants represent an essential source for producing pure inbred lines, which are homogeneous and show no segregation. Haploid and dihaploid plants considerably accelerate and simplify breeding and selection processes. Using the method of haploidization it is possible to obtain a homozygosity for genes in cases where this is normally difficult to achieve, for example for self-incompatible alleles. Haploid cell cultures are also useful material for mutation

analysis and cell modification. Microspores as single cells represent an ideal system for in vitro cell selection and genetic manipulation. Microspores can be used for microinjection, electroporation, particle bombardment and co-cultivation with *Agrobacterium tumefaciens* resulting in transgenic haploid and homozygous plants.

Arabidopsis thaliana: Characteristics and Annotation of a Model Genome

Tanya Z. Berardini

Seung Y. Rhee

Carnegie Institution of Washington, Stanford, California, U.S.A.

INTRODUCTION

Arabidopsis thaliana is an annual plant of the Brassicaceae family and is commonly found in temperate regions of the world. Its suitability for molecular and genetic experiments has made it one of the most widely studied plants today. *Arabidopsis* is the first plant to be completely sequenced and remains the most completely sequenced eukaryotic genome to date. Approximately 11,000 researchers around the world are currently engaged in unraveling the functions of this genome. Lessons learned from this reference plant will facilitate more systematic and targeted approaches for manipulating and managing plants that impact humans and the environment.

GENOME COMPOSITION AND ORGANIZATION

The genome of *Arabidopsis*, one of the smallest among angiosperms, has been estimated at approximately 146 Mb^[1] and is highly dense with genes. To date (January, 2003), 117.3 Mb of nonredundant sequence have been completely sequenced. The remaining gaps are in the centromeres and other highly repetitive regions (The *Arabidopsis* Information Resource (TAIR), <http://www.arabidopsis.org/info/agi.html>). Approximately 15–20% of each chromosome is composed of heterochromatin around the centromere and, additionally, in two heterochromatic knobs of chromosomes 4 and 5.^[1] In the euchromatic regions, the average gene density is 5 kb per gene with 50% of the euchromatic sequence allotted to genes.

Most characteristics such as gene density, distribution of repetitive DNA, and guanine/cytosine (GC) content are constant within and among all 10 euchromatin chromosome arms.^[1] This organization is quite different from the organization of most crop plant genomes, where most of the gene-rich tracts are clustered and separated by huge stretches of repetitive DNA.^[2] The average GC content over the five chromosomes is 34.9%^[1] with about 4–6% of the cytosine residues in the *Arabidopsis* genome being methylated, compared to 30–33% and 22% cytosine methylation in tobacco and wheat, respectively.^[3] The repeti-

tive fraction of the genome is more highly methylated than single and low-copy genes.

The most recent genome reannotation by The Institute for Genome Research (TIGR) includes approximately 29,000 genes (<http://www.tigr.org/tdb/e2k1/ath1/>) containing an average of five exons per gene with a mean unprocessed transcript length of 2085 bp (1584 bp mode) and a mean protein length of 425 amino acid residues (221 mode). Both size distributions are extremely right-skewed with over 90% of the genes being smaller than 4 kb. Approximately a third of the genes identified by computer prediction have been verified with full-length cDNA information and about 64% of the genes have full or partial length cDNA sequences associated with them (TAIR, <http://www.arabidopsis.org/servlets/sv>). Preliminary results from analyzing hypothetical genes (i.e., genes with no transcript sequence or sequence similarity information) indicate that approximately 80% of them have detectable transcripts.^[4] This suggests that approximately 95% of the identified genes (approximately 27,500 transcripts) are part of the transcriptome. In addition, comparison of 5000 full-length cDNAs to the genome reveals that about 2% of the genes are alternatively transcribed, suggesting that the transcriptome size is likely to increase as more experimental data are generated.^[5] Taking into account post-translational modifications like phosphorylation and glycosylation, the *Arabidopsis* proteome is likely to be even larger than its transcriptome.

Unlike the human and many other plant genomes, only about 10% of the *Arabidopsis* genome is composed of repetitive DNA. It consists largely of 5S rRNA arrays, 18S-5.8S-25S rRNA arrays, centromere-associated repeat sequences, nucleolar organizers, telomeres, and transposons. *Arabidopsis* contains a rich diversity of most known transposons, as well as some that are structurally unique.

Most repetitive sequences are found in the centromeres and telomeres. Genetically defined centromeres contain a central region composed of 180 bp repeat microsatellites and Athila transposable elements, flanked by sequences containing a number of additional microsatellites, transposable elements, 5s rDNA, and unique sequences containing expressed genes.^[6] The unique sequences in the five centromeres are not similar to each other. The

only conserved elements appear to be those in the central domain, suggesting that these structural aspects may be sufficient for centromere function.^[1] Telomeres consist of tandemly repeated blocks of CCCTAAA, similar to the

DNA patterns found in lower eukaryotes.^[7] Unlike animals, *Arabidopsis* can tolerate a severe reduction of telomeric DNA for up to ten generations.^[8] It is unknown how this tolerance is achieved, what additional factors

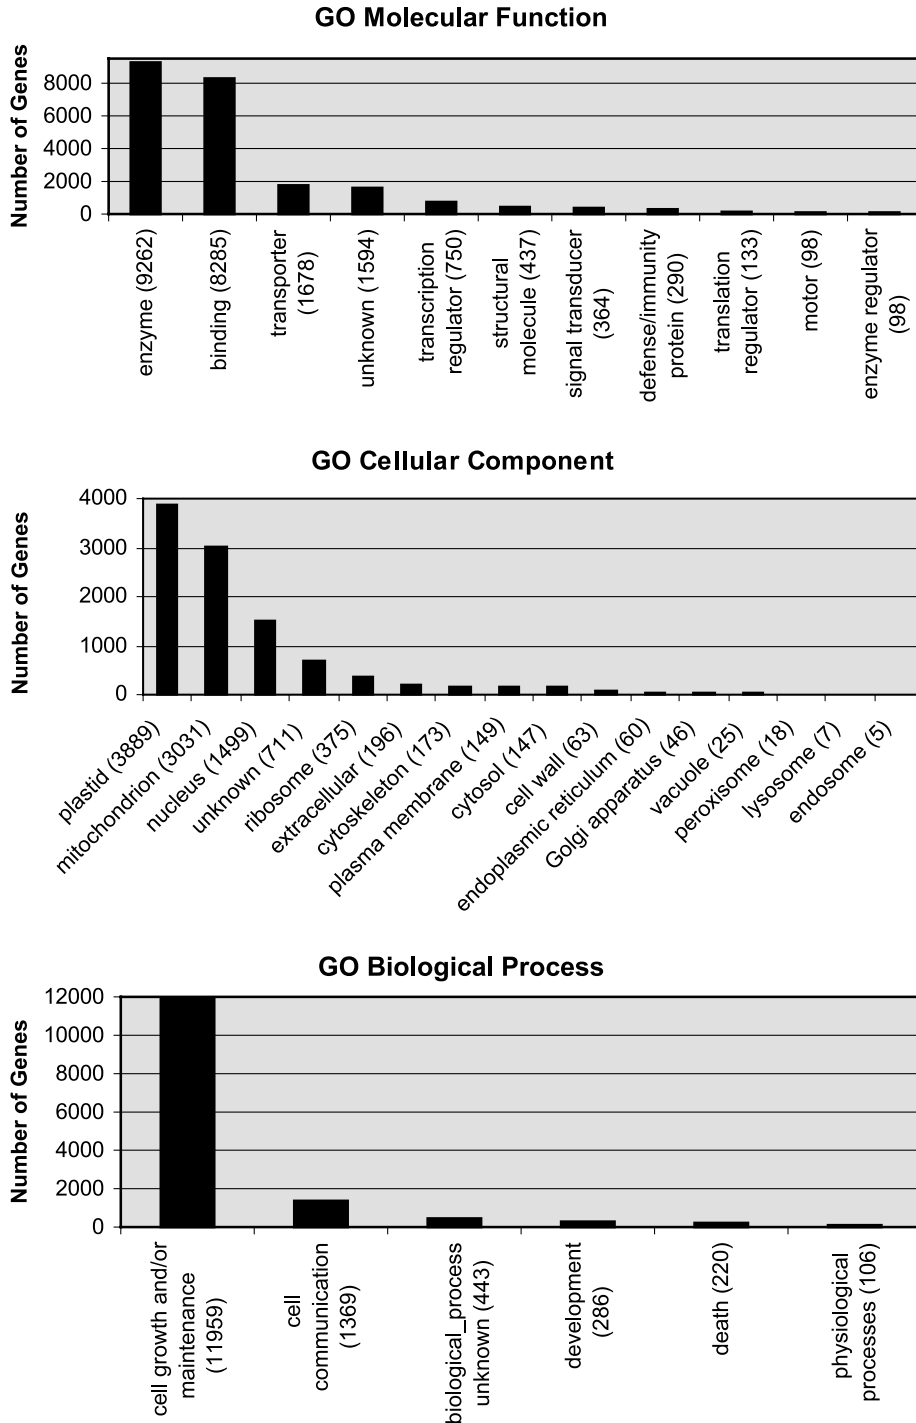

Fig. 1 Genes annotated to the gene ontology (GO) vocabularies as of December 2002. Numbers of genes per term are in parentheses. A. 21,425 genes (74% of all predicted genes) annotated to molecular function terms. B. 16,921 genes (58% of all predicted genes) annotated to cellular component terms. C. 13,816 genes (48% of all predicted genes) annotated to biological process terms.

contribute to the maintenance of chromosomal integrity, or whether this phenomenon occurs in other plants.

Sequence analysis of the *Arabidopsis* genome has revealed a history of genome rearrangements, most notably duplications followed by gene loss.^[1] Approximately 60% of the genome has been duplicated, with at least two rounds of large segmental duplications occurring approximately 112 million years ago.^[1,9] The estimated timing of the duplication events suggests that the ancient duplications occurred before the divergence of the tomato and *Arabidopsis* lineages.^[9] In addition to these large segmental duplications, the genome has undergone many smaller gene duplication events. Approximately 17% of the genes are tandemly repeated and approximately 4000 genes belong to about 1500 gene families with more than five members each.^[1]

A very recent rearrangement in the *Arabidopsis* genome involves one of its organellar genomes. Approximately 620 kb of mitochondrial DNA has inserted near the centromeric region of chromosome 2 in the Columbia ecotype.^[10] This mitochondrial DNA is not found in other ecotypes such as *Landsberg erecta*, indicating that the rearrangement occurred very recently.

Functional Composition

The *Arabidopsis* genome is being functionally annotated based on data from the literature and from sequence comparisons by TAIR and TIGR. Using the controlled vocabularies developed by the Gene Ontology consortium (<http://www.geneontology.org>), approximately 20,100 genes have been annotated to terms describing a gene product's molecular function, biological process, and subcellular localization. Fig. 1 illustrates the current distribution of annotations of these genes. About 2020 of the 29,000 genes have been described in the literature (TAIR analysis). Many of these genes are involved in agronomically important processes such as responses to drought, cold, light, and disease as well as processes not found in animal systems such as secondary metabolism.

The challenge of characterizing the remaining 26,980 genes is being addressed using multifaceted approaches to predict gene function followed by in planta assays. Based on conserved domains, there are approximately 11,000 gene families, similar to the number found in other sequenced multicellular eukaryotes such as *Drosophila* and *Caenorhabditis elegans*.^[1] An ongoing analysis of the *Arabidopsis* proteome with respect to known metabolic pathways (AraCyc, <http://arabidopsis.org/tools/aracyc/>) has so far resulted in the assignment of about 1000 genes to 174 pathways, including plant-specific pathways like those involved in secondary metabolism.

Characterization of the *Arabidopsis* transcriptome is facilitated by the extensive use of microarrays to analyze

gene expression patterns. Available technologies include targeted cDNA arrays as well as high-density oligonucleotide arrays representing 25,000 genes. Results from over 570 *Arabidopsis* cDNA arrays and multiple high-density oligonucleotide arrays are available to the research community (<http://www.arabidopsis.org/info/expression/index.html>). Cluster analysis of these experimental results can reveal patterns of possible co-regulation between genes as yet unknown and experimentally characterized genes, and can shed light on the composition and characteristics of the *Arabidopsis* transcriptome.

Finally, functions of genes are being elucidated using forward and reverse genetic approaches. Functional analysis of specific genes is facilitated by the availability of a suite of insertion lines (<http://arabidopsis.org/links/insertion.html>). The ability to obtain insertions in specific genes allows construction of appropriate double or triple mutant lines to uncover potentially redundant functions among members of gene families. Functions of redundant genes may also be inferred from the phenotypes of engineered dominant mutations created by activation tagging and by the characterization and eventual cloning of loci defined by mutation and quantitative trait loci assessed in natural populations.

CONCLUSION

The sequencing of the *Arabidopsis* genome opened unprecedented opportunities for plant biology and agronomy. It confirmed previous hypotheses about the genome and simultaneously raises many new questions. Understanding the organization and evolutionary history of the *Arabidopsis* genome is important in making an accurate assessment of its relatedness to other plant species and in leveraging knowledge gained from studying this plant to other plants. Using the sequenced genome and a set of rapidly developing genomic analysis tools, researchers are now able to address biological questions in ways that were impossible just a few years ago. These new investigative methods and the results they generate will undoubtedly change the way research is conducted and published. Furthermore, advances made in this small weed serve as both a reference for understanding processes shared with agronomically important plants, and as a tool for understanding the genetic basis for diversity.

Arabidopsis Transcription Factors: Genome-Wide Comparative Analysis Among Eukaryotes

José Luis Riechmann

California Institute of Technology, Pasadena, California, U.S.A.

INTRODUCTION

Transcription factor coding–genes are abundant in the genomes of eukaryotic organisms. In the dicotyledonous plant *Arabidopsis thaliana*, which has a genome of approximately 125 megabase pairs (Mbp) of DNA that contains over 25,000 genes,^[1] more than 1500 genes of such type have been identified.^[2] The rice (*Oryza sativa*) complement of transcription factors is similar in size and composition to that of *Arabidopsis*.^[3] In addition, different cereals are known to have a similar repertoire and arrangement of genes in their genomes. Thus, the research model plant *Arabidopsis* has a set of transcriptional regulators similar to those of the main staple crops rice, maize, and wheat. Moreover, many *Arabidopsis* transcription factor genes have been shown to retain their native functions when introduced as transgenes into other plant species.

TRANSCRIPTION FACTORS: WHAT THEY ARE AND WHAT THEY DO

Gene transcription (the synthesis of RNA molecules from the genomic DNA) is carried out by a multitude of proteins of different biochemical activities that act in concert. These proteins can be classified into different functional groups: the basic transcription apparatus, large multisubunit coactivators, chromatin-related proteins, and transcription factors, which comprise the most numerous of all these groups of proteins.^[4] Transcription factors are proteins that show sequence-specific DNA binding and are capable of activating and/or repressing transcription. They are responsible for the selectivity in gene regulation, and are often themselves expressed in a tissue, cell-type, temporal, or stimulus-dependent–specific manner. Transcription factors are modular proteins, and can be grouped into families according to their DNA binding domain.^[4]

Many of the biological processes in eukaryotic organisms are controlled at the level of gene expression, primarily through regulation of transcription. In plants, these processes include development, adaptation to the

environment, the defense response against pathogens, and metabolic pathways. Moreover, it is now known that morphological changes that occurred during plant domestication and crop improvement were due to mutations in transcription factors, alterations in their expression, or changes in the expression of other types of regulatory proteins,^[4] underscoring the importance of this class of genes for plant and crop biotechnology.

TRANSCRIPTION FACTOR GENE CONTENT OF THE ARABIDOPSIS GENOME

The *Arabidopsis thaliana* genome is the first from a higher plant to be sequenced.^[1] It comprises approximately 125 Mbp of DNA, and shows a compact organization of high gene density. On average, there is one gene per 4.5 kilobase (kb) of DNA: approximately 2 kb correspond to exons and introns, and approximately 2.5 kb correspond to intergenic regions, which include regulatory sequences such as the promoter and enhancers.^[1] Other plants—maize, for example—have genomes that are much larger than that of *Arabidopsis*, but have similarly organized coding and regulatory sequences. In monocots, active genes are usually distributed in compact gene-rich islands, where much of the genomic DNA corresponds to repetitive sequences. Despite its simplicity, the *Arabidopsis* genome bears extensive duplications, including many tandem gene duplications and large-scale duplications between different chromosomes,^[1] which might affect 40% of its total genes. Duplications can be an obstacle to gene functional analysis, because they often result in functional redundancy or overlap between the duplicated genes.^[2,4,5]

The *Arabidopsis* complement of transcription factor coding–genes has been described and reviewed in detail elsewhere.^[2,4] In brief, the *Arabidopsis* genome codes for at least 1572 transcription factors (or approximately 6% of its approximately 26,000 total genes), which can be grouped into more than 45 different gene families. Such global content of transcriptional regulators is comparable to those of other eukaryotic organisms (for instance,

Fig. 1 Content and distribution of transcriptional regulator (TR) coding genes in the Arabidopsis genome. The different families of transcription factors are ordered according to the number of members they contain. Families that are specific to plants are indicated in green (or dark gray), and those that are also present in other eukaryotic kingdoms in blue (or light gray). The data represented in this figure, including the gene family names, are from Refs. 2 and 4. Single-copy transcription factor genes that do not belong to families are depicted, but not listed; these are *LFY*, *NZZ*, *SAP*, *FIE*, and *EYA-like*. (From Ref. 4.) (View this art in color at www.dekker.com.)

approximately 4.6% of the genes in the fruit fly *Drosophila melanogaster* code for transcription factors^[2]). However, it is well known that many transcription factor gene families exhibit great disparities in abundance among the different eukaryotic kingdoms, and that some families are kingdom-specific. Approximately 45% of the Arabidopsis transcription factors belong to plant-specific gene families, and approximately 53% belong to families found in plants, animals, and fungi. Some of the plant-specific transcription factor families are large, such as AP2/ERF, NAC, WRKY, ARF/IAA, and Dof (Fig. 1). Some other groups, such as the MYB, MADS, and bZIP, which are not particularly numerous in animals or yeast, have been significantly amplified in the plant lineage. This points to the large degree of diversity in transcriptional regulators present in the different eukaryotic kingdoms.^[2,4]

In general, it appears that most of the transcription factor families in Arabidopsis are involved in a variety of different biological functions, and vice versa (i.e., in a given function, genes from several families can be involved^[2,4]). There are, however, some exceptions; for instance, MADS box genes are most frequently involved in developmental processes.^[6,7]

HOW SIMILAR ARE ARABIDOPSIS TRANSCRIPTION FACTORS TO THOSE FROM OTHER PLANTS?

The determination of the sequence of the rice genome, and the large collection of cDNA sequences from other plants available in databases, answer this question.

Despite the very different appearance and lifestyle of Arabidopsis and rice, and the fact that the rice genome contains a higher total number of genes, their respective complements of transcription factor genes are similar.^[3] The largest transcription factor families in Arabidopsis also appear to be the most prevalent ones in monocotyledonous plants (Fig. 2). In addition, many examples of orthology can be identified among Arabidopsis transcription factor genes and those from rice or maize (for example, in the MADS gene family^[6,7]). Putative orthologous MADS-box genes have regularly maintained conserved functions, even after substantial sequence divergence.^[7] Moreover, Arabidopsis transcription factors from several different families have been shown to retain their function when introduced into a heterologous species, and vice versa. For example, *LEAFY*, a meristem identity gene that controls the reproductive switch in Arabidopsis, also triggers flowering when introduced as a transgene in aspen or citrus.^[8]

In summary, the complement of transcription factors appears to be, in its general characteristics, very similar among monocots and dicots; and individual genes can conserve their native function across species. It is also clear, however, that differences exist. For instance, whereas most of the amplification of the MYB-(R1)R2R3 gene family occurred prior to the separation into monocots and dicots, several subgroups in maize appear to have originated recently or undergone duplication.^[9] These recent expansions could have allowed a functional diversification that might not be present in Arabidopsis. Conversely, there are also gene families that are larger in Arabidopsis than in rice (Fig. 2).

Fig. 2 Comparison of Arabidopsis and rice transcription factor gene families. The number of members of a subset of the transcription factor gene families of rice and Arabidopsis is represented. Arabidopsis data are from Refs. 2 and 4; rice data are from Ref. 3.

FUTURE PROSPECTS

The vast majority of Arabidopsis transcription factors have not been genetically and functionally characterized yet. For those that have been, characterization is usually limited to the description of phenotypic differences between mutant and wild-type plants, and to the determination of their expression patterns. However, there is still very little knowledge of the genes that each of the transcription factors regulates. Thus, the function of the Arabidopsis complement of transcription factors, considered as a whole, and the dynamic relationship between the genome and the transcriptional regulators remain largely unexplored.^[4] These areas of research can now be pursued with a variety of reverse genetic methods and functional genomic technologies.^[5] In addition to helping elucidate the complex logic of transcription at a genome-wide level in multicellular eukaryotes, such research will have a profound impact on plant biotechnology and agriculture.^[4]

ACKNOWLEDGMENTS

I wish to acknowledge my former colleagues at Mendel Biotechnology for their input and work in our transcription factor genomics research program.

Archaeobotanical Remains: New Dating Methods

Lawrence Kaplan

University of Massachusetts, Boston, Massachusetts, U.S.A.

INTRODUCTION

Since the mid-nineteenth century the disciplines of archaeology and botany have collaborated to form an important tool in the study of crop plant origins. The importance of this collaboration has always been enhanced by some means of dating the plant remains that were recovered. In regions such as Italy and Greece or the Middle East, classical texts and historic reconstruction aided in dating. In the American Southwest, dating of ruins by means of tree ring counts served a similar function. Today, radiocarbon dating is the most important method of determining the age of organic materials.

RADIOCARBON DATING

In 1949 W. F. Libby and associates at the University of Chicago showed that organic remains of known age from ancient sites in Egypt, Syria, and the American Southwest could be accurately dated by assessing their content of radioactive carbon.^[1] Since that time radiocarbon dating has become a foundation technique in archaeology and an important tool in the study of ancient plant remains.

Radiocarbon dating is based on the ability to measure the proportion of the radioactive isotope ^{14}C (carbon-14) to the stable (nonradioactive) isotopes ^{12}C (carbon-12) and ^{13}C (carbon-13) in a sample of organic matter. The rate of decline of any radioactive isotope is stated by its "half life." The radioactive isotopes of other elements decay more rapidly or less rapidly than carbon-14, whose half life is about 5730 years,^[2] but the half life of each type of radioactive element whether rapid or slow is always the same. Because of this it is possible to determine the age of ancient plant remains and other organic materials.

TRADITIONAL AND ACCELERATOR DATING

Traditional radiocarbon dating, as developed by Libby, measured the emission of beta particles from wood charcoal, or some other organic material and is now sometimes called "indirect dating." Because the amount of carbon-14 in such material is very low to begin with,

and continually grows smaller, a fairly large sample is required and the detectable elapsed time from the death of the organism to the present is limited to about 50,000 years. The degree of error in the measurement increases with age.

Another method of carbon-14 dating makes use of instruments (a particle accelerator and a mass spectrometer) combined in a system developed by physical scientists in the late 1970s.^[2] The system is called accelerator mass spectrometry (AMS), or sometimes "direct dating" and has the ability to detect and count very small amounts of radiocarbon in a specimen. Both methods are destructive, that is, the sample to be dated must be destroyed in the process of dating. Early in the development of radiocarbon dating it was assumed that the proportion of carbon-14 to other forms of the element had remained constant^[2] up until the time of extensive atomic bomb testing. The year 1950 was accepted as the end of constant proportions of carbon-14 in the atmosphere. It soon became apparent, however, that there were differences, or an offset, between age in "radiocarbon years" and age in actual years due to the lack of constancy of carbon-14 levels in the atmosphere.

CALIBRATION

In order to determine the magnitude of the offset, growth ring samples of the remarkably long lived bristlecone pine and the giant sequoia were radiocarbon dated after an actual date had been determined by counting the annual rings of the trees. In order to provide regional standards, the procedure was repeated with other trees and other methods of dating that were applied to diverse organisms including corals. These tests showed that in the past there were variations in the amount of carbon-14 in the atmosphere, probably due to changes in the earth's magnetic field. As noted previously, more recent changes in the proportion of atmospheric carbon-14 have resulted from the testing of atom bombs.

Knowing the magnitude of these variations in atmospheric radiocarbon allowed the age in radiocarbon years to be corrected to give the actual or calibrated age of a specimen. The result of carbon-14 determinations of the age of archaeological plant remains are reported in

uncorrected or uncalibrated age as radiocarbon years before present time (b.p.), where present time is set at 1950. The calibrated age is reported in calendar years; hence, one half of a seed of *Phaseolus acutifolius* (teparty bean) from a cave in the Tehuacán Valley of Mexico dates by AMS to 2300 ± 50 b.p. in radiocarbon years and 400–210 B.C. in dendrocalibrated calendar years.^[3]

ACCELERATOR MASS SPECTROMETRY DATES: ADVANTAGES

The great advantage of AMS, over traditional radiocarbon dating, is the ability of AMS to give accurate dates on very small samples, for example, on one-half or less of a single maize kernel. The method is also much more rapid than traditional radiocarbon dating. Prior to the development of AMS the amount of early crop plant material retrieved from a particular level in an archaeological site was seldom sufficient for radiocarbon dating and this was later found to lead to errors. For example, when a piece of wood charcoal excavated in the late 1940s (prior to the development of AMS dating) from Bat Cave in New Mexico was radiocarbon dated to about 6000 b.p. by the traditional method, that date was assigned to other materials associated with it.^[4] Among these other materials to receive the date of 6000 b.p. were small maize ears (not sufficient material to be dated by the traditional or indirect C-14 method). These small ears, because of their age, size, and other characteristics, resembled a hypothetical wild maize, which was presumed to be extinct. Years later small samples of the Bat Cave maize were dated by AMS and found to be not older than 3120 b.p. This brought the Bat Cave maize more into line with the earliest dates for prehistoric maize in other Southwestern sites, but it also demonstrated that traditional radiocarbon dates based on associated material could lead to erroneous conclusions. The disturbance of Bat Cave remains by burrowing rats meant that different objects in the same stratum may vary widely in age. Furthermore, because “smaller” and “older” did not necessarily go together, the smaller ears were not necessarily more primitive.^[5]

EARLY AGRICULTURE IN MEXICO

The pursuit of archaeological evidence for the origin of maize brought famed archaeologist R. S. MacNeish to Mexico, where he led major excavation projects, especially in the Tehuacán Valley south of Puebla during the early 1960s. It was in Mexico that the wild growing nearest relatives of maize had been found by botanists. MacNeish and his colleagues were successful in recovering important collections of maize, beans, squashes, and

other cultivated and wild plant remains. The strata of prehistoric cave deposits were dated by traditional radiocarbon methods and the results of the excavations were widely recognized as the most important to have been made for the understanding of the origin of major American crop plants. Excavation levels dated within a cultural period extending from 7000 to 5350 b.p. contained small maize ears, which in the opinion then prevalent among maize experts matched the hypothetical wild form. Published in 1967^[6] the radiocarbon dates from the time of these earliest maize ears to the most recent, just prior to the Spanish conquest, were widely cited as the most authoritative archaeological timeline for the domestication of maize and the development of agriculture and human society in the high cultures of Mexico. When AMS dating became available, tiny samples of the ancient maize ears themselves were dated and were found to be from 4700 b.p. or about 1500 years younger than the radiocarbon dates previously obtained by the indirect method.^[7] These more recent dates are especially significant for understanding the beginnings of Mesoamerican agriculture because they appear to reduce the perplexingly long time period between the first presence of maize and the period in which it became the primary component of the human diet. Accelerator dates on beans recovered from the same sites in the Tehuacán Valley were, like the maize dates, much younger than the dates on associated remains had indicated. In fact, the oldest accelerator dates for beans at Tehuacán were about 2300 b.p.,^[3] which shows that, contrary to the historic unity of maize and beans in the Indian diet, there was a substantial period in which maize became a mainstay of the diet without the presence of beans.

PREMAIZE CULTIVATION IN EASTERN NORTH AMERICA

The value and reliability of AMS dates on small samples of seeds from sites where disturbance caused critically important specimens to be mixed with earlier or later charcoal or other organic remains is widely recognized. One of the most significant applications of AMS dating is found in east central North America where seeds and fruit parts of a suite of four indigenous plants [a cucurbita gourd, sunflower, marsh elder, and chenopod (*Chenopodium berlandieri*)] showing characteristics of domesticates were AMS dated to the period of 2000–1000 B.C. The structural characteristics developed during this time period are regarded by most archaeologists specializing in eastern North America as evidence for an agricultural system predating the adoption of maize as the primary crop in this region.^[8] The AMS dates of prehistoric maize from this region showed it to be later than previously

thought, which fell in nicely with the proposal of a premaize eastern North American cultivation system based on indigenous plant species.^[4]

AMS APPLIED TO AFRICAN AND ASIAN CROP PLANTS

The complex and still controversial evolution of domesticated maize contrasts with the evolution of African and Asian cereal grains where the wild ancestors of the domesticates are known and there has been less structural transformation in the evolution of the domesticated crop. Nevertheless, AMS dating now plays an important role in assessing the process of domestication in Africa (especially sorghum) and Asia (especially rice). Carbonized rice grains embedded in ceramic potsherds from east central China^[9] were AMS dated to 6400–5800 b.p. In this instance, the antiquity of the pottery, a non-organic ceramic material, as well as the rice, was determined.

CAUTIONS

Radiocarbon dates obtained by AMS and by traditional radiocarbon dating do not always disagree. Nor, when they disagree, are the AMS dates always more recent.

CONCLUSION

The application of structural and taxonomic botanical methods to the analysis of archaeological plant remains furthered the understanding of crop plant origins from the mid-nineteenth century until the present time. When botanical analysis was combined with radiocarbon dating

methods, the study of crop plant origins took a great leap forward.

Aromatic Plants for the Flavor and Fragrance Industries

Brian M. Lawrence

B.M. Lawrence Consultant Services, Winston-Salem, North Carolina, U.S.A.

INTRODUCTION

Essential oils—also known as volatile or ethereal oils or essences—are the odoriferous principles found in the aromatic plants that are the raw materials of the flavor and fragrance industries. The term essential, which has alchemical roots, results from the coined phrase “quinta essentia,” or “quintessence,” the fifth element (the other four being land, fire, wind, and water). Alchemists believed that within the plant kingdom there was a single extractive principle that could prolong life indefinitely, hence the importance of quinta essentia. The term “oil” probably originated from the observation that certain plants contain glands or intercellular spaces filled with oily droplets found to be nonmiscible with water. Unlike fatty or fixed oils, which are lipids, essential oils are complex mixtures of volatile compounds that are biosynthesized by living organisms.

For an essential oil to be genuine, it must be isolated by physical means only from a whole plant or plant part of known taxonomic origin. The physical methods used to isolate an essential oil are water, water/steam or steam distillation, or expression (also known as cold pressing, a process unique to the production of citrus peel oils). A limited number of plants (onion, garlic, wintergreen, sweet birch, and bitter almond) yield their oils during processing. In this process, warm water is mixed with the macerated plant material, causing the release of the enzyme-bound volatiles into the water from which the oil is subsequently removed by distillation.

Although the practice of distillation was first discovered in the Indus Valley in Pakistan around 3000 B.C., it was not until around 1300 A.D. that distilled aromatic waters were extensively used as medicaments. Essential oils did not appear as items of commerce until sometime in the 1400s with cedarwood oil, cinnamon oil, rose oil, sage oil, etc. among the earliest.

It is estimated that of the 17,500 aromatic plant species found in the vegetable kingdom, approximately 270 are used to produce essential oils of commerce. Of these 270 oils, ca. 40% are produced from cultivated plants; the other 60% are produced from by-products of a primary industry or from readily accessible wild growing plants.

The plant families that possess species that yield a majority of the most economically important essential oils

are Apiaceae or Umbelliferae (fennel, coriander, and other aromatic seed/root oils), Asteraceae or Compositae (chamomile, *Artemisia* sp. oils, etc.), Cupressaceae (cedarwood, cedar leaf, juniper oils, etc.), Geraniaceae (geranium oil), Illiciaceae (star anise oil), Lamiaceae or Labiatae (mint, patchouli, *Lavandula* sp., and many herb oils), Lauraceae (litsea, camphor, cinnamon, sassafras oils, etc.), Oleaceae (jasmine oil), Pinaceae (pine and fir oils, etc.), Poaceae or Graminae (vetiver and aromatic grass oils), Rosaceae (rose oil), and Santalaceae (sandalwood oil).

WHERE ARE ESSENTIAL OILS FOUND?

Essential oils are contained in special glands or secretory tissues,^[1] the type being important characters of the plant family within which the aromatic plant is found. In the Asteraceae (Compositae), schizogenous oil ducts occur in the leaves and stems frequently associated with vascular bundles. In the Lamiaceae (Labiatae), there are characteristic multicellular-headed glandular trichomes present on the leaves and calyx of the plant. The secretion produced by a multicellular head accumulates under a common cuticle that is raised like a blister. In the Lauraceae, there are large oil cells in the stem barks, whereas in the leaf, oil cells tend to be mesophyllic (i.e., found in the interior of the leaf). In the Myrtaceae and Rutaceae, the secretory tissues arise from a special mother cell. This cell divides and the daughter cells separate from one another schizogenously (i.e., they split apart from each other) to leave a central cavity. The cells surrounding the cavity produce an essential oil and the cavity continues to enlarge as the lining walls undergo lysis. Thus, large rounded oil cavities or glands are produced schizolytically and are visible to the naked eye (as seen in the oil glands on the peel of an orange, e.g.). Essential oils in the Apiaceae (Umbelliferae) are present in long secretory ducts called vittae that arise schizogenously on the fruits and roots. In the Zingiberaceae, a continuous layer of large rectangular oil cells occurs in the testa (the seed coat); in fact, the oil cells are just within the thin aril and epidermis of the seed and on the rhizome. In addition, isolated oil cells are scattered throughout a scaped rhizome.

Table 1 Oil yield of selected aromatic plants

Species	Common name	Plant part	Oil yield (%)
<i>Syzygium aromaticum</i> (L.) Merr. et L. M. Perry	Clove	Dried buds	16–20%
<i>Myristica fragrans</i> Houtt.	Nutmeg	Kernel	8–16%
<i>Foeniculum vulgare</i> Mill.	Fennel	Dried fruit (seed)	1.5–10.0%
<i>Santalum album</i> L.	Sandalwood	Heartwood	4.5–6.5%
<i>Cinnamomum zeylanicum</i> Blume	Cinnamon	Innerbark	0.8–1.5%
<i>Myrtus communis</i> L.	Myrtle	Twigs and leaves	0.25–1.15%
<i>Ocimum basilicum</i> L.	Basil	Above ground plants	0.01–0.30%

ESSENTIAL OIL EXAMPLES

Examples of plants cultivated for oil production are basil, cinnamon (leaf and bark), dill (weed and seed), mint (cornmint, Native and Scotch spearmint, and peppermint), patchouli, ylang ylang, etc. Examples of by-product oils are citrus peel oils such as orange, (a by-product of the orange juice industry) and eucalyptus leaf and conifer needle oils (by-products of the lumber industry). In contrast, armoise, bois-de-rose, galbanum, juniperberry, star anise, Peru balsam, etc. exemplify those oils produced from plants or exudates collected in the wild.

Essential oils are generally found to predominate in one particular organ of a plant such as leaves/calyces (sage), buds (clove), flowers (rose), fruits (lemon), seeds (cardamom), inner bark (cinnamon), heartwood (cedarwood), roots/rhizomes (ginger), resin (mastic), and exudates (Peru balsam). The essential oil content of aromatic plants varies according to the plant and the plant part from which it is obtained (Table 1). In addition to the oils produced from different parts of aromatic plants, some oils are produced from balsams, gums, or exudates. Generally, an incision or hole is made in the stem/trunk of a tree or shrub, from which the balsam or gum exudes. Steam distillation of this exudate produces an oil whose yield varies according to the exudate. A selected list of exudates and their oil yields is shown in Table 2.

From a chemical composition standpoint, an essential oil is a complex mixture of secondary metabolic com-

pounds composed mainly of monoterpenes, sesquiterpenes, and aliphatic and aromatic compounds that can exist as hydrocarbons, ethers/oxides, alcohols, esters, acids, ketones, aldehydes, lactones, phenols, phenol ethers, etc. An essential oil contains between 50 and 300 components present in amounts greater than 1 ppm (0.0001%).

Some aromatic plants yield oils of different composition depending on which plant part is distilled. Cinnamon (*Cinnamomum zeylanicum* Blume) is an example of such a plant, as the leaf oil is rich in eugenol,^[2] the flower oil is rich in cinnamyl acetate,^[3] the fruit oil is rich in sesquiterpenoid compounds,^[4] the inner bark oil is rich in cinnamaldehyde,^[2] and the root oil is rich in camphor.^[2]

During the nineteenth century, Europe—in particular, France—was the major region for essential oil production. Currently, France is a major producer only of lavandin (*Lavandula xintermedia* Emeric ex. Loisel), and produces only limited quantities of other major volume oils. At present, Asia (China, India, and Indonesia) is by far the largest oil producing region except for the production of citrus oils. For over 100 years the United States has been a major producer of mint, cedarwood (Texas—*Juniperus ashei* Bucholz; Virginia—*J. virginiana* L.), and citrus oils [orange—*Citrus sinensis* (L.), Osbeck, and lemon—*C. limon* (L.) N. L. Burm.]. However, over the past 50 years Central and South America have become major citrus producing regions, surpassing the quantities produced in the United States, e.g., Brazil (orange—*C. sinensis*), Argentina (lemon—*C. limon*), Mexico and Peru (lime—*C.*

Table 2 Oil yield of selected balsams and gums

Species	Common name	Oil yield (%)
<i>Myroxylon balsamum</i> (L.) Harms var. <i>pereirae</i> (Royle) Harms	Peru balsam	60–65%

14. Native spearmint	<i>Mentha spicata</i> L.	980
15. Sassafras—Brazil	<i>Ocotea pretiosa</i> (Nees) Benth.	900
16. Cedarwood—Chinese	<i>Chamaecyparis funebris</i> (Endl.) Franco	800
17. Ho or shiu	<i>Cinnamomum camphora</i> L.	800
18. Scotch spearmint	<i>Mentha gracilis</i> Sole	760
19. Grapefruit	<i>Citrus paradisi</i> Macfady	700
20. Patchouli	<i>Pogostemon cablin</i> (Blanco) Benth.	650

aurantifolia (Chrism. et Panzer) Swingle. The approximate volumes of the top twenty essential oils are shown in Table 3. A brief description of five major oils follows.

ORANGE OIL

Orange oil (also known as sweet orange oil to differentiate it from bitter orange oil, which is obtained from *Citrus aurantium* L.) is produced as a by-product of the orange juice industry because the juice is the most valuable end product.

Four major processes are used to isolate orange and other citrus oils that are located irregularly in oblate-spherical oil glands found at different depths in the colored portion of the peel (flavedo). These processes are Pellatrice, and Sfumatrice (Italian processes) and Brown Peel Shaver and the Food Machinery Corporation (FMC) process (U.S. processes). FMC, a whole fruit isolation process, has become the predominant method of oil isolation because of its efficiency. In this process, the fruit is positioned in a lower cup made of metal fingers above which is a second cup. Through the converging action of the upper and lower cups, the fruit is peeled and the peel

crushed, causing the oil glands to burst. The oil is flushed away with a fine spray of water that removes it from the peel. Simultaneously, a plug is cut from the bottom of the fruit, so that as the two cups come together, the juice, peel remnants, seeds, and pulp are removed into separate streams. The oil is recovered from the oil/water emulsion by filtration followed by a three-stage centrifugation.^[5]

Although numerous cultivars of orange are grown, those principally used for oil production are Washington Navel, Parson Brown, Hamlin, Pineapple, Midsweet, and Valencia (Florida, California, Arizona, Texas); Peralina, Valencia, Pera, Westin Natal, and Bahianintia (Sao Paulo state in Brazil); Castellana, Navelina, Newhall, Verna, and Salustiana (Spain); and Biondo Commune, Navelina, Ovale, and Belladonna (Reggio Calabria and Sicily, Italy).^[6]

Oranges are sold in box quantities. In Florida, for example, 1000 boxes of Valencia oranges weigh 90,000 lbs. Processing this quantity of oranges yields 39,750 lbs. of peel, pulp, and seeds; 50,000 lbs. of orange juice; and 250 lbs. of cold-pressed orange oil.^[7]

For the 1996/1997 season in the United States, the number of boxes of oranges processed were 215,427, Florida (90 lb/box); 12,000, California (75 lb/box); 565, Texas (85 lb/box); and 63, Arizona (75 lb/box).^[8] As

Table 4 Regional orange oil production

Brazil	28,600
United States	19,250
Italy	1375
Spain	880
Australia	825
Greece	523
Israel	501
Others ^a	3046

^aIncludes Algeria, Argentina, Belize, China, Costa Rica, Cyprus, Guinea, Ivory Coast, Mexico, Morocco, South Africa, Tunisia.

noted in Table 3, ca. 55,000 tonnes of orange oil were produced in 2000. A more specific regional breakdown for this oil production^[9] is shown in Table 4.

PEPPERMINT AND NATIVE AND SCOTCH SPEARMINT OILS

As noted in Table 3, approximately 3500 tonnes of peppermint oil, 980 tonnes of Native spearmint oil, and 760 tonnes of Scotch spearmint oil are produced annually. The largest share (more than 90%) of the peppermint oil production is in the United States. A breakdown of the regions of production is shown in Table 5.^[10]

Of ca. 980 tonnes of Native spearmint oil produced, 55% was produced in the United States, with 52.5% produced in the West (Washington, Montana, Idaho, Oregon) and 2.5% in the Midwest (Michigan, Indiana, Wisconsin). China and India produced 23% and 19%, respectively.^[6] In contrast, of 760 tonnes of Scotch spearmint oil produced worldwide, the United States produced 72% (59% in the West and 13% in the Midwest). The other principal countries of production were Canada (17%) and India (10%).^[10]

Although peppermint and both spearmints are produced in the U.S. Midwest and West, the yield of oil is much higher in the West because of its longer, hotter growing season. All U.S. mints are produced clonally from stolons. Because of the widespread incidence of a peppermint wilt fungus (*Verticillium dahliae*), disease-free rootstock is used to replenish or commence a new area of planting. Similarly, both spearmints are susceptible to mint rust (*Puccinia menthae*), so disease-free stolons are used to also commence or replenish new spearmint plantings.^[11]

Unlike the spearmints, peppermint is considered a long-day plant because it needs a minimum midsummer

day length of 15 hours for flowering and for production of oil of commercially acceptable aroma and quality. This day length can be achieved north of the 40th parallel. To yield commercially acceptable oil quality, the plants are harvested just as the first flowers start to form. This is done to ensure that the undesirable oil component menthofuran^[12] is minimized. Day length and flowering have little effect on the oil composition of either Native and Scotch spearmint. In fact, to produce the highest oil yield, both spearmints are harvested in full flower. Even though Scotch and Native spearmints are produced from different *Mentha* species, they are both rich in L-carvone; however, the subtle differences in oil composition make them discernibly different. This in turn affects their end use. Unlike peppermint oil production in the United States, a marketing order is in place for both the Scotch and Native spearmint oils covering an area of the Pacific Northwest due north of the west Wyoming border to the Canadian border, south to the southern border of Utah, and west from the Utah border to the Pacific coast. The administration of the marketing order controls the quantity of oil produced by each grower annually and sets a price for the oil.^[13]

ROSE OIL

Although only a small quantity of rose oil is produced annually, it is an extremely high-priced oil, selling for as much as \$3500 per kg. The main countries where damask rose (*Rosa damascena* Mill.) is grown are Bulgaria (around Kazanlik), Turkey (in Isparta and Budur provinces), Ukraine, Morocco, and Moldova, whereas *R. centifolia* L. is grown mainly in France and Morocco. The world production of both rose oils is estimated at ca. 5 tonnes (4 tonnes damask and 1 tonne centifolia).

In Turkey, shallow holes 50 cm × 50 cm are prepared in which bare root cuttings are planted and trimmed so that the cutting just shows above the soil level. The cuttings are watered regularly so that 3 years after planting, the

Table 5 Regional quantities of U.S. peppermint oil production in 2000

Region	Quantity (tonnes)
Midwest (Michigan, Indiana, Wisconsin)	390
Willamette Valley (W. Oregon)	360
Madras Valley (E. Oregon)	200
Lagrande (N.E. Oregon)	280
Idaho/Oregon border	540
W. Montana	70
Yakima Valley (Washington)	1330

starts have reached maturity and the roses are ready for harvest. A mature planting yields ca. 5 tonnes of flowers per hectare and can continue producing flowers for 20–30 years.^[14] It takes ca. 3.5–4.0 tonnes of flowers to yield 1 kg of oil.^[15] The flowers are harvested early in the morning, the time when their oil yield is maximized.

At one time, all rose oil was produced by steam and water distillation in which rose flowers were placed on a grid above the water in the bottom of a still. The water was boiled by direct fire; the steam generated released the oil that was condensed with a standard condenser. Today, more than 95% of exported oil is produced with steam distillation in which the steam is generated in a satellite boiler and passed through a still containing evenly spaced, stacked, multiple grids on which the flowers are placed. This allows the oil to be readily removed without the flowers becoming a waterlogged mass, as happens in steam and water stills.

More rose flowers are used to produce a rose concrete and rose absolute than are used to produce rose oil. A concrete is a hydrocarbon extract of the fresh flowers generally produced by percolation of the flowers with hexane, with the spent flowers and residual hexane removed. The concrete is rich in hydrocarbon-soluble materials and devoid of water soluble materials. It is generally a waxy, semisolid, dark-colored mass.^[16] An absolute is a highly concentrated alcoholic extract of the concrete. It is prepared from the concrete by dissolving the concrete in hot alcohol and then rapidly cooling the mixture to precipitate the waxes that are removed, generally by filtration or by a cooled surface scraping of the slurry. The alcohol is then removed by distillation under high vacuum. The resultant absolute contains the concentrated aromatic portion of the flowers.^[16] The yield of oil from rose flowers is ca. 0.02%; the yield of concrete is 0.22–0.25%, whereas the yield of absolute from the

	Eriocephalus oil	<i>Artemisia afra</i> L.
	Lanyana oil	<i>Pteronia incana</i> L.
	Pteronia oil	

concrete is 50–60%. It is estimated that ca. 15.0 tonnes of rose concrete are produced annually, from which ca. 8.0 tonnes of rose absolute are produced.

QUALITY OF ESSENTIAL OILS

Commercial essential oils are sold in compliance with standards of physico-chemical characteristics such as odor and color, specific gravity, refractive index, and optical rotation, and chemical characteristics such as gas chromatographic analysis. Standards for oil acceptance can be of national or international origin. Standards are set out as monographs on each oil, such as International Standards Organization (ISO), French Standards (AFNOR), German Standards (DIN), and Food Chemical Codex Standards (FCC).^[17]

USES AND TRENDS OF ESSENTIAL OILS

In 1990, it was estimated that 50% of all essential oils produced were used in flavors.^[18] This can be readily understood because in the United States the per capita consumption of soft drinks is 166 L annually, whereas the annual per capita consumption for the rest of the world is ca. 6 L. As a result, if soft drink consumption increased 3% worldwide, it would result in a 40% increase in essential oils needs.^[18] Over the past 25 years the production levels of some oils have changed for a number of reasons: 1) synthetics have partially replaced their use (spike lavender oil, camphor oil); 2) replacement oils are richer in desirable components than original oil (litsea cubeba oil has partially replaced lemongrass oil because it is a better source of citral, lavandin has replaced lavender because it is a cheaper source of a similar odor-character); 3) wild collection of plant material has been reduced because of the scarcity of raw material (amyris oil, cascarrilla oil); and 4) wild collection has been restricted by legislation, by either regional or federal mandate (sassafras in Brazil).

Over this same period, the use of oils such as orange, lemon, and lime has increased. Although citrus-flavored soft drinks have mainly driven the increase in use of citrus oils, their use in such top-selling fragrances as K One, Cool Water, Drakkar Noir, Escape (male), Eternity (for men), Hugo, Polo Sport (male and female), and Tommy has also helped maintain this increase.^[19]

The production of cornmint oil has also increased, not for the value of the oil but for the natural isolate L-menthol obtained from the oil by freeze crystallization. The pharmaceutical, oral hygiene, cosmetic, tobacco, and confectionery industries are responsible for the use of an es-

timated 23,000 tonnes of L-menthol (both natural and synthetic).^[20] There is a particularly increased use of menthol in India (in chewing tobacco); the use of oral care products in China is also on the increase.

The production of tea tree oil [*Melaleuca alternifolia* (Maiden et Betche Cheel)] for use as a natural additive and home care treatment for burns and wounds has also increased in recent years. This oil is produced in commercial quantities only in Australia, where most households are thought to keep a vial of it in the medicine cabinet.^[21] Most other oils have relatively stable levels of production, although their production level in one country may be negatively affected by their production in other countries. Since the mid-1980s there has been increased awareness of essential oils due to the popularization of aromatherapy. Although the use of essential oils in aromatherapy does not affect world production by more than 1.0%, it has led to an increase in the number of oils new to commerce. A list of these oils and their countries of origin is shown in [Table 6](#).

ESSENTIAL OIL MARKET

Although it is difficult to determine the exact size of the essential oil market, it has recently been estimated at \$310 million with a projected annual increase of 4%.^[22] The \$310 million approximation is probably an underestimate, however, because the value of the top twenty oils listed in [Table 3](#) totals ca. \$325 million. Consequently, the total worldwide market size for all essential oils is probably closer to \$400 million.

CONCLUSION

Aromatic plants are of value because of their aromatic principles, namely their essential oils. The type and methods of essential oil production have not changed much over the centuries. However, the volumes and origins have changed. Over the past century, there has been a shift in essential oil production from Europe and the Americas to Asia primarily because of labor and fuel costs and the urbanization of rural areas. Currently, there is a worldwide reduction in essential oil development funding and the number of scientists familiar with these specialty crops is diminishing. Nevertheless, essential oils continue to be important ingredients of food, cosmetic, and pharmaceutical products. Over the next century, the need for cooperation between the consumer and producer will become mandatory even though there may be further global changes in areas of production.

Ascorbic Acid: An Essential Micronutrient Provided by Plants

Patricia L. Conklin

State University of New York, Cortland, New York, U.S.A.

INTRODUCTION

In 1753 James Lind published his *Treatise on the Scurvy*, in which he described his research on the curative effects of citrus fruits on scurvy, the devastating disease that plagued sailors of the era. However, it was not until 1932 that L-ascorbic acid, the agent responsible for the prevention of scurvy, was purified and chemically synthesized. Today, ascorbic acid is a well-known antioxidant and enzyme cofactor with many roles in human health. Humans, unable to synthesize this micronutrient, depend on obtaining the majority via a diet that includes plants. Despite this, it was only recently that the plant ascorbic acid biosynthetic pathway was unraveled.

AFR AND DHA

Chemically, ascorbic acid can be oxidized to the relatively unreactive ascorbate free radical (AFR). Loss of a second electron produces dehydroascorbate (DHA). Ascorbate free radical can also disproportionate to form DHA and ascorbic acid. Both AFR and DHA can be reduced to ascorbic acid in mammalian cells by a number of systems, including glutaredoxin, thioredoxin reductase, AFR reductase, NADPH-dependent DHA reductase and NADH:ascorbate radical oxidoreductase.^[1] Extracellular AFR can be reduced back to ascorbic acid with the use of intracellular ascorbic acid.^[2] These chemical properties of ascorbic acid make it an ideal antioxidant. By donation of an electron, it can reduce (and therefore detoxify) highly reactive oxygen intermediates such as singlet oxygen, superoxide, and hydroxyl radicals, forming instead fairly non-reactive AFR or DHA, both of which can be enzymatically recycled back to the fully reduced ascorbic acid. In addition, ascorbic acid can reduce oxidized forms of α -tocopherol (vitamin E), maintaining this membrane antioxidant in its active state^[3] (Fig. 1).

ASCORBIC ACID AND HUMAN HEALTH

Oxidative damage is thought to be one of the leading factors contributing to the degenerative processes that result in

conditions such as aging cardiovascular disease and cancer. However, in the prevention of cardiovascular disease, the role of ascorbic acid is difficult to differentiate from the overall role of a healthy diet and lifestyle.^[4] Ascorbic acid has been shown to decrease oxidative DNA damage. People with low ascorbic acid diets risk elevated DNA damage via oxidation. In contrast, supplementation of healthy subjects with additional ascorbic acid results in no change in the level of oxidized DNA. It is thought that the current US RDA for ascorbic acid may be the level at which the maximum benefit for protection against DNA damage is achieved (reviewed in Ref. 5). However, those who either do not meet the U.S. RDA or have lifestyles that are known to decrease serum ascorbic acid levels (such as smoking) would most likely realize decreased damage to their DNA via supplementation. Protection of DNA against oxidative damage has led to the suggestion that ascorbic acid is involved in cancer prevention. However, the main role of ascorbic acid in prevention of gastric cancer may be due to the vitamin's inhibition of nitrosoamine production^[6] rather than via detoxification of reactive oxygen species.

Ascorbic acid is also a cofactor of many dioxygenases and it is a deficiency in this activity that leads to scurvy. Ascorbic acid reduces prosthetic metal ions and also keeps other cofactors such as tetrahydrobiopterin in a reduced state. In addition to its well-known role in collagen biosynthesis, ascorbic acid also acts as a cofactor for enzymes involved in carnitine, progesterone, oxytocin, catecholamine, and nitric oxide synthesis and has been shown to improve vasodilation by enhancing the synthesis of NO in endothelial cells.^[7]

The current U.S. RDA for ascorbic acid is 90 mg/day. In a 1994–95 USDA-sponsored survey, only 63.5% of Americans were meeting 100% of the U.S. RDA for ascorbic acid (two-day average). However, supplementation with single high daily doses of ascorbic acid may not be effective at increasing the intracellular pool of ascorbic acid as expression of SVCT1 (the Na_2^+ -dependent transporter that facilitates uptake of dietary ascorbic acid in epithelial cells) decreases substantially when cells are exposed to high levels of ascorbic acid.^[8] This finding may help explain the lack of consensus regarding the role of single daily supplemental doses of ascorbic acid in prevention of degenerative disease.

Fig. 1 The chemical structure of L-ascorbic acid.

ASCORBIC ACID PATHWAYS

Despite the dependence of humans on plants for meeting ascorbic acid requirements, the plant ascorbic acid biosynthetic pathway was only recently determined. In 1998, Wheeler and Smirnoff presented evidence for a plant pathway via intermediates that included D-mannose and L-galactose.^[9] Prior to this seminal paper, two different plant ascorbic acid pathways were proposed, one analogous to the animal pathway, and the other quite different, involving the osones glucosone and sorbosone. Evidence for the pathway similar to animals rested primarily on the fact that plants harbor a mitochondrial-localized L-galactono-1,4-lactone dehydrogenase with similarity to a L-gulonono- γ -lactone oxidase in the animal pathway. This plant enzyme can convert exogenously supplied L-galactono-1,4-lactone to ascorbic acid (reviewed in Ref. 10). The second pathway took into account evidence that (unlike the animal pathway) inversion of the carbon skeleton in the final product (ascorbic acid) relative to that in the primary substrate, D-glucose, does not occur in plants. However, there is little evidence for the proposed enzymatic activities necessary for conversion of these osone intermediates into ascorbic acid (reviewed in Ref. 10).

Wheeler and Smirnoff presented two key findings that reconcile the existence of the L-galactono-1,4-lactone dehydrogenase (similar to the animal pathway) and the non-inversion of the glucose carbon skeleton in plants. The first was the demonstration that L-galactono-1,4-lactone is produced in plants from L-galactose by an L-galactose dehydrogenase. Secondly, they found that plants synthesize L-galactose very efficiently from D-mannose, most likely via a GDP-D-mannose-3,5-epimerase. The ascorbic acid biosynthetic pathway constructed from this data is shown in Fig. 2.^[9] Early supportive evidence for this biosynthetic pathway came from analysis of the *Arabidopsis* ascorbic acid-deficient mutant, *vtc1*. The *Vtc1* gene was found to encode a GDP-mannose pyrophosphorylase,^[11] the activity that catalyzes the generation of GDP-mannose substrate for the aforementioned epimerase. Potato lines expressing an antisense copy of this pyrophosphorylase gene have diminished ascorbic acid levels, independent confirmation of the role of this enzyme in ascorbic acid biosynthesis.^[12]

In addition to the GDP-mannose pyrophosphorylase gene (*Vtc1*), several additional genes involved in plant

ascorbic acid biosynthesis have been identified. The L-galactono-1,4-lactone dehydrogenase gene has been cloned from several plant species including cauliflower, sweet potato, and tobacco (reviewed in Ref. 10). In addition, annotated sequences with high similarity to known L-galactono-1,4-lactone dehydrogenase sequences are found in the *Arabidopsis thaliana* genomic database. The peptide sequence of a purified GDP-mannose-3,5-epimerase from *Arabidopsis* led to the identification of the epimerase gene.^[13] Using a similar strategy, the Smirnoff lab has cloned the L-galactose dehydrogenase gene from *Arabidopsis*.^[14] In addition to the ascorbic acid-deficient *Arabidopsis* mutant *vtc1*, three other *VTC* alleles have been identified by virtue of mutant alleles negatively affecting ascorbic acid synthesis.^[15] To date, one of these (*Vtc2*) has been cloned^[16] although the role of the *Vtc2* gene product in ascorbic acid biosynthesis is yet to be determined.

In the future it will be theoretically possible to engineer plants to produce elevated levels of ascorbic acid as the plant ascorbic acid biosynthetic pathway is better understood, and genes encoding key rate-limiting enzymes in the pathway have been identified. In fact, transgenic tobacco have been described that overexpress the rat L-gulonono-1,4-lactone oxidase enzyme (which may have the same activity as plant L-galactono-1,4-lactone dehydrogenase) and accumulate somewhat elevated levels of ascorbic acid.^[17]

Fig. 2 The biosynthetic pathway of ascorbic acid synthesis in higher plants. (Revised from Ref. 6.)

CONCLUSION

Although scurvy in the modern world is quite rare and occurs at <10 mg/day ascorbic acid,^[18] it is clear that ascorbic acid has many roles beyond that of a cofactor in collagen biosynthesis, and obtaining at least the U.S. RDA for ascorbic acid is beneficial. Given the fact that many do not meet this minimum RDA, engineering edible plants to produce more of this essential vitamin may lead to improvements in health. Consuming elevated levels of a vitamin such as ascorbic acid via “functional foods” would also result in consumption of other beneficial phytochemicals, a benefit that would not be achieved via a vitamin supplement. The introduction of such plants may also reduce the commercial dependence on sulfites as antibrowning agents. Alternatively, crop plants engineered to have increased levels of ascorbic acid may be indirectly beneficial to human health in that such crops may be resistant to environmental stresses that generate ROS and thus produce higher yields, especially in inhospitable environments. As mentioned above, several of the genes in the plant ascorbic acid biosynthetic pathway have been cloned, and research on engineering plants with elevated levels of ascorbic acid is currently underway.

ATP and NADPH

Wayne Frasch

Arizona State University, Tempe, Arizona, U.S.A.

INTRODUCTION

The energy to drive the metabolic processes of all life-forms on earth is ultimately derived from photosynthetic processes. The principal means used by a living organism to store this energy is through the production of adenosine 5'-triphosphate (ATP) or the reduced form of nicotinamide adenine dinucleotide (NADH) and its phosphorylated variant nicotinamide adenine dinucleotide phosphate (NADPH) that is used in photosynthetic processes. Due to the wide variety of metabolic processes that use ATP as an energy source, this molecule is often referred to as the energy currency of a cell. Energy stored in the high-energy phosphoryl bond of ATP is released when this bond is cleaved by an ATPase reaction to form ADP and inorganic phosphate (Pi). The energy stored in reduced NADPH derives from its negative redox potential relative to other cellular components.

During photosynthesis, ATP is synthesized from ADP and Pi by the chloroplast F_0F_1 ATP synthase. This enzyme is composed of the thylakoid membrane-embedded F_0 protein complex, and the attached F_1 protein complex that protrudes into the aqueous stroma of the chloroplast. The F_0 is composed of subunits a, b, b', and c (also known as subunits IV, I, II, and III, respectively), while F_1 contains subunits α , β , γ , δ , and ϵ . The reduction of $NADP^+$ to NADPH is catalyzed by ferredoxin $NADP^+$ reductase (FNR), a peripheral membrane protein on the stromal side of the thylakoid that is associated with an intrinsic membrane protein in the thylakoid.

INVOLVEMENT OF PHOTOSYNTHETIC LIGHT REACTIONS

The energy used by F_0F_1 to drive the synthesis of ATP from ADP and Pi is derived from the capture of light by light-harvesting and reaction center protein complexes in thylakoid membranes.^[1] Once absorbed, light energy is transferred to Photosystem I (PSI) or Photosystem II (PSII) where it induces oxidation of the reaction center chlorophyll and reduction of an electron acceptor that is far more electronegative than the ground state chlorophyll. Since molecules with a more electronegative redox potential store more energy upon reduction, the reduction

of the initial electron acceptors in PSI and PSII can be considered to be the step in which light energy is first captured as chemical energy during photosynthesis. Due to the instability of this initial product, a series of sequential redox reactions occurs to prevent the recombination of charges in the reaction center chlorophyll and the initial electron acceptor. These reactions result in the reduction of a molecule that is less electronegative than the initial acceptor but still substantially more electronegative than the reaction center chlorophyll. The oxidized PSII reaction center abstracts electrons from water to release molecular oxygen and protons into the thylakoid lumen (Figs. 1 and 2).

Reduction of plastoquinone by PSII consumes two protons from the stroma. The reduced, lipid-soluble quinol is then oxidized by the cytochrome b_6/f protein complex in the thylakoid, which results in the deposition of the protons in the thylakoid lumen. The reducing equivalents then transfer to oxidized PSI reaction center chlorophyll. The reducing equivalents generated by PSI reduce the iron-sulfur cluster of ferredoxin, a water-soluble protein in the stroma. Ferredoxin in turn reduces $NADP^+$ via the enzyme ferredoxin $NADP^+$ reductase (FNR), a peripheral membrane protein on the stromal side of the thylakoid that is associated with an intrinsic protein in the thylakoid. The net result of the photosynthetic electron transfer reactions is that electrons from water with a redox potential of +0.81 V are used to reduce $NADP^+$ that has a redox potential of -0.32 V that accompanies vectorial movement of protons from the stroma to the thylakoid lumen.^[1]

For $NADP^+$ to be reduced, it must accept two electrons from a donor. However, the redox active iron-sulfur complex of ferredoxin is capable of transferring only one electron at a time. FNR mediates these one- and two-electron reactions by using the bound coenzyme flavine adenine dinucleotide (FAD) that forms a semiquinone upon accepting an electron from the first ferredoxin. After FAD becomes completely reduced to a hydroquinone by a second ferredoxin, $NADP^+$ is reduced to NADPH. The two-electron reduction of $NADP^+$ is accompanied by one proton and is therefore a hydride (H^-) transfer. FNR consists of two domains, one that binds FAD and the other that contains the $NADP^+$ binding site. Ferredoxin binds in the cleft between the domains in an orientation that positions its iron-sulfur cluster close to FAD.^[2]

CHEMIOSMOTIC ENERGY COUPLING

Some of the energy initially captured by the photosynthetic light reactions is used to power the vectorial movement of protons from the stroma to the thylakoid lumen, thereby forming a transmembrane proton gradient.^[3] This proton translocation causes a small pH increase of the stroma and a much larger pH decrease in the lumen due to its relatively small volume. This leads to the nonequilibrium condition of a pH difference of 3 to 4 units across the thylakoid membrane during the photosynthetic light reactions. The rate that protons escape from the lumen to the stroma is relatively fast ($t_{1/2}$ of decay of the transmembrane proton gradient is approximately 1 sec). Consequently, the instability of the proton gradient makes it unsuitable for long-term energy storage. Instead, the proton gradient is used by the F_0F_1 ATP synthase as the energy source to drive ATP synthesis. In this manner, the photosynthetic light reactions are coupled to the synthesis of ATP via the proton gradient. Reagents like ammonia that can transport protons across the membrane more rapidly than the F_0F_1 ATP synthase will inhibit ATP synthesis because they collapse the proton gradient. These reagents that uncouple ATP synthesis from electron transfer reactions, called uncouplers, typically increase the rate of the latter reactions by relieving back-pressure from the proton gradient.

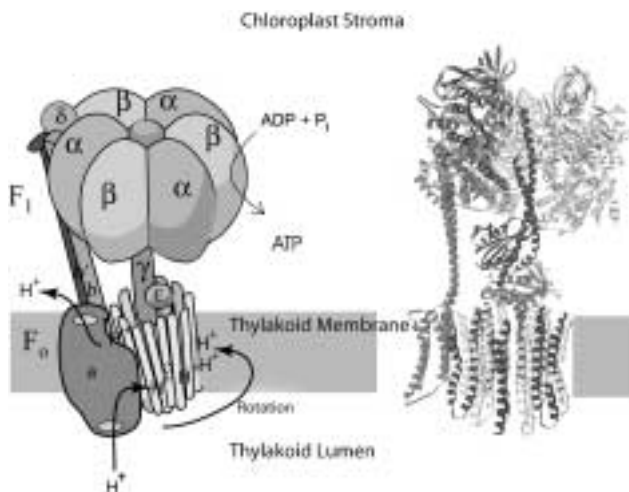

Fig. 1 Subunit composition of the chloroplast F_0F_1 ATP synthase produced from a composite of Protein Data Bank files 1H8E, 1C17, 1L2P, 1ABV, and 1B9U for the analogous subunits of the enzyme from bovine mitochondria and *Escherichia coli* using Web Lab Viewer from Molecular Simulations, Inc. The location of a catalytic site is indicated by Mg^{2+} -ADP, shown in red. An α subunit has been removed to reveal the coiled coil of the γ subunit. (View this art in color at www.dekker.com.)

Fig. 2 Spinach chloroplast ferredoxin $NADP^+$ reductase structure produced from Protein Data Bank file 1GJR using Web Lab Viewer from Molecular Simulations, Inc. The domains that bind FAD and $NADP^+$ are shown in green and blue, respectively, with the bound coenzyme. (View this art in color at www.dekker.com.)

Energy coupling occurs because F_0 serves as an efficient conduit to move protons across the thylakoid membrane and back toward equilibrium with the stroma. Protons move to the stroma in response to the energy gradient that is derived from the concentration difference across the membrane (ΔpH). Because each proton also carries a positive charge, the charge difference across the membrane ($\Delta\Psi$) also contributes to this proton energy gradient. A proton concentration difference of about 1000-fold across the membrane ($\Delta pH = 3$) provides sufficient energy for F_0F_1 to drive ATP synthesis. Even though F_0F_1 transports only protons across the membrane, nonequilibrium concentration gradients of other ions such as K^+ can contribute to the energy of the proton gradient by changing the $\Delta\Psi$ if the ion is permeable to the membrane.

In this chemiosmotic coupling process, the magnitude of the energy gradient, designated the proton-motive force (pmf or μ_{H^+}), is related to the transmembrane concentration and charge differences in mV at 30°C by Eq. 1. The proton-motive force translates into more conventional energy terms because it is the sum of the free energy derived from the transmembrane concentration difference (Eq. 2) and the electrical potential gradient generated by the transmembrane concentration gradient of charged species (Eq. 3), where n is the charge on the ion (+1 for protons). This relationship simplifies to Eq. 4.

$$\Delta\mu_{H^+} = \Delta\Psi - 60\Delta pH \quad (1)$$

$$\Delta G = 2.3RT \log \frac{[H^+]_{\text{lumen}}}{[H^+]_{\text{stroma}}} = 2.3RT\Delta pH \quad (2)$$

$$\Delta G = -nF\Delta E = -nF\Delta\Psi \quad (3)$$

$$\Delta G = -F\Delta\mu_{H^+} \quad (4)$$

ALTERNATING SITE MECHANISM OF THE F_0F_1 BIOMOLECULAR MOTOR

The F_0F_1 ATP synthase operates as a molecular rotary motor.^[4] The protein subunits that compose the rotor and stator of this motor are γ , ϵ , c and α , β , δ , a , b , b' , respectively. The c subunits assemble into a ring that is currently estimated to contain 14 subunits. Each transmembrane helical c subunit has an aspartic acid that is protonated by the protons of the lumen via a channel located on subunit a . An arginine at a separate location on subunit a displaces the proton from subunit c to release it to the stroma. Each successive proton displacement induces the stepwise rotation of the c subunit ring, driven by the transmembrane proton gradient.

The γ and ϵ subunits, docked to the c subunit ring, also rotate in response to the proton gradient-driven stepwise rotation and compose the rotor of the biomolecular motor. The N and C termini of the γ subunit form a coiled coil that protrudes through a ring composed of three α and β subunit heterodimers that compose each catalytic site. The ring of $\alpha\beta$ heterodimers along with subunits a , b , b' , and δ compose the stator of the motor.

Each catalytic site adopts a conformation in response to the rotational position of the γ subunit such that the three catalytic sites are in different conformations with one site empty. Completion of a catalytic cycle at any one site requires 360° rotation of the γ subunit. In what is known as the binding-change or alternating-site mechanism, the binding of a Mg^{2+} -ADP complex and Pi to the empty site triggers a 120° step rotation of the γ subunit, driven by the proton gradient, that releases ATP from a different catalytic site.^[5] The energy from the flux of three protons through the membrane is minimally required to drive a 120° rotation and ATP production, although the measured ratio of protons/ATP is approximately 4.

The F_0F_1 ATP synthase uses the nonequilibrium proton gradient to drive the reaction, $ADP + Pi = ATP + H_2O$, far beyond the point of equilibrium, in favor of the products. Most enzymes that use ATP hydrolysis as a source of energy derive the energy from the reaction by returning the concentration ratio of ATP/ADP+Pi toward equilibrium. Sequential changes in catalytic site conformation maintain this ratio away from equilibrium. In the initial conformation, the binding of ADP and Pi is preferred to ATP. The first conformational change increases the affinity of the catalytic site for substrates and products and has a low activation energy barrier for ATP synthesis that allows rapid interconversion of substrates and products. The second conformational change converts the site to one that favors ATP over ADP and Pi, while the third decreases the affinity for ATP so that, even when the ATP/ADP + Pi ratio is high, ATP hydrolysis is minimized and ATP dissociates.

REGULATION OF ATP SYNTHESIS IN CHLOROPLASTS

After chloroplasts have reached steady state in the light, the onset of darkness leads to a condition in which the proton gradient rapidly dissipates, while the ATP/ADP + Pi ratio remains high. Under these conditions, F_0F_1 initially catalyzes ATPase-dependent proton pumping back to the lumen, the reverse of synthase activity. This wasteful consumption of the energy captured in light is rapidly halted by formation of a disulfide bond in the γ subunit that stops rotation and ATP hydrolysis.^[6] Upon illumination, the first reducing equivalents from PSI that reduce ferredoxin are diverted from FNR to thioredoxin reductase that catalyzes the reduction of thioredoxin. Thioredoxin in turn reduces the disulfide of the γ subunit to activate F_0F_1 .

B Chromosomes

R. N. Jones

University of Wales, Aberystwyth, Wales, U.K.

INTRODUCTION

The earliest record of B chromosomes in plants comes from Anne Lutz in 1916 who found them in *Oenothera*, and referred to them as “diminutive chromosomes.” Later, they also became known as accessories or extra fragment chromosomes. The term B chromosomes is credited to Randolph, who used this name in 1928 to describe certain additional chromosomes found in some plants of maize, and to distinguish them from those of the regular chromosome complement ($2n = 2x = 20$), which are the A chromosomes. B chromosomes is now the universally accepted term, and can be conveniently shortened to B or Bs.

DISCUSSION

The special feature of Bs, which makes them so fascinating and enigmatic, is that they are only found in some individuals of a species and are completely absent from others: In other words, they are dispensable. We may look upon them as optional extras, which is a puzzling idea. It would not be puzzling were it not for the fact that Bs are not rarities at all, but are known in more than one thousand plants and several hundred animals. Bs are part of the genome in those species that carry them, but not an obligatory part like the basic set of A chromosomes. The standard reference that covers all aspects of Bs through the 1980s is by Jones and Rees; two other recent reviews update the story.

The photos of Bs in rye (*Secale cereale*) in Fig. 1 are representative of how we see them in many plant species.

In general terms we can profile them as follows:

- At mitosis, Bs are morphologically distinct from the As in size (usually smaller), centromere position, and status of chromatin (often more heavily heterochromatic), which is how we first recognize them and distinguish them from extra copies of the As.
 - Their diagnostic feature is that they show no homology with any of the As and never pair or recombine with them—they follow their own evolutionary pathway.
 - They display non-Mendelian modes of inheritance due to their presence in variable numbers in different individuals and their special property of “selfishness” in terms of their numerical increase over generations.
- In high numbers they reduce the vigor and fitness of plants.
 - Their phenotypic effects are of a quantitative nature, and they lack genes with major effects.

OCCURRENCE

The latest estimate^[1] gives the number of flowering plants with Bs as 1372, of which 12 are conifers and 1360 angiosperms. A few examples are known in ferns and fungi. Among flowering plants they occur in 738 monocots and 622 dicots, and they are found in polyploids as well as diploids. Their presence among families varies enormously, but this variation cannot be interpreted to fit any special pattern. The only thing we can say with any certainty is that they are most often seen in species favored for chromosome studies, such as the Liliaceae and Gramineae.

INHERITANCE

The non-Mendelian mode of transmission of Bs occurs because their number is variable, and meiosis is irregular due to complexities in pairing. In addition, there are systems of mitotic drive in some species (especially Gramineae) based on nondisjunction in gametophytes. In rye there is directed nondisjunction at the first pollen grain (Fig. 1) and first egg cell mitosis; this leads to an unreduced number of Bs being directed into the gametes. In maize the nondisjunction takes place at the second pollen mitosis, followed by preferential fertilization of the egg by the B-carrying sperm, and likewise constitutes a selfish drive mechanism that causes the Bs to spread in natural populations.^[2] Equilibrium frequencies of Bs are reached when the forces of accumulation are balanced by those of meiotic loss and reduced fitness.

PHENOTYPIC EFFECTS

In general the phenotypic effects of Bs are either neutral (when they are present in low numbers) or harmful (when

Fig. 1 B chromosomes of rye ($2n = 2x = 14 + Bs$) at mitosis and meiosis. (a) c-metaphase in a root meristem cell in a plant with 2 Bs (arrowed). (b) Metaphase I of meiosis showing 7 A-chromosome bivalents and a single unpaired B. The single B will divide at anaphase I and undergo loss at anaphase II. When 2 Bs are present they form a bivalent in most cells, but with higher numbers multivalents are formed and meiosis is irregular. (c) First mitosis of the pollen grain, showing a single B (arrowed) undergoing directed nondisjunction to the generative nucleus. The two chromatids of the B remain joined at sensitive sticking sites on each side of the centromere, and these receptors receive a signal from a genetic element near the end of the long arm of the B. When this element is deleted the Bs disjoin regularly. The spindle at first pollen grain mitosis is asymmetrical, with the equator nearest to the generative pole; it is thought that the sticking of the B chromatids delays their separation long enough for them to be passively included in the generative nucleus as the nuclear membrane encloses them at telophase. (d) c-metaphase in a root meristem cell of a plant with 2 Bs after fluorescent in situ hybridization (FISH) with probes made from the D1100 and E3900 B-specific sequences. (View this art in color at www.dekker.com.)

they are found in high numbers). These effects are manifested in all characters in a quantitative manner, but with some intriguing and unexplained differences depending on their occurrence in odd- or even-numbered combinations.^[3] Fertility is especially affected in a negative way by high B-numbers. There are some special diploidizing effects on meiosis in hybrid polyploid grass species,^[4] which has led to some optimism that Bs may have practical applications.^[5]

STRUCTURE AND ORGANIZATION

There are no known cases where the size of the Bs exceeds that of the As: They are not only smaller but often have a number of different morphological forms present in the same individual, as in the case of *Aster* species where up to 29 polymorphic forms have been found. More important is the question of their genes—or

to be precise, their lack of genes. Bs are not only optional for a species, but as far as we know they are a silent part of the genome, with the only exception being some rRNA genes in some species, such as the Australian daisy *Brachycome dichromosomatica*.

Brachycome ($2n = 2x = 4 + 0-3Bs$) is interesting in another aspect: It is one of the few species, together with rye and maize, wherein some detailed DNA sequence data are available for the Bs.^[6] It seems that up to 10% of the larger of the two kinds of Bs found in *Brachycome* is made of a B-specific family of a 176 base pairs (bp) tandem repetitive DNA sequence, with up to 1.8×10^5 copies of the 3.36×10^8 bp of DNA in each B. The rRNA genes are not transcribed, and there is evidence from chromatin remodeling studies, using immunolabeling with antibodies for differently acetylated forms of histone H4, to suggest that transcriptional activity of the Bs may be silenced in a way similar to that involved in X-chromosome inactivation in mammals.

Molecular studies in rye^[7] also point to the absence of genes, and in addition, to two families of sequences, D1100 and E3900, that are B-specific and located at the end of the long arm (Fig. 1). These B-specific families are composed of fragments of a number of unrelated elements, originating from parts of the A chromosomes, which have undergone amplification and simplification. E3900 derives from a Ty3-gypsy retrotransposon.

In maize there is a B-specific repeat sequence (pZmBs) that makes up most of the B centromere and is also found at the telomeres.^[8] This sequence is thought to play a key role in the meiotic function of the maize B.

NATURAL POPULATIONS

Large issues in terms of effects are to what extent B chromosomes are of adaptive significance and to what extent their natural polymorphisms are selfishly generated by mitotic drive, where this exists.^[9] There are two schools of thought, according to the system being investigated.

In rye—one of the most intensely studied of all plant species—the situation is clear enough and was resolved by a computer simulation model. This model demonstrated that the drive process based on nondisjunction in the gametophytes is strong enough to overcome all negative effects of the Bs on vigor and reproductive fitness, and that the only factor that can negate the Bs is their own failure to pair and to segregate well at meiosis.^[3] The argument then becomes more esoteric and involves the antagonism and coevolutionary dynamics of Bs and anti-B genes in A chromosomes. We enter the dimension of host–parasite interactions, where we find the plants as hosts and the Bs as genome parasites.^[10] The B-drive in maize is less strong than in rye, but the outcome is essentially the same and resolves the issue of how Bs come to exist so extensively in natural or seminatural populations.^[10] In maize, as in rye, Bs are not found in modern cultivars of these crops, and this is because of heavy selection for high fertility that quickly eliminates the B chromosomes.

Chives (*Allium schoenoprasum* $2n = 2x = 16 + 0-20$ Bs) have Bs in natural populations, and tell a different story. There is no obvious method of accumulation of the Bs in this species. In fact they are transmitted at a mean of 0.39 in some populations, which is lower than the Mendelian rate of 0.5, and there is a net loss in progenies compared with their parents. Furthermore, their presence in high numbers reduces fitness of the carriers, and this prompts the question of how they are maintained in nature. The hypothesis that is proposed, based on greenhouse experiments, is that there is differential

selection operating at the seedling stage (based on drought tolerance) and that Bs confer some selective advantage in this respect.

CONCLUSION

In the final analysis Bs remain enigmatic and intriguing. There is a wealth of data about their occurrence in populations, but a serious deficiency of understanding about the dynamics of their natural world. The glimpses we have been able to glean suggest a rich harvest of population genetics still awaits to be gathered before we even begin to close the book on this story. To complete the narrative we will also need more sequence data and a view of their mode of origin, which is missing at the present time.

Bacterial Attachment to Leaves

Martin Romantschuk

University of Helsinki, Lahti, Finland

INTRODUCTION

Attachment of bacterial cells to colonizable surfaces is a common event that in many environments absolutely determines the fate of the bacterium. In other environments and for other bacteria, the requirement for attachment is not absolute, but the adherence may still give a selective advantage, and therefore capacity to adhere is a fitness factor. In this context, the term “surface” should be understood broadly, to include not only colonizable tissues or inanimate surfaces but also the surface of other microbes and bacterial cells in, for example, biofilms.

In the case of plant leaf-associated bacteria, both plant pathogenic and saprophytic bacteria harbor a capacity for more or less specific adherence, and they often do carry the genes for expressing attachment-associated surface structures such as pili or fimbriae. But apparently leaf surface attachment is in most, if not all, cases not an absolutely required trait—at best merely a fitness factor improving the chances for successful colonization in competition with other microbes. This may, however, be decisive in natural environmental conditions where any contribution to fitness determines the outcome of the bacterial competition of the limited resources of the leaf surface or the limited access to the inner leaf tissue.

BACTERIAL STRUCTURES INVOLVED IN ATTACHMENT

When spreading through rainsplash, etc., the initial interaction of a bacterial cell with a plant leaf surface is a random event. The distribution of bacteria deposited on a leaf surface after the droplet has dried is, however, far from random (Fig. 1). The distribution—high relative bacterial cell densities on trichomes, leaf veins, and stomates—is likely to reflect nonspecific hydrophobic interaction in combination with degree of access to leaf surface structures, rather than specific interaction of a bacterial adhesin with a receptor, although this type of specificity has not been ruled out. At any rate, the presence or absence of bacterial appendages, such as pili, fimbriae, flagella, and other bacterial cell surface structures, does influence the ability to attach.

Pili and Fimbriae

The main, but not exclusive, focus will be on pili and fimbriae produced by various plant-associated, and in most cases plant-pathogenic, bacteria (Table 1). In contrast to polysaccharides and flagella, most pili or fimbriae have one primary function, and that is attachment. The direct effect of the presence of these surface appendages is adhesion of the carrier bacterial cell to surfaces, solid particles, etc. The secondary events following attachment may be very diverse, including successful colonization of a surface, twitching motility, biofilm formation, aggregation of bacterial cells, which helps in moisture retention and UV tolerance, etc. On the other hand, neither attachment nor pili are indispensable in most cases, but they are apparent epiphytic fitness factors, although very few studies have been performed to confirm this.

Type IV Pili

Type IV pili that also go by several alternative names (type 4 fimbriae, common pili, bundle-forming pili, etc.) are produced by a great number of gram-negative bacteria, including, as it seems, most gram-negative plant pathogens (Table 1). The genes for biogenesis of type IV pili show homology to those of type II secretion (general secretory pathway), and although many bacteria carry the genes required for pilus biogenesis, pilus production has not always been observed. The fact that pili have not been observed in the case of a certain strain does not signify lack of pili, since a clear phenotype is not always associated with the presence of pili. The pili are often expressed in very low numbers and have in some cases been shown to be inducible in certain specific conditions. In the case of *Pseudomonas syringae* this type of pili was observed at an early stage as the receptors for phage $\phi 6$, but only later^[1] their identity was confirmed as type IV pili. At that point, it was already known that the pili also have a function in promoting attachment of bacteria to plant leaf surfaces,^[2] in aggregating bacteria to form pellicle on the surface of stationary cultures^[3] and clusters, which influences the UV resistance of the bacteria,^[4] and possibly also in formation of biofilms on plant surfaces. No plant surface receptor for the type IV

Fig. 1 Confocal laser scanning micrograph of bacteria inoculated by spraying onto plant leaves followed by live/dead staining of the bacterial cells. The bar denotes 50 μm . Living bacteria appear green against a background of dark red fluorescing leaf tissue. Brighter red spots indicate the presence of chloroplasts. A: *Pseudomonas syringae* pv. *tomato* DC3000 scattered over the lower surface of a tomato leaf. The guard cells and opening of a stomate is seen in the middle of the picture. Plant cell outlines cannot be distinguished, but in equivalent scanning electron micrographs (not shown) bacteria can be seen in crevices between neighboring cells and occasionally clustering at and on top of stomata as well as attached to trichomes. B: *Erwinia carotovora* subsp. *carotovora* cells aggregating onto the trichome of an *Arabidopsis* leaf. (Pictures provided by Tristan Boureau.) (View this art in color at www.dekker.com.)

pilus has been isolated, and it is possible that the attachment is merely a result of hydrophobic interaction between the pilus and the leaf cuticle. These pili are not required for pathogenesis as such, since nonpilated

mutant strains still cause HR in nonsusceptible plants and disease symptoms in susceptible plants when infiltrated into the plant tissue. The pili are, however, apparently epiphytic fitness factors, the effect of which is seen in a situation of competition. Nonpilated bacterial mutants initiate colonization less efficiently than the parental wild-type strain, and this difference is maintained in a situation of competition. In the absence of competition, even the nonpilated strain reaches high population densities but is more sensitive to dislocation by flushing water.^[5]

Among the plant pathogens, type IV pili have been observed in at least *Xanthomonas hyacinthi*,^[6] *Xanthomonas campestris* pv. *vesicatoria*,^[7] many pathovars of *P. syringae*,^[1,8] and *Ralstonia solanacearum*,^[9] and the list is likely to grow as the genomes of more bacteria become characterized. Indeed, in the case of Pierce's disease of grape and similar diseases of other plants caused by *Xylella fastidiosa*, the presence of pili was suspected when it was found that the genome contained the type IV pilus genes. The bacterium is spread by insects and colonizes the vascular tissue of the plant with wilting as the result. The bacterium forms colonylike structures in the plant tissue, and it is conceivable that type IV pili are required to cement the colonies and to resist the flushing by water in the xylem. Table 1 lists plant-associated bacteria where pili have been observed and partially characterized. Not all of those bacteria are leaf-associated; some are specialized root colonizers (*Klebsiella* spp., *Azoarcus*, *Pseudomonas fluorescens*) or pathogens (*Ralstonia solanacearum*),

whereas others are found both in the rhizosphere and in the phyllosphere (*Agrobacterium*, *Erwinia* spp.).

Fimbriae: Type 1, Type 3, etc.

Many bacteria of the Enterobacteriaceae family form type 1 and type 3 fimbriae, which have been shown to mediate attachment of bacterial cells to target tissues in the case of animal diseases. Also, in some plant-pathogenic and other plant-associated bacteria, these fimbriae have been observed^[10] (Table 1), but a direct correlation to pathogenicity or virulence is in most cases missing. *Erwinia rhapotici* produces fimbriae with a specific adherence to N-acetyllactoseamine.^[11] The bacterium infects rhubarb leaves but also infects wheat, causing pink grains to be formed. Receptor analogues, particularly N-acetyllactoseamine, were able to inhibit bacterial attachment and grain coloration. The true pathogenic and ecological role of the Enterobacterial fimbriae/pili is, however, unclear.

Attachment Inside the Leaf Tissue: The Hrp Pilus

The Hrp pathogenicity island (PAI) is essential for pathogenesis of hypersensitivity reaction in the case of many biotrophic plant pathogenic bacteria species such as *P. syringae*. Recently Hrp genes were also shown to play a role in the interaction of the necrotrophic pathogen *Erwinia carotovora* ssp. *carotovora* with its host,^[12] and the Hrp-PAI has been observed in many additional bacterial species (see Table 1 for partial listing). The Hrp pathogenicity island contains a type III secretion system with homology to the gene cluster required for flagellar synthesis. Type III protein secretion is widespread among gram-negative pathogens of both animals and plants. Apparently, the products of so-called avirulence genes and some pathogenicity determinants are translocated from the bacterial cell, possibly directly inside the plant cell cytoplasm. An idea of how this might take place emerged when the Hrp pilus was discovered.^[13] Recently the pilus was shown to grow by addition of pilin (HrpA) monomers at the pilus tip^[14] and to function as a fountain secreting harpin (HrpZ) at the growing tip.^[14,15] The pilus grows through the plant cell wall, until it reaches and possibly penetrates the plasma membrane, enabling pathogenicity determinants to enter the plant cell.^[15,16] At this point, the bacteria are attached and directly linked to the plant cell, and although the Hrp pilus-mediated attachment is not necessarily physically strong, it is required for proper functioning of the interaction. In *R. solanacearum* bacterial cells were observed to attach in a polar manner to plant cells, but this form of attachment was not dependent on Hrp pili. Instead, a different pilus/fimbria might be involved.^[17] Whether foliar pathogens depend on a

primary or additional adhesin for successful Hrp pilus-mediated interaction is not known.

The results obtained with the Hrp pilus show that proteins can be transported in the lumen of the apparently hollow pilus. It is likely that in order to fit through the tube that the pilus constitutes, the protein has to be unfolded. The pilin itself, HrpA, possibly folds as it emerges at the pilus tip and attaches to the previous HrpA residue. Whether a specific link to a plant receptor is formed when the pilus tip reaches the plant cell membrane is presently not known, but other bacterial proteins, such as the harpin, may also play a role here.

Attachment of *Agrobacterium*

Attachment to plant cells is a necessary and early step in disease of dicot plants caused by *Agrobacterium*. The bacterium colonizes the rhizosphere but attaches also to wounded aerial plant tissues. Chemotactic motility towards wounds is followed by attachment, the first step of which apparently is dependent on one or more bacterial cell surface protein(s). Several types of mutants with impaired binding have been observed, but it appears that in some cases the effect is pleiotrophic and can be overcome by changing the incubation conditions, such as temperature or osmolarity.^[18] After initial binding, cellulose fibrils produced by the bacterium anchor the cells to the wounded plant tissue.^[19] Early binding steps are followed by specific cell-to-cell interactions characteristic for only *Agrobacterium*. The bacterial cell transfers genetic material directly from the bacterial cell to the cytoplasm of the plant cell through a direct link formed by the bacterium. The molecular and structural details of how the transfer takes place is still partly obscure; whether transfer requires a direct contact between participating cells, which are brought together by retraction of the *Agrobacterium* T-pilus, or whether the translocation of the protein-DNA complex is mediated by the elongated pilus is still a matter of controversy. The *Agrobacterium* type IV secretion system, showing homology to the F-conjugation system, shares no homology to the Hrp system (type III secretion) of *P. syringae* and other pathogens, but these two secretion systems do show mechanistic similarities.

CONCLUSION

Bacterial attachment to leaf surfaces is not an absolutely required trait, shown by the fact that plant-associated bacteria can colonize and plant-pathogenic bacteria can cause disease even if genes normally associated with attachment are mutated. The testing scenarios in these cases are, however, never natural. The bacteria are applied alone and usually in large quantities, whereas in natural conditions where any inoculum is likely to be mixed,

chance plays a great part, in combination with the fact that there is competition for space and resources and a battle against harsh environmental conditions, such as high UV irradiation or alternation between flushing water and drought or between high and low temperatures. Here, even small differences in fitness translate into successful colonization or failure. This should be kept in mind when considering the whole ecology of a plant-associated bacterium. Such matters are of particular significance when attempting to achieve biocontrol of plant disease or when trying to understand the epidemiology of bacterial diseases the causative agent of which is a more or less opportunistic pathogen. Sequencing of a growing number of bacteria is likely to reveal that they all carry genes associated with attachment and that these genes are there not as a genetic load but for a specific reason—optimal fitness.

Bacterial Blight of Rice

Bart Cottyn

Tom Mew

International Rice Research Institute, Los Baños, Philippines

INTRODUCTION

Bacterial blight caused by *Xanthomonas oryzae* pv. *oryzae* is one of the most serious diseases of rice worldwide. The disease was first reported in 1884 from Japan. In the 1960s, bacterial blight epidemics occurred in other Asian regions as a result of the introduction of modern, high yielding but susceptible rice cultivars such as TN1 and IR8. Subsequently, the disease was also reported in Latin America in the 1970s, and in Africa and North America in the 1980s.

Over the past 20 years, mainly due to the spectacular developments of new molecular techniques, advances have been made in understanding the epidemiology, population biology, and host–pathogen interaction of bacterial blight of rice. Substantial research has been done on the population genetics of *X. oryzae* pv. *oryzae* to understand the adaptation of the pathogen population on deployed resistance in the field. The cloning and characterization of pathogen avirulence genes and plant resistance genes has provided new insights into the molecular mechanisms of pathogenesis. The practical approaches of applying knowledge of *X. oryzae* pv. *oryzae* population genetics in disease management strategies have made the rice-bacterial blight system one of the most widely used models for studying host–pathogen interaction.

SYMPTOMS

Bacterial blight is prevalent in the tropics during the rainy season in irrigated or rain-fed lowland and deepwater rice production systems. Bacterial blight symptoms usually develop in the field at the tillering stage, and the disease incidence increases with plant growth, peaking at the flowering stage. Lesions on the leaf blade are initially water-soaked and typically associated with the leaf tips and edges. Lesions gradually enlarge, turn yellow, and may coalesce to cover the entire leaf blade. Older lesions appear as bleached, white to straw-colored necrotic areas, and severely infected leaves wither quickly (Fig. 1). Young plants are the most susceptible, and a severe form of the disease termed “kresek” may develop if roots or leaves are damaged and infected during transplanting.

Such early infection usually results in seedling death within one to six weeks.

THE PATHOGEN

Taxonomy

The present taxonomic status of *Xanthomonas oryzae* pv. *oryzae*^[1] is the result of integrated phenotypic and genotypic analyses. Earlier classifications were *Pseudomonas oryzae* (by Uyeda and Ishiyama in 1926) *Xanthomonas oryzae* (by Dowson in 1943), and *Xanthomonas campestris* pv. *oryzae* (by Dye in 1978). The species *X. oryzae* includes the two pathovars *oryzae* and *oryzicola*, the causal organism of bacterial leaf streak of rice.^[1] The two pathovars share a genomic relatedness of over 85% DNA-DNA homology and occupy a distinct position in the genus *Xanthomonas*, which supported the creation of a new species, *X. oryzae*. The different symptoms produced and the distinct phenotypes of the two rice pathogens supported their classification as separate pathovars within the species *X. oryzae*. The two pathogens can also be differentiated by whole-cell fatty acid and protein profiles, reaction to monoclonal antibodies, and DNA fingerprinting.

Population Structure

Traditionally, *X. oryzae* pv. *oryzae* populations have been characterized by virulence typing on a set of differential cultivars carrying different resistance genes, thus establishing races or pathotypes.^[2] In the Philippines, ten races of *X. oryzae* pv. *oryzae* have been defined based on a set of near-isogenic lines (IRBB lines) carrying 12 individual bacterial blight resistance genes in a common genetic background (Table 1). Analysis of genomic variation of the pathogen was initiated with the development of DNA fingerprinting techniques in the 1980s and the discovery of repetitive DNA elements in *X. oryzae* pv. *oryzae*.^[3] Several repetitive elements such as insertion sequences (IS1112 and IS1113), transposable elements (TNX6 and TNX7), and avirulence genes, have been identified

Fig. 1 Rice field severely infected by bacterial blight in Yunnan province, China. Inserts illustrate bacterial leaf blight symptoms at various stages of infection. (Photographs by I. Oña and compiled by E. Panisales, IRRI.)

in copy numbers varying from 3 to 80 in the genome of *X. oryzae* pv. *oryzae*. A high genomic diversity within *X. oryzae* pv. *oryzae* was detected by DNA fingerprinting using the repetitive elements and avirulence genes as markers (Fig. 2), which, combined with virulence typing, allowed the description of *X. oryzae* pv. *oryzae* populations across major rice growing regions^[4] and the monitoring of changes in the pathogen population structure.

THE DISEASE CYCLE

X. oryzae pv. *oryzae* is a vascular pathogen and infects the plant through hydathodes or wounds. Upon entering the leaf through hydathodes, the pathogen multiplies in the intercellular spaces of the mesophyll and gains access to the xylem vessels. Its multiplication and spread within leaf-lesions is more extensive in compatible (susceptible) than incompatible (resistant) interactions. Histological studies of diseased leaf tissue indicated that in resistant interactions the pathogen is enveloped by plant polymers resulting in densely packed bacterial cells that are unable to colonize the intercellular spaces.^[5] More recently, genes encoding peroxidases that are predominantly expressed in rice leaves during resistant interactions have been identified, and increased peroxidase has been correlated with accumulation of lignin-like phenolic compounds. During the development of the resistant and the susceptible reaction, almost identical biochemical changes occur in the rice leaves, but their induction is delayed in the susceptible reaction. The pathogen multiplies rapidly during the susceptible interaction and drops

of bacterial ooze, which are produced on the surface of leaf-lesions, can be passed directly from plant to plant by contact, or indirectly via irrigation water. Secondary spread of *X. oryzae* pv. *oryzae* in the tropics is associated strongly with occurrence of typhoons, which not only disperse inoculum but also cause wounds that promote infection.

X. oryzae pv. *oryzae* survives in rice stubble and on numerous weed hosts, which are considered as primary sources of initial inoculum for bacterial blight epidemics. The pathogen does not survive well outside of its host and saprophytic survival in soil is short-lived. *X. oryzae* pv. *oryzae* can be seedborne, but the epidemiological significance of its seedborne phase remains to be determined. The *X. oryzae* pv. *oryzae* strains from North America and Africa, although previously assumed to be introduced via seed from Asia, are clearly different from Asian strains based on phenotypic and genotypic characteristics. Isolation of *X. oryzae* pv. *oryzae* from seed is difficult due to its low population size, its slow growth, and its poor competitive ability relative to the large background seed microflora. *X. oryzae* pv. *oryzae* detection methods that require cultivation are inadequate and lack sensitivity for routine seed testing. Moreover, it has become clear in the past 10 years that saprophytic xanthomonads similar in appearance can commonly be isolated from rice seed,^[6] and may have contributed to conflicting reports regarding the seed transmission of bacterial blight. The presence of nonpathogenic xanthomonads may also present a potential identification problem for seed certification agencies. A polymerase chain reaction (PCR)-based detection method that provides the required sensitivity for seed assays and can differentiate nonpathogenic xanthomonads from *X. oryzae* pv. *oryzae* has been developed. A disadvantage of the PCR method, however, is that it cannot ascertain viability or genotype of the detected cells.

DISEASE MANAGEMENT

Chemical control of bacterial blight by mercuric and copper compounds, and antibiotics such as streptomycin and its derivatives, has not proven effective. Cultural practices such as fallow and drying the field after harvest, removing of diseased rice straw, and eradication of possible alternate host plants around paddy fields are useful but often difficult to implement.

The deployment of host plant resistance has been the most efficient control strategy for bacterial blight. Over 25 genes that confer resistance to specific races or clusters of races of *X. oryzae* pv. *oryzae* have been identified from cultivated varieties, wild rices, and induced mutation. Two resistance genes, *Xa21* and *Xa1*, have been cloned and molecularly characterized.^[7,8] So far, *Xa4* has been

^aResistance or susceptibility of rice plants to *X. oryzae* pv. *oryzae* is expressed in lesion lengths measured at 14 days after inoculation. Resistant (R): <5 cm; moderately resistant (MR): 5 to 10 cm; moderately susceptible (MS): 10 to 15 cm; susceptible (S): >15 cm. All NILs were inoculated at 40 to 45 days after sowing.

^bA representative strain of *X. oryzae* pv. *oryzae* for each of the defined Philippine races is given in parentheses.

^cRace 3B belongs to race 3, lineage B; race 3C belongs to race 3, lineage C; race 9a differs from race 9b and 9c in the absence of *avrXa7*, the avirulence gene that corresponds to *Xa7*. (Data provided by C.M. Vera Cruz, IRRI.)

Fig. 2 Restriction fragment length polymorphism (RFLP) analysis of strains of *Xanthomonas oryzae* pv. *oryzae* using a cloned avirulence gene *avrXa10* as hybridization probe. (Data provided by C. M. Vera Cruz, IIRRI.)

the most commonly deployed gene in many modern semi-dwarf cultivars grown in the tropics. However, the widespread deployment in monoculture of single-gene resistant cultivars often led to the breakdown of plant resistance as a result of rapid changes in the pathogen population and the emergence of new virulent races.^[5] The three avirulence genes (*avrxa5*, *avrXa7*, and *avrXa10*) isolated from *X. oryzae* pv. *oryzae* belong to the *avrBs3* gene family, a common type of avirulence gene found in different species and pathovars of *Xanthomonas*. Mutagenesis analysis of the avirulence genes^[9] indicated that assessing the fitness penalty imposed on the pathogen by the loss of both avirulence and aggressiveness functions of an avirulence gene could be useful in predicting the durability of a corresponding plant resistance gene.^[10] Current breeding programs are being optimized by incorporating molecular marker techniques, and aim to transfer resistance genes identified as being effective against the predominant population of the bacterial blight pathogen. Recently, near-isogenic lines with pyramids of the resistance genes have been developed for use as resistance donors in breeding programs (Table 1). Strategic deployment of individual race-specific resistance genes or pyramiding of genes that have complementary resistance against multiple pathogen races may limit the build up of particular races.

CONCLUSION

The population biology of the bacterial blight pathogen has been intensively studied to understand the population structure changes in response to planting resistant cultivars. The integration of knowledge of *X. oryzae* pv. *oryzae*

population genetics into breeding and deployment strategies for resistant cultivars may provide a basis to design gene-based disease management strategies. The principle behind such a population approach is that use of host plant resistance should be guided by knowledge of temporal and spatial changes in the pathogen population structure. Detailed knowledge of the pathogen population diversity in the field can also be useful in clarifying questions of the initial source of inoculum for bacterial blight epidemics. The information that will become available from the large-scale genome sequencing efforts will provide new opportunities to investigate genetic mechanisms of host-pathogen interactions and to analyze factors important for durable resistance.

Bacterial Pathogens: Detection and Identification Methods

Jan M. van der Wolf

Cor D. Schoen

Plant Research International, Wageningen, The Netherlands

INTRODUCTION

Detection and identification of plant pathogenic bacteria is a prerequisite for implementing effective disease management strategies. In the past, bacterial diseases were detected by field inspections and accompanied by lengthy isolation and identification procedures, including laborious biochemical reactions and pathogenicity tests. These procedures are often impractical for routine detection. Consequently, there is a continuing search for rapid and reliable methods that can replace those used traditionally. This chapter discusses the current techniques used in the detection of phytopathogenic bacteria as well as newer technology that promises to improve the efficiency of identification.

SEROLOGICAL ASSAYS

The introduction of serological assays in the 1960s signaled an important advance in the identification of phytopathogenic bacteria.^[1] In particular, the enzyme-linked immunosorbent assay (ELISA) and immunofluorescence (IF) antibody staining have been widely adopted in testing programs. For example, in the Netherlands, 60,000 potato samples are tested annually with IF to detect *Ralstonia solanacearum*, the causal organism of brown rot. For epidemiological studies, immunofluorescence colony-staining (IFC), in which bacterial colonies grown in agar pour plates are stained with fluorophore-tagged antibodies and detected by fluorescence microscopy, provides a sensitive and quantitative method for detecting culturable plant pathogenic bacteria in complex substrates.^[1]

Initially, much of the serology-based assays relied on polyclonal antibodies that, in some cases, lacked the desired specificity and were difficult to reproduce. However, the introduction of hybridoma and phage display technologies significantly improved the selection of consistent and specific monoclonal antibodies.^[2]

The latest development in serology-based techniques is the application of flow cytometry (FCM), which allows

the rapid and quantitative detection of IF-stained bacterial cells^[3] (Fig. 1). In FCM, large numbers of individual bacterial cells are counted as they flow through a capillary tube and pass a laser beam. Multiple cellular parameters are determined simultaneously based on the cell's fluorescence and its ability to scatter light. A flow cytometer is expensive, but it may replace labor intensive IF microscopy for analysis of antibody stained cells. Sample preparation for FCM analysis is simple and comprises filtration of the cells and suspension and incubation with fluorochrome-labeled antibodies. It also allows combining antibody staining and the use of fluorescent markers for viability (vital stains), such as propidium and hexidium iodide for red fluorescent staining of dead and carboxy fluorescein diacetate and calcein AM for green fluorescent staining of viable cells.

NUCLEIC ACID-BASED DETECTION AND IDENTIFICATION METHODS

A second major breakthrough in routine detection of phytopathogenic bacteria was the introduction of techniques targeting nucleic acid sequences. In particular, techniques that rely on specific amplification of nucleic acid sequences, such as the polymerase chain reaction (PCR), are widely accepted.^[4] These techniques are rapid, specific, and allow detection of genes associated with pathogenicity and virulence. PCR-based procedures have been developed for many economically important plant pathogenic bacteria. Under optimal conditions, PCR allows detection of nucleic acids from 1 target cell per reaction. However, inefficient DNA extraction and/or inhibition of amplification by sample contaminants frequently result in reduced sensitivity. Inclusion of sample controls, which are co-extracted and co-amplified, can indicate false-negative results due to poor extraction and inhibition. False-positive results, caused by cross-contamination, can be circumvented by using real-time PCR amplification procedures in sealed tubes.^[4] During real-time PCR amplification, amplicon production is coupled with the light emission generated by the excitation of

Fig. 1 Flow cytometry (FCM) for detection of *Xanthomonas campestris* pv. *campestris* (*Xcc*), stained with fluorescein isothiocyanate (FITC)-labelled monoclonal antibodies, in a cabbage seed extract. Analysis was done on the basis of particle size (Y-axis) and green fluorescence intensity (X-axis). On the left side of each graph a large group of background bacteria with low green fluorescence intensity is visible. The *Xcc* population is indicated with an arrow. A. no *Xcc* added, B. 10^3 *Xcc* cells/ml added, C. 10^5 *Xcc* cells/ml added, D. 10^7 *Xcc* cells/ml added. (View this art in color at www.dekker.com.)

fluorophores. The increasing fluorescent signal can be automatically monitored by a fluorometer indirectly indicating increases in amplicon concentration. The found cyler threshold values are related to initial concentrations of template DNA; hence, real-time PCR can allow initial populations of target bacteria to be estimated. Additionally, real-time PCR is rapid and eliminates the need for electrophoretic analysis of amplicons.

Enrichment of target bacteria by plating samples on selective growth media prior to PCR can result in improved detection sensitivity. Moreover, tedious DNA extraction methods can be avoided, because PCR inhibitory substances are absorbed into the agar medium and bacterial cells harvested from plates can be detected via PCR without DNA extraction.

Recently, nucleic acid sequence-based amplification (NASBA) has been introduced for detecting plant pathogenic bacteria. NASBA results in the exponential amplification of single-strand RNA molecules, is performed at a constant 41°C, and is based on concurrent activity of three enzymes, reverse transcriptase, RNaseH, and T7 RNA polymerase.^[5] Amplicons can be detected by Northern blotting, and in real-time by using molecular beacons (single-stranded oligonucleotides with a stem-loop structure that specifically anneal with the amplicons, generating a fluorescent signal). This homogeneous assay, called AmpliDet RNA, allowed detection of *R. solanacearum* and *Clavibacter michiganensis* subsp. *sepedonicus* rRNA in potato peel extracts, with a detection threshold of 1000 colony-forming-units (CFUs)/mL.^[5] One drawback of standard PCR, targeting DNA, is the inability to distinguish between viable and nonviable cells. Most RNA molecules rapidly degrade after a cell dies and its presence can indicate cell viability. Therefore, AmpliDet RNA can be an important epidemiological tool.

DNA amplification procedures revolutionized not only detection but also identification of plant pathogenic bacteria. Large portions of a bacterial genome can be analyzed with genetic fingerprint techniques. Using small oligonucleotides (approximately 10 nucleotides (nt)) as primers in random amplified polymorphic DNA (RAPD)-PCR, multiple fragments from complex bacterial genomes are generated. The use, however, of small oligonucleotides can lead to inconsistent results. Robustness is higher in rep-PCR techniques that employ larger oligonucleotides (approximately 20 nt) to amplify fragments flanked by conserved repetitive DNA sequences that are randomly dispersed throughout the bacterial genome. The availability of representative fingerprint libraries allows rep-PCR techniques to be employed for identification of unknown isolates within the group of *Clavibacter michiganensis*, phytopathogenic xanthomonads, and pseudomonads.^[6] Most other genotypic fingerprinting methods lack these libraries and are used only to study genomic diversity and population structures. Bacteria can also be identified and classified by the RiboPrinter system based upon an automated restriction fragment length polymorphism analysis of phylogenetically conserved rRNA sequences. The system includes DNA extraction from bacteria, followed by enzymatic restriction digestion and probing with a hypervariable region of the rRNA operon. Restriction patterns are compared with those in a database, which comprises patterns of over 600 strains, although most of these are medical strains.

Nearly all nucleic acid-based detection methods involve an amplification reaction. One exception is the fluorescence in situ hybridization (FISH) technique, by which DNA in permeabilized bacterial cells is stained with an oligonucleotide labeled with a fluorescent dye. Bacteria can subsequently be visualized by UV

microscopy.^[7] Cell permeabilization procedures are often time consuming, and bacterial cells stained by FISH are often not as bright as those stained by IF. Specificity of detection can be improved by combining FISH with IF.

FATTY ACID METHYL ESTER ANALYSIS

Fatty acid profiling is the technique by which the composition of (methylated) fatty acids in bacteria is analyzed by gas chromatography. The equipment is expensive, but when bacteria are cultivated under standardized conditions, the technique has proven to be highly reliable for identification of many groups of bacteria, even at the subspecies level.^[1] In general, the automated Microbial Identification System from Microbial ID (Delaware, U.S.A.) is used, which includes an extended database for plant pathogenic bacteria.

SUBSTRATE UTILIZATION ASSAYS

The MicroLogTM system (Biolog, Hayward, CA, U.S.A.) allows identification of bacteria based on their ability to utilize a combination of 95 different substrates in a convenient microplate format. Conversion of an indicator (tetrazolium violet, a redox dye) by metabolically active bacteria results in a color change, which can be observed visually or measured with a microplate reader. Substrate utilization profiles are compared with those in an extended library that comprises over 1900 bacteria. Unfortunately,

the range of phytopathogenic bacteria included in the Biolog database is limited.^[8]

INTEGRATED DETECTION AND IDENTIFICATION PROCEDURES

Micro-array technology represents the next generation of DNA diagnostic tools for the simultaneous identification of multiple plant pathogenic organisms. Micro-arrays have many oligonucleotides (>10,000) spotted or synthesized in approximately 1 cm² area on a solid surface to serve as hybridization targets. Single-strand (ss) DNA isolated from a bacterial sample is then hybridized to immobilized complementary DNA targets, generating double strand DNA. Fluorescent dyes, most commonly used to detect the capture of target oligonucleotides are excited by laser energy, and the emission is analyzed with confocal microscopy or charge-coupled device technologies (Fig. 2).^[9] Alternatively, the difference in electrical conductivity between dsDNA and ssDNA can be used to indicate whether hybridization has occurred, thus avoiding use of fluorophore-tagged DNA probes.^[10] The presence of many different targets will improve specificity, allow detection of variants of the pathogens in question, and avoid laborious confirmation procedures.

Microfabrication processes are also being explored for manufacturing silicon, glass, or plastic arrays with diverse analytical functions. Analyzers using these arrays hold great promise in simplifying the processing of crude biological samples, running biochemical reactions, and detecting the results. Systems with these characteristics

have been termed “laboratory-on-a-chip,” which implies the ability to process crude biological samples to isolate target molecules of interest.^[11] An integrated computer-controlled nanoliter device for DNA analysis that automatically extracts and amplifies target DNA and analyzes the resulting amplicons using electrophoresis^[12] has been recently described (Fig. 3). All the system components are contained on single glass and silicon substrates. This technology provides a glimpse of the future techniques for detection and identification of phytopathogenic bacteria.^[13]

Bacterial Pathogens: Early Interactions with Host Plants

Gwyn A. Beattie

Iowa State University, Ames, Iowa, U.S.A.

INTRODUCTION

From the perspective of inducing plant diseases, the importance of the early interactions of pathogenic bacteria with plant hosts is usually in the build-up of pathogen populations. The ability of most pathogenic bacteria to develop large populations can be attributed to their invasion and multiplication within healthy plant tissue, traits that are rare among the diverse bacteria that associate with plants. The ability to establish large populations often involves bacterial modification of the inhabited microsites—such as by inducing the secretion of plant nutrients—and may be enhanced by cooperative interactions among the bacteria. Although large pathogen populations are usually required for disease induction, this alone is not sufficient, as indicated by the fact that large populations of foliar pathogens are often present on asymptomatic leaves.^[1] In addition to large pathogen populations, disease induction requires a susceptible host and environmental conditions conducive to disease.

COLONIZATION OF PLANT SURFACES

Bacterial pathogens may immigrate directly into the plant tissue, for example via an insect vector, but most immigrate onto the surfaces of leaves, blossoms, fruits, and roots. The presence of large phytopathogen populations on aerial plant surfaces suggests that bacteria can colonize these surface sites. This is supported by micrographs showing their abundance on plants, by their recovery in large numbers in plant washings, and by their ability to be killed by treating plants with surface sterilants.^[1,2] Furthermore, pathogen inoculation onto plants often results in large pathogen populations on the surface before disease symptoms appear. Several pathogens have been demonstrated to multiply on plant surfaces. The foliar pathogen *Rhodococcus fascians* multiplies on leaf surfaces before entering the plant, although this pathogen is unusual in that it also induces symptoms in the absence of large internal (endophytic) populations.^[3] The pathogen *Erwinia amylovora* multiplies on the stigma surface in pear and apple blossoms, a surface that is particularly moist due to hygroscopic stigmatic secretions. Instead of multiplication, large

surface populations may reflect efficient movement to the surface by bacteria that multiplied within the plant tissue. For example, endophytic populations of many *Pseudomonas syringae* and *Xanthomonas campestris* pathogens extrude through stomata and onto the leaf surface.^[2]

The bacterial traits required for colonizing plant surfaces are probably distinct from those required for colonizing internal plant tissues.^[2] For example, bacterial colonization of leaf surfaces may require the ability to tolerate large and rapid fluctuations in environmental conditions. In contrast, bacteria that colonize internal leaf tissues may need to overcome the defense responses induced in the plant during microbial invasion. If the maintenance of traits that promote multiplication on plant surfaces imposes a fitness cost on a pathogen, then those traits are likely to be lost. The extent to which most pathogenic bacteria maintain traits for surface colonization is currently unknown.

MOVEMENT INTO THE PLANT TISSUE

Entry of bacterial pathogens into plants occurs through natural openings such as stomata and hydathodes on leaves, modified stomata known as nectarhodes on blossoms, lenticels on woody stems and tubers, and at the sites of lateral root emergence. Bacteria also enter wounds, including those resulting from broken trichomes, damage by hail and wind-blown sand, and various cultivation practices. Bacterial pathogens may migrate to these entry sites on the plant surface. For example, *Agrobacterium tumefaciens* and *P. syringae* pv. *phaseolicola* exhibit directed movement, or chemotaxis, toward wounds.^[4] Although other pathogens exhibit chemotaxis toward plant extracts in vitro, most pathogens have not been evaluated for their ability to move toward entry sites on plants, nor for a role for chemotaxis in promoting bacteria migration into the plant.

For many pathogens, bacterial motility enhances bacterial movement to, or into, the entry sites on the plant. As evidence of this, nonmotile mutants of several pathogens were significantly reduced in virulence in tests that required bacteria to enter through natural entry sites.^[5,6] Interestingly, these nonmotile mutants were fully

virulent when introduced directly into the plant tissue, indicating that bacterial motility may not be important for movement after entry into the plant.

MULTIPLICATION IN INTERCELLULAR SPACES

Suppression of Plant Defense Responses

While bacteria on the plant surface are separated from the epidermal cells by the waxy plant cuticle, bacteria within the plant are in close contact with plant cells. This contact is believed to trigger plant defense responses. Pathogenic bacteria may exhibit a higher level of tolerance to these defense responses than nonpathogenic bacteria. Furthermore, at least one bacterial pathogen, *P. syringae* pv. *phaseolicola*, has been demonstrated to suppress the plant defense responses in plant tissue.^[7] Most pathogenic bacteria have a type III protein secretion system that transfers bacterial proteins into plant cells.^[8] This secretion system and many of the secreted proteins contribute to the establishment of large endophytic populations. Although the functions of the secreted proteins are mostly unknown, one or more of them may suppress plant defense responses that are normally induced in the presence of bacterial invaders.

Modification of Environment in Plant Tissue

The internal tissue of healthy plants protects bacteria from large environmental fluctuations, and it may provide sufficient resources to support limited bacterial growth. Active modification of this habitat to increase nutrient concentrations and water availability is probably critical to the establishment of large endophytic populations. Exposure of plant cells to pathogens typically increases the permeability of the plant cell membrane. Some pathogens also exhibit specific traits that may increase this permeability, including the production of particular phytotoxins and plant growth hormones.^[2] All bacterial pathogens that exhibit extensive multiplication within plants have the type III secretion system described above. One or more of the secreted proteins may function to alter the plant physiology and make the plant tissue more favorable for bacterial growth, such as by inducing the release of nutrients.

Another bacterial trait that could alter the local environment of a pathogen in plant tissues is the production of a hygroscopic matrix, composed of one or more types of exopolysaccharide (EPS), around the cells. This matrix probably increases the amount of water

available to the bacteria. The introduction of purified EPS from some foliar phytopathogens into leaves induces persistent water-soaking (the release of cellular water into intercellular spaces), which has been shown to promote bacterial growth in these spaces. EPS can affect bacteria-plant interactions in many ways, including enhancing bacterial colonization and survival within plant tissues as well as contributing to wilting and other disease symptoms.^[9]

Cooperation Among Bacteria

Extensive habitat modification may be augmented by, or depend on, cooperative interactions among bacteria. A major form of cooperation is the density-dependent induction of specific bacterial traits. This density dependence is mediated by the production of extracellular diffusible signal molecules, which upon achieving a threshold concentration induce the expression of various target genes. Density-dependent signal molecules in pathogenic bacteria include *N*-acyl homoserine lactones (HSL) and a volatile fatty acid. Pathogenic bacteria have been demonstrated to regulate a diversity of traits in this manner,^[10] including the production of EPS, exoenzymes, antibiotics, pigments, and conjugal plasmid transfer. Several of these traits can strongly influence the interactions between the plant and the pathogen. For example, the production of exoenzymes by *Erwinia carotovora* subsp. *carotovora* (*Ecc*) is controlled by an HSL derivative. These enzymes—including pectinases, polygalacturonases, and cellulases—are particularly good elicitors of plant defense responses. At low cell densities, *Ecc* can multiply in the plant without producing exoenzymes, and thus can avoid inducing a major plant defense response. When the *Ecc* cells attain a high density, however, they cooperate to produce sufficiently large amounts of exoenzymes to degrade the plant tissue without being hindered by a plant defense response. This plant tissue degradation greatly increases the nutrients available to the pathogen.

MOVEMENT WITHIN THE PLANT

Some pathogens exhibit little migration from the initial site of infection, whereas others exhibit extensive movement within the plant. For example, some vascular pathogens that enter the stomata or root cracks must spread through the intercellular spaces of the inner cortex until they reach the vascular parenchyma. This movement may involve flagellar motility, twitching motility, or spreading due to an increased mass of bacterial cells and EPS.

CONCLUSION

From the perspective of bacteria, the plant is merely a habitat for growth and survival. Following their immigration to a plant, bacteria may colonize the sites at which they arrive, move to sites that are more favorable for multiplication, and/or modify the environment in their immediate habitat to enhance their growth. Populations that develop on the plant surface result, at least in part, from bacterial movement from the internal tissues, and these surface populations serve as an important inoculum reservoir for further infections. However, with the exception of only a few bacterial pathogens—including the tumor-inducing pathogens *Agrobacterium tumefaciens* and *Rhodococcus fascians*—disease induction requires that large populations develop within the plant tissues. Traits that are currently believed to favor this population development include motility and/or chemotaxis toward entry sites, tolerance and/or suppression of plant defenses, communication within bacterial populations, and active habitat modification. Further efforts to better define the bacterial traits contributing to endophytic colonization are key to improving our understanding of the early interactions of pathogenic bacteria with plants.

Bacterial Products Important for Plant Disease: Cell-Surface Components

P. K. Chakrabarty

University of Florida, Gainesville, Florida, U.S.A.

A. Chatterjee

W. Gassmann

A. K. Chatterjee

University of Missouri, Columbia, Missouri, U.S.A.

INTRODUCTION

Cell surface components play important roles in pathogenicity and virulence of plant pathogenic bacteria. Besides maintaining the cellular integrity, these components play major roles in mobility, communication, survival, and interaction with host cells. They consist of three main components: cell envelope, cell appendages, and extra-cellular polysaccharides (EPSs).

CELL ENVELOPE

The cell envelope of gram-negative bacteria consists of an inner cytoplasmic membrane, a periplasmic space, a thin layer of peptidoglycan, and an outer lipoprotein membrane. Gram-positive bacteria have much thicker cell walls relative to gram-negative bacteria and lack outer lipoprotein membranes. The lipopolysaccharide (LPS) molecules on the outer surface of lipoprotein membranes of gram-negative bacteria have a major role in determining the surface characteristics of bacterial cells and are also largely responsible for their antigenicity. LPSs are structurally diverse, ubiquitous, indispensable components that apparently have diverse roles in bacterial plant pathogenesis.^[1] The polysaccharide moiety of LPSs (the O-antigen) is presumed to contribute to the exclusion of plant-derived antimicrobial compounds and thereby facilitates plant infection by the pathogen. The O-antigen layer is also important in the initial interaction between bacterium and plant cells in determining compatibility or incompatibility.^[2]

The presence of membrane-bound receptors is thought to be important for bacterial functions both outside and within plants.^[3] A few examples are the outer membrane receptor of siderophore complexes in *Pseudomonas syringae* pv. *syringae* and *Erwinia chrysanthemi* and the VirA inner membrane chemoreceptor for acetosyringone in *Agrobacterium tumefaciens*. Mutants of *P. syringae*

pv. *syringae* deficient in iron-pyoverdine receptors fail to take up chelated iron, while the tumor formation by *A. tumefaciens* is abolished with mutation of *virA*.

CELL SURFACE APPENDAGES

Flagella

The mobility of bacteria is an important aspect of infection and is mediated by helical rotation of flagella, long and delicate threadlike proteinaceous appendages that extend beyond the outer lipoprotein membrane of bacterial cells. Flagella are generally thin (diameters of approximately 20 nm) and long, with some having a length 10 times the diameter of the cell. Bacteria may be monotrichous with a single polar flagellum (as in *Xanthomonas*), lophotrichous with a tuft of polar flagella (as in *Pseudomonas*), or peritrichous with flagella arranged around the entire cell (as in *Erwinia*). *A. tumefaciens* swims with its flagella after sensing a chemical signal emanating from the host. Nonflagellated mutants of this pathogen are defective in virulence and induce fewer and smaller tumors on its host.^[4] Similarly, *Escherichia carotovora* ssp. *atroseptica* mutants defective in flagellin biosynthesis and motility are less virulent compared to the wild-type strain. HexA⁻ (hyperproduction of exoenzymes) mutants of the same species, which overexpress flagellar biosynthesis genes and are hypermotile, are also hypervirulent.

Fimbriae or Pili

In addition to flagella, many bacteria possess appendages referred to synonymously as fimbriae or pili. Pili are typically thin proteinaceous filaments radiating from bacterial cells and are smaller and more numerous compared to flagella. The presence of certain pili has been demonstrated

in several plant pathogenic bacteria, including *Ralstonia solanacearum*, *P. syringae*, and *A. tumefaciens*.^[5] There are multiple types of pili, but they may be divided into two groups: adhesive pili and pili required for transfer of DNA and protein between cells.^[6]

Adhesive pili have been found to play an important role in pathogenesis by enabling bacterial attachment to host surfaces. In the case of *P. syringae* pv. *phaseolicola*, a direct correlation exists between the number of pili per bacterial cell and bacterial attachment to the plant surface. Cells devoid of pili do not show any increase in attachment above a low basal level, while wild-type and superpiliated cells show a progressive increase in association over time. When directly infiltrated into leaf tissue, both piliated and nonpiliated strains of this bacterium cause disease, but only piliated strains cause infection when sprayed onto the outer surface of the leaf. This suggests that pili-mediated attachment to leaf surfaces may be important in early stages of the infection process. Pili in *R. solanacearum* are shown to be important for virulence, autoaggregation, biofilm formation, and polar attachment of the bacterium.^[7] Adhesive pili are also involved in twitching motility, bacteriophage adsorption, and UV tolerance based on cell aggregation on leaf surfaces.^[6,8]

The second group of pili includes the *Escherichia coli* sex pilus (F pilus), the *A. tumefaciens* *vir* gene–encoded T pilus, and the *P. syringae* *hrp* gene–encoded Hrp pilus. The F pilus is required for DNA transfer between bacteria, whereas the T pilus functions in the transfer of T-DNA and proteins from *Agrobacterium* to plant cells. Finally, the Hrp pilus plays a distinct role in virulence protein secretion via the type III secretion system in *Pseudomonas*. They have been the subject of active research^[9] and several recent reviews.^[10,11] *R. solanacearum* mutants defective in Hrp pilus production are impaired in interactions with plants and in secretion of the PopA protein involved in eliciting the host defense response. However, they are not impaired in their ability to attach to plant cells.^[12]

EXTRACELLULAR POLYSACCHARIDES

Most plant pathogenic bacteria are enveloped in a viscous material mainly composed of polysaccharides, but polypeptides and glycopeptides may also occur. When thin and diffuse, this material is called a slime layer, whereas it is called a capsule when the layer is thick and spatially well-defined. EPSs play important roles in the pathogenicity and virulence of several bacterial pathogens, including species of *Erwinia*, *Clavibacter*, *Pantoea*, *Pseudomonas*, *Ralstonia*, and *Xanthomonas*.^[13] Specifically, EPSs are

thought to function in pathogenicity through induction and maintenance of water soaking, protection of bacteria from desiccation, prevention of detection by the host, and occlusion of xylem vessels of infected plants causing restriction of water movement.

Erwinia amylovora, the fire blight pathogen of apple and pear, produces amylovoran, which is required for its pathogenicity.^[14] Amylovoran aids in bacterial movement through the cortex of host plants, clogs the vascular system, and causes wilting. Similarly, *Pantoea stewartii* ssp. *stewartii* causes vascular wilt and leaf blight of corn by producing EPSs, which are implicated in pathogenicity by causing water-soaked lesions and systemic wilting. At least five genes govern EPS production in this pathogen, all of which are required for wilting. *R. solanacearum*, the causal agent of vascular wilt of diverse plants, produces large amounts of EPSs, which are present as a soluble slime rather than as an insoluble capsule. Mutants of *R. solanacearum* specifically blocked in EPS synthesis rarely wilt or kill plants, even when large numbers of cells are directly injected into the stem.^[15] At least two gene clusters important for EPS biosynthesis have been identified in this pathogen. *Xanthomonas campestris* pv. *campestris*, the causal agent of black rot of crucifers, produces the EPS xanthan, which is implicated in its virulence and pathogenicity.^[16] EPS has also been shown to be important in the pathogenicity of *X. axonopodis* pv. *malvacearum*, which causes angular leaf spot and blight of cotton.^[17] In contrast, EPSs appear to play an ancillary role in *E. chrysanthemi* pathogenesis, as EPS-deficient strains are still capable of causing disease, but disease symptoms are less severe as compared to those caused by wild-type strains.

CONCLUSION

Cell surface components of plant pathogenic bacteria play a major role in bacterial survival and pathogenicity. They not only provide rigidity and structural integrity but also include external appendages that function in mobility and conjugation. Cell membranes are the active sites for signal receptors and transport of components associated with pathogenicity. Capsules or slime layers form outer envelopes that prevent desiccation of bacteria and are directly or indirectly involved as virulence factors. EPSs that form the bulk of capsule or slime layers are necessary for several pathogens to cause disease symptoms such as water soaking and wilting. Far from being static, the formation of cell surface components such as pili and EPSs is often induced by physiological conditions within the host or in a cell density–dependent manner. They are thus part of the dynamic response of bacterial pathogens to overcome preformed and induced plant defense responses.

Bacterial Products Important for Plant Disease: Diffusible Metabolites As Regulatory Signals

INTRODUCTION

Many plant pathogenic bacteria produce diffusible secondary metabolites that act as quorum-sensing signals. These metabolites accumulate in bacterial cultures and regulate a diverse array of genes, including those involved in virulence and pathogenicity. Quorum-sensing derives its name from the observation that these diffusible signals reach a threshold level based on bacterial cell density (a “quorum”) and thus regulate expression of target genes within a population in a cell density–dependent manner. This phenomenon was originally observed with bioluminescence induction in the marine bacterium *Vibrio fischeri* and was termed autoinduction because induction occurred in sealed cultures without external stimuli.

AHL-DEPENDENT QUORUM SENSING

The best-studied quorum-sensing signaling system, which is conserved across many bacterial genera, involves signaling molecules that are classified as *N*-acyl homoserine lactones (AHL). The basic structure of AHLs consists of a homoserine lactone ring connected to a fatty acyl side chain (Fig. 1). AHLs vary with respect to the length of their *N*-acyl chain, which may range from 4 to 14 carbon atoms, be saturated or unsaturated, and have a hydroxy or an oxo group at the third carbon.^[1,2]

AHL-mediated gene regulation generally involves a transcriptional activator (a homologue of LuxR, which controls bioluminescence in *V. fischeri*) and an AHL synthase (encoded by a *luxI* homologue of *V. fischeri*). In general, LuxR homologues bind AHL, and the complex activates the expression of AHL synthase and other genes regulated by quorum-sensing. Thus, homologues of *luxR* and *luxI* typically form a regulatory pair controlling many phenotypes. AHL production has been reported to regulate pathogenicity and virulence factors in several genera of plant pathogenic bacteria including *Agrobacterium*, *Erwi-*

nia, and *Pantoea*.^[3–6] In plant-associated pseudomonads, multiple traits are regulated by more than one quorum-sensing system. For example, in the nonpathogen *Pseudomonas aureofaciens*, a potential biocontrol agent of several fungal pathogens, two separate quorum-sensing systems control cell surface features, exoprotease activity, and antibiotic and secondary metabolite production. All these traits are important for survival of bacteria on the plant surface.^[7]

Among plant pathogens, the most studied quorum-sensing systems are those operating in *Erwinia carotovora* ssp. *carotovora*, *Erwinia chrysanthemi*, and *Pantoea* (*Erwinia*) *stewartii* ssp. *stewartii*. In the soft-rot bacterium *E. carotovora* ssp. *carotovora*, *N*-3-oxo-hexanoyl-L-HSL (OHL) regulates production of extracellular enzymes, harpins, and antibiotics.^[8] The acyl-HSL synthases involved in the production of OHL have been identified in three strains of *E. carotovora* ssp. *carotovora*: ExpI in strain SCC3193,^[9] CarI in strain GS101,^[10] and HsII in strain 71.^[11] In strain SCC3193, the *expl* (*luxI* homologue) and *expR* (*luxR* homologue) loci are linked. ExpI and ExpR are presumed to constitute a quorum-sensing regulatory pair coordinating the cell density–dependent expression of the genes encoding extracellular enzymes. In *E. carotovora* ssp. *carotovora* strain GS101, CarI coordinates the synthesis of the antibiotic carbapenem along with the expression of macerating enzymes. OHL-regulated expression of carbapenem biosynthetic enzymes is dependent on the LuxR homologue CarR. Interestingly, CarR does not activate expression of macerating enzymes, indicating that the CarI-synthesized OHL may bind to two distinct transcriptional factors. Mutants of *E. carotovora* ssp. *carotovora* strain 71 deficient in HsII are devoid of AHL activity, indicating that OHL probably is the only AHL analogue produced by this bacterium.^[12] OHL production by HsII appears to be constitutive and not inducible via a cognate LuxR homologue.

In contrast to the single quorum-sensing systems in *E. carotovora* ssp. *carotovora* strains, multiple AHLs

Fig. 1 Structure of the AHL *N*-3-oxo-hexanoyl-*L*-homoserine lactone (OHL).

are produced in *E. chrysanthemi* strain 16. Similarly, *E. chrysanthemi* strain 3937 produces three AHLs, of which two OHLs are synthesized by *expI* and a third compound, *N*-(decanoyl)-*L*-homoserine lactone, is synthesized by an unidentified gene. ExpR, a LuxR homologue of *E. chrysanthemi* strain 3937, binds and activates pectate lyase gene promoters in the presence of AHL but binds its own promoter in its absence, presumably to repress its expression.

In *Pantoea stewartii* ssp. *stewartii*, the causal agent of Stewart's wilt of corn, stewartan is an exopolysaccharide that functions as a major virulence factor. Growth-phase-dependent production of stewartan in strain DC283 is regulated by OHL.^[13] The *esaI* gene encoding OHL synthase and the *esaR* gene encoding the cognate transcription factor are tightly linked. In contrast to typical LuxR-type activators of other bacteria, EsaR in strain DC283 functions as a repressor of stewartan production in the absence of OHL. EsaR⁻ mutants overproduce stewartan and are less virulent than the wild-type strain, indicating that premature or excessive production of stewartan interferes with steps in the infection cycle of *P. stewartii* ssp. *stewartii*.

In *Agrobacterium*, two bioactive and related AHLs (3-oxo-C8-HSL and 3-oxo-C6-HSL) are involved in tumor induction in host plants and in conjugation.^[6,14] Conjugal transfer of tumor-inducing Ti plasmids between *Agrobacterium* cells is stimulated by high cell densities and requires opines produced by host tumor tissue. These AHLs were therefore originally called conjugation factors (CF). The *Agrobacterium* LuxR homologue, TraR, is the receptor of the AHLs and induces the expression of conjugal transfer (*tra*) genes only in the presence of AHLs. Expression of TraR, in turn, is regulated by opines. The additional requirement for an external factor in regulation of *tra* gene expression is distinct from the original autoinduction model formulated for *V. fischeri*.

In *Pseudomonas syringae* pv. *syringae*, the synthesis of AHL has not been linked to the production of any pathogenicity factor. AHL mutants produced extracellular protease and phytotoxins and elicited the hypersensitive response in tobacco leaves. Possibly, the AHL in *P. syringae* pv. *syringae* strains plays a role in determining fitness on plant surfaces.^[15] Likewise, a canonical quorum-sensing system dependent on the *luxI/luxR* homologues *solI/solR* has been described in *Ralstonia solana-*

cearum, but the function of this system in regulating expression of virulence factors appears limited.^[16]

NON-AHL CELL DENSITY-SENSING SYSTEMS

Pathogenicity of some plant-associated bacteria is regulated through non-AHL cell density-sensing signals.^[16] In *R. solanacearum*, the Phc (phenotypic conversion) bacterial sensor kinase/response regulator two-component system controls production of exopolysaccharides (EPS) and other pathogenicity factors. The activating signal of this regulatory system is the volatile 3-hydroxy palmitic acid methyl ester (3-OH PAME).^[17] The target of the 3-OH PAME-responsive two-component system is PhcA, which, although showing homology to LysR, is a global transcriptional regulator of many genes. Accumulation of 3-OH PAME results in increased functionality of PhcA and expression of virulence factors. Mutants in PhcA display severely reduced virulence. Unlike the canonical quorum-sensing systems, the Phc regulatory system is not exclusively cell density-dependent, since exogenous addition of 3-OH PAME to cultures at low cell density does not activate gene expression.

In *Xanthomonas campestris* pv. *campestris* strain 8004, production of extracellular enzymes important for pathogenicity is regulated by a diffusible signal factor (DSF) of unknown structure.^[18] No AHL has been identified in *X. campestris* pv. *campestris*, and the genes involved in regulating expression of these extracellular enzymes do not show homology to *luxI/luxR* genes. *X. campestris* pv. *campestris* strain B24 produces another non-AHL diffusible signal called diffusible factor (DF), which regulates production of the membrane-bound pigment xanthomonadin and EPS. DF may be a butyrolactone derivative and is active at very low concentrations.^[19] Available evidence suggests that DSF and DF are independent molecules regulating extracellular enzyme and xanthomonadin production, respectively, but both also regulate EPS production in the respective *X. campestris* pv. *campestris* strains.

CONCLUSION

It is clear that several plant pathogenic bacteria utilize diffusible metabolites to regulate the expression of various genes that encode the products for interacting with their hosts (e.g., pathogenicity/virulence factors) or with other bacteria (e.g., antibiotics or bacteriocins). In many cases, the quorum-sensing system of bacterial pathogens is interlinked with other regulatory systems of gene expression. Therefore, the exact roles of diffusible signals in

regulating bacterial pathogenicity are not always clearly understood. One plausible role is delaying the expression of pathogenicity/virulence factors, which may prevent elicitation of host defense responses until the bacterial population has reached a quorum (threshold) sufficient to overcome these responses.

University of Missouri, Columbia, Missouri, U.S.A.

INTRODUCTION

The degradation of plant cell walls is an important feature of soft-rot bacteria and bacteria that cause tissue necrosis and vascular wilt diseases. Once inside the host, these pathogens secrete a wide array of macerating enzymes to facilitate degradation of host cell wall components that in turn can be absorbed and assimilated by the invading pathogens. This chapter will focus on the extracellular enzymes that degrade three main constituents of plant cell walls (cellulose, pectin, and proteins) and the secretion pathways used by these enzymes.

CELLULASES

Cellulose is an unbranched polymer of β -1,4-linked D-glucose and is the most abundant plant polysaccharide, accounting for 15 to 30% of the dry mass of all primary cell walls. The cellulose polymers in plant cell walls form microfibrils, which are paracrystalline assemblies of parallel β -1,4-glycan chains hydrogen-bonded to one another.^[1] Microfibrils in turn are linked to each other by hydrogen bonding with another class of polysaccharide, the cross-linking glycans (formerly called hemicelluloses). Cross-linking glycans are linear chains with a β -1,4-glucan backbone and relatively short side chains. Unlike cellulose, cross-linking glycans do not hydrogen-bond with each other and as such do not aggregate to form microfibrils.

Enzymes that hydrolyze cellulose are commonly produced by soft-rot pathogens and are generally called cellulases.^[2] The cellulase activity of enzymes is mostly determined by their ability to hydrolyze substrates such as carboxymethyl cellulose (CMC) or fibrous cellulose, which are different from paracrystalline cellulose itself. Accordingly, these enzymes are sometimes also specified as carboxymethyl cellulases. However, since the term cellulase is generally accepted in the literature for

enzymes that hydrolyze both paracrystalline cellulose or constituents thereof, we will follow this convention for simplicity unless stated otherwise.

The breakdown of cellulose by cellulases results in the production of glucose by a series of separate enzymatic reactions. Thus, some cellulases attack cellulose by cleaving cross-linking glycans, and others break cellulose chains into shorter fragments. The hydrolyzed products are then acted upon by a third group of cellulases, called 1,4-endoglucanases, which produce cellobiose (β -1,4-linked disaccharide of glucose). Cellobiose is the substrate for β -glucosidase, which catalyzes its hydrolysis into glucose molecules.

Two cellulase (*cel*) genes each have been cloned from the two phytopathogenic bacteria *Erwinia chrysanthemi* and *Erwinia carotovorum* ssp. *carotovorum*.^[3,4] In *E. carotovorum* ssp. *carotovorum* strain LY34, two cellulases, referred to as CelA and CelB, have been characterized based on their hydrolysis of carboxymethyl cellulose. Five cellulase enzymes have been detected in *E. chrysanthemi* by gel activity staining on CMC-SDS-PAGE (carboxymethyl cellulose–sodium dodecyl sulfate–polyacrylamide gel electrophoresis), although only two cellulase genes, *cel5Z* and *cel8Y*, have been cloned and characterized.^[4] Strains in which the genes for major cellulases have been deleted display reduced virulence. *Ralstonia solanacearum* possibly produces two extracellular glucanases based on sequence homology, and the hydrolytic activity on β -1,4 glycosidic linkages has been demonstrated for one of them.^[5] Cellulase-deficient *R. solanacearum* mutants are also significantly less virulent on tomato plants.

PECTINASES

Pectic acid is a polymer composed chiefly of galacturonic acid units linked by α -1,4-glycosidic bonds. Pectin is

formed by methyl esterification of the carboxyl groups in the pectic acid chains. Pectic substances are a major component of the middle lamella and matrix of primary cell walls and thus play an important role in tissue cohesion. The enzymes that degrade pectic substances are known as pectinases or pectolytic enzymes and are of three main types: hydrolases such as polygalacturonase (Peh), lyases such as pectate lyase (Pel) and pectin lyase (Pnl), and esterases such as pectin methyl esterase (Pem). Peh hydrolyzes α -1,4-glycosidic linkages between two galacturonic acid units. Pel and Pnl break the α -1,4-glycosidic bond by elimination, creating a double bond between C4 and C5 in the galacturonosyl residue. Peh, Pel, and Pnl enzymes are further subdivided into endopectinases and exopectinases. Endopectinases act at random sites within pectin chains, whereas exopectinases act only on terminal linkages. Lastly, Pem hydrolyzes the methyl ester bonds in pectin to yield pectic acid and methanol. Pem enzymes do not affect overall chain length but alter the solubility of pectic substances and the rate at which they are degraded by the chain-splitting enzymes.

The role of pectinases in bacterial pathogenicity has been well documented for the soft-rot bacteria *E. chrysanthemi* and *E. carotovora* ssp. *carotovorum*, and in the vascular wilt pathogen *R. solanacearum*.^[3,5,6] *E. chrysanthemi* strain EC16 produces four Pel enzymes encoded by four independently regulated genes.^[7] *E. chrysanthemi* strain 3937 secretes an arsenal of at least eight endo-Pels, two exo-Pels, and four Pehs, including the most recently characterized polygalacturonase N.^[8] Multiplicity of pectolytic enzymes found in soft-rot bacteria may reflect the availability of different substrates occurring in different hosts. In addition, there may be a requirement for cooperation between different enzymes for optimal maceration of invaded tissues. For example, Peh differs from Pel in being inhibited by higher calcium ions and pH. At the beginning of tissue maceration, Peh may play a major role in cell wall degradation, but increasing levels of calcium and pH would result in increased Pel activity.

Deletion of all Pel genes in *E. carotovora* ssp. *carotovora* results in 98% reduction in maceration of potato tuber tissue.^[9] A single Pel gene is necessary for pathogenicity of *Pseudomonas viridiflava*, and mutation of the single Peh gene of *Agrobacterium vitis* decreased the virulence of this pathogen on grape. *R. solanacearum* produces one Pem and three Pehs (Peh-A, B, C) but no Pel enzyme. A PehA-PehB-deficient double mutant of *R. solanacearum* invades and colonizes stems more slowly than wild type strains. However, deletion of individual pectinases in these pathogens does not always affect pathogenicity. For example, endo-Peh defective mutants of *E. carotovora* with unaltered Pel activity still retain pathogenicity on several hosts.^[9]

PROTEASES

The primary cell wall matrix contains several classes of glycoproteins in addition to polysaccharides. Secretion of proteases (Prt) appears widespread among phytopathogenic bacteria.^[7] *Xanthomonas campestris* pv. *campestris* produces four proteases. At high inoculum levels, protease-deficient mutants of *X. campestris* pv. *campestris* show wild-type virulence on turnip leaves. However, a pronounced reduction in virulence is observed at low inoculum levels.^[10] Most soft-rotting *Erwinia* produce extracellular proteases, many of which are metalloproteases.^[3] Strain SCC3193 of *E. carotovora* ssp. *carotovora* produces an extracellular metalloprotease designated PrtW,^[11] which is distinct from previously described proteases from the same pathogen. Mutants deficient in PrtW produced normal levels of Peh, Pel, and Cel, but were considerably reduced in their virulence. *E. chrysanthemi* also produces four protease isozymes organized in two clusters.^[12] Among soft-rot pseudomonads, protease production rather than pectolytic enzyme production was more strongly correlated with the ability to macerate plant tissues.^[6]

SECRETION SYSTEMS FOR EXTRACELLULAR ENZYMES

Extracellular enzymes must be secreted out of bacterial cells into host intercellular spaces to function in pathogenicity. In plant-associated gram-negative bacteria, there are four distinct pathways for secretion of extracellular pathogenicity factors, referred to as type I to type IV secretion systems.^[13] The exoenzymes discussed in this chapter are substrates for type I or type II secretion systems. Type III and type IV secretion systems are associated with export of Hrp/Avr pathogenicity factors and *Agrobacterium* T-DNA, respectively (see articles by Vivian and by Burr).

The type I secretion system, exemplified by the secretion of metalloproteases of *E. chrysanthemi*, targets substrates directly through bacterial inner and outer membranes to the exterior. Translocation across the cytoplasmic membrane is performed by PrtD, an ATP-binding cassette (ABC) transporter, which recognizes a C-terminally located secretion signal in the secreted protein.^[13] The one-step secretion of proteases in *E. chrysanthemi* requires two additional proteins: PrtE, which belongs to the membrane fusion protein family and spans the inner and outer membrane, and PrtF, an outer membrane protein. Besides extracellular proteases, such systems export siderophores for metal uptake, toxins, and antimicrobial peptides in several phytopathogenic bacteria.^[14]

The general or type II secretion system has two parts: the export pathway for transport across the inner membrane and the so-called main terminal branch pathway for secretion through the outer membrane.^[13] Secretion via the type II secretion system requires an N-terminal signal peptide that is cleaved off after the protein is translocated across the inner membrane into the periplasm, where it is folded into its mature form prior to transport across the outer membrane. Many bacteria utilize this system, e.g., *Erwinia* for secretion of pectinases and cellulases, *X. campestris* for secretion of pectinases, cellulases, and proteases, and *R. solanacearum* for secretion of Pehs, Pem, and endoglucanase.

CONCLUSION

Bacterial plant pathogens produce an arsenal of extracellular enzymes capable of degrading plant cell wall components composed chiefly of pectin, cellulose, and glycoproteins. These host components are liable to be degraded by bacterial pectinases, cellulases, and proteases, respectively. These enzymes cause softening and disintegration of cell wall materials and facilitate penetration and spread of the pathogen in the host. In the case of vascular diseases, the liberation of large oligomers into transpiration channels may interfere with normal movement of water. The extracellular enzymes of bacterial plant pathogens constitute pathogenicity/virulence factors and are secreted out of bacterial cells through specialized protein secretion systems. Model representatives of type I and type II secretion systems have been well studied in terms of membrane topology, as well as the structure and biochemical functions of the constituent proteins. A better understanding of the mechanisms and regulation of extracellular enzyme secretion in phytopathogenic bacteria may allow improved control of bacterial diseases in plants.

INTRODUCTION

Toxins are low molecular weight, non-enzymatic virulence factors produced by many phytopathogenic bacteria. They have a wide range of physiological and biochemical effects on the host plant and produce diverse symptoms, such as chlorosis, water soaking, necrosis, growth abnormalities, and wilting. They cause chemical injury to the host either by affecting the permeability of cell membranes or by inactivating or inhibiting host enzymes. Unlike many fungal toxins, bacterial toxins are not host-selective and therefore do not determine host range. These toxins, generally considered as secondary metabolites, are secreted by bacteria growing both in vitro and in planta.

Some pathogens also produce naturally occurring plant growth regulators such as auxins, cytokinins, gibberellins, and ethylene in their hosts during infection. This causes an imbalance in the host's hormonal system, thereby resulting in abnormal growth and function. The role of microbial growth factors in plant pathogenesis has been extensively studied with reference to gall- and tumor-forming bacterial pathogens.

TOXINS

Some well-studied toxins secreted by plant pathogenic bacteria are listed in Table 1. Most of these are produced by pseudomonads. Coronatine, syringomycin, syringopeptin, tabtoxin, and phaseolotoxin are the most intensively studied phytotoxins of *Pseudomonas syringae*, and each contributes significantly to bacterial virulence.^[1] Their modes of action, regulation, and biosynthesis have been reviewed recently by Bender et al.^[2]

Coronatine

P. syringae pvs. *atropurpurea* (a pathogen of rye grass), *glycinea* (soybean), *maculicola* (bean), *morsprunorum* (*Prunus*), and *tomato* (tomato) produce the toxin corona-

tine. This toxin consists of a polyketide structure linked to a cyclopropane component. Although rare outside *P. syringae* pathovars, coronatine has been reported to be produced by *Xanthomonas campestris* pv. *phormiicola*, a pathogen of flax.^[3] Coronatine functions partly as a mimic of methyl jasmonate, a hormone synthesized by plants undergoing biological stress, and induces symptoms of chlorosis, stunting, and hypertrophy. Coronatine has been shown to play a distinct role in virulence based on studies of coronatine biosynthesis mutants of *P. syringae* pathovars.^[2]

Syringomycin and Related Toxins

Syringomycin is representative of cyclic lipodepsinonapeptide phytotoxins produced by most strains of *P. syringae* pv. *syringae* from diverse plant hosts.^[2] It is composed of a polar peptide head of nine amino acids and a hydrophobic 3-hydroxy fatty acid tail (Fig. 1). An amide bond attaches the 3-hydroxy fatty acid to an N-terminal serine residue, which in turn is linked to 4-chlorothreonine at the C terminus by an ester linkage to form a macrocyclic lactone ring. Other distinctive structural features are three uncommon amino acids (2,3-dehydroxyaminobutyric acid, 3-hydroxyaspartic acid, and 4-chlorothreonine) at the C terminus and the presence of D-isomers of serine and 2,4-diaminobutyric acid. Syringopeptins represent another class of lipodepsipeptide phytotoxins produced by strains of this pathogen.^[2] In contrast to lipodepsinonapeptides, syringopeptins contain either 22 or 25 amino acids depending on the specific bacterial strain (Fig. 2). An ester bond between allo-threonine and the C-terminal tyrosine residue forms a lactone ring. Both syringomycin and syringopeptin are necrosis-inducing toxins; however, the two related toxins differ in their biological properties and antimicrobial specificity against different groups of microbes.^[4] These toxins form pores in plasma membranes that lead to electrolyte leakage. In addition to being phytotoxic, they

Table 1 Toxins in plant pathogenesis

Toxins	Bacterium	Host	Target
Coronatine	<i>Pseudomonas syringae</i> pv. <i>atropurpurea</i> pv. <i>glycinea</i> pv. <i>tomato</i> pv. <i>morsprunorum</i> pv. <i>maculicola</i>	Rye Soybean Tomato Prunes Beans	Not known
Tagetitoxin	<i>P. syringae</i> pv. <i>tagetis</i>	Tagetis	Chloroplast RNA polymerase
Phaseolotoxin	pv. <i>phaseolicola</i>	Beans	Ornithine carbamoyl transferase
Syringomycin Syringopeptin	pv. <i>syringae</i>	Stone fruits, pome fruits, and grasses Mushroom	Plasma membrane
Tolaasin	pv. <i>tolaasii</i>	Mushroom	Plasma membrane
Tabtoxin	pv. <i>tabaci</i> pv. <i>atropurpurea</i> pv. <i>coronafaciens</i> pv. <i>garcea</i>	Tobacco Rye Oats	Glutamate synthetase
Rhizobitoxine	<i>Pseudomonas andropogonis</i> <i>Rhizobium</i> sp.	Corn, sorghum, sudan grass Legumes	β -cystathionase
Carboxylic acid	<i>Xanthomonas oryzae</i> <i>Xanthomonas</i> pv. <i>manihot</i> , <i>Xanthomonas campestris</i> pv. <i>campestris</i>	Rice	Not known

exhibit broad antibiotic activity against prokaryotes and eukaryotes. Toxin-deficient mutants of *P. syringae* pathovars are either reduced in their virulence or are non-pathogenic.

Tabtoxin

Tabtoxin is a monocyclic β -lactam produced by *P. syringae* pvs. *tabaci*, *coronafaciens*, and *garcae*.^[1] It is a dipeptide composed of threonine linked by a peptide bond to an uncommon amino acid, tabtoxinine- β -lactam (Fig. 3). Tabtoxin itself is not toxic but is hydrolyzed by aminopeptidases of plant or bacterial origin in the plant's intercellular spaces. This releases the biologically active compound tabtoxinine- β -lactam, which is actively taken up by the plant amino acid transport system. The toxin inactivates the enzyme glutamine synthetase that is in-

involved in assimilation of ammonia within chloroplasts, and consequently leads to an accumulation of ammonia to toxic levels. The latter uncouples photophosphorylation and destroys the thylakoid membrane of the chloroplasts, causing chlorosis and eventually necrosis of the infected tissues. Tabtoxin is associated with the symptoms of wildfire disease of tobacco and halo blight of oats but is considered to be a virulence factor rather than an essential component of these diseases. This is because the non-toxicogenic strains of these pathogens can still induce necrosis without producing the characteristic yellow halos.

Phaseolotoxin

Phaseolotoxin is a modified ornithine-alanine-arginine tripeptide carrying a sulfodiaminophosphinyl group (Fig. 4). In plants, the tripeptide is cleaved by peptidases

Fig. 1 Structure of Syringomycin. Abbreviations of nonstandard amino acids: Asp(3-OH), 3-hydroxyaspartic acid; Dab, 2,4-diaminobutyric acid; Dhb, 2,3-dehydroaminobutyric acid; Thr(4-Chl), 4-chlorothreonine.

Fig. 2 Structure of Syringopeptin form SP22. Abbreviations of nonstandard amino acids: Dab, 2,4-diaminobutyric acid; Dhb, 2,3-dehydroaminobutyric acid; *a*Thr, *allo*threonine.

to release alanine, arginine, and the biologically active moiety, sulfodiaminophosphinyl ornithine. The toxin inactivates ornithine carbamoyl transferase (OCT), an enzyme of the urea cycle, which normally converts ornithine to citrulline, a precursor of arginine. Inhibition of OCT leads to accumulation of ornithine and depletion of citrulline and arginine. Phaseolotoxin also seems to inhibit biosynthesis of pyrimidine nucleotide, reduce the activity of ribosomes, interfere with lipid synthesis, change the permeability of plant cell membranes, and result in accumulation of large starch grains in the chloroplasts. A direct correlation exists between the amount of phaseolotoxin produced by strains of *P. syringae* pv. *phaseolicola* and the extent of chlorotic haloes on infected plants. Toxin-deficient mutants survive and multiply at the site of inoculation but fail to move systemically inside host plants.

Other Toxins

Tagetitoxin is a cyclic compound^[1] produced solely by *P. syringae* pv. *tagetis*, a pathogen of several members of the Compositae family. Unlike other toxins, tagetitoxin is mainly produced in planta, where it induces symptoms of apical chlorosis and yellow haloes on leaves. The toxin mainly affects chloroplasts by inhibiting chloroplast RNA polymerase.^[5] Tolaasin is a lipodepsipeptide composed of 18 amino acid residues with a β -octanoic acid at the N terminus. This toxin is produced by *P. syringae* pv. *tolaasii*, a pathogen of mushroom, and it causes disruption

Fig. 3 Structure of tabtoxin, which consists of the toxic moiety tabtoxinine- β -lactam linked to threonine. The arrow shows the site of aminopeptidase cleavage, which releases tabtoxinine- β -lactam.

of the host plasma membrane.^[6] Rhizobitoxine secreted by *Rhizobium* and the unrelated pathogen *Pseudomonas andropogonis* is a vinylglycine compound that causes inhibition of homocysteine synthesis by β -cystathionase inactivation.^[7] Carboxylic acid toxins are produced by several pathovars of *Xanthomonas campestris* in culture and may be involved in disease symptom induction.^[5]

In addition to producing toxins directed against the host, many plant pathogenic bacteria produce secondary metabolites to compete with other bacteria. Several strains of *Erwinia carotovora* ssp. *carotovora* and *Pantoea agglomerans* produce antibiotics and bacteriocins.^[8,9] Bacteriocins are mostly proteinaceous antibiotics with very narrow specificity against strains of the same or closely related species.

GROWTH FACTORS

Growth hormones are important in the pathogenicity of gall-forming phytopathogenic bacteria such as *Agrobacterium*, *Pseudomonas* and *Erwinia*.^[10] They initiate high rates of cell division (hyperplasia) and cause extensive cell enlargement (hypertrophy) in infected tissue. This proliferation of host tissue results in a range of distinct symptoms characteristic of the causative pathogen. These include crown gall and tumors of pome, stone, and other fruits by *Agrobacterium tumefaciens*, hairy root of apple caused by *A. rhizogenes*, galls of olive and oleander by *P. savastanoi* pv. *savastanoi*, and galls of *Gypsophila paniculata* by *Erwinia herbicola* pv. *gypsophilae*. Two major phytohormones that are associated with these diseases are auxins and cytokinins. In the case of

Fig. 4 Structure of phaseolotoxin. Plant peptidases cleave phaseolotoxin (arrow) to release alanine and arginine resulting in the formation of (N' sulfodiaminophosphonyl)-L-ornithine.

P. savastanoi pv. *savastanoi*, the roles of auxins and cytokinins in disease development are not well understood, although auxin production has been demonstrated to increase pathogen fitness. In the case of *A. tumefaciens*, the production of auxins and cytokinins plays a direct role in pathogenicity by increasing the cell mass of transformed host cells that produce opines, which in turn serve as a nutrient source only for the pathogen (see the related article "Crown Gall"). In *E. herbicola* pv. *gypsophylae*, although gall initiation is triggered by other virulence factors, the biosynthesis of auxin and cytokinin enhances the gall formation in *G. paniculata*.^[11]

Genes involved in the synthesis of auxins and cytokinins have been cloned and characterized in *P. savastanoi* pv. *savastanoi*, *A. tumefaciens* and *E. herbicola* pv. *gypsophylae*. A high degree of homology exists between the auxin and cytokinin genes of these pathogens.

CONCLUSION

Many bacterial pathogens produce an array of toxins that are important virulence factors. In recent years, some studies have used molecular approaches to construct bacteria deficient in individual toxins and have clearly shown that toxins can contribute quantitatively to pathogen virulence and disease development. Several of these toxins affect the metabolic processes of the host, thereby facilitating the multiplication and spread of the pathogen. Toxins can also alter permeability of the plasma membrane and produce visible chlorosis and necrosis of the host. Plant pathogen-derived phytohormones produce deleterious effects on the host's growth regulatory system in infected plants. While bacterial toxins appear to be indiscriminate weapons against the host, the deployment of growth regulators reveal an intricate and well-adapted interplay between host and pathogen.

Bacterial Soft Rots: *Erwinia* as a Paradigm

Holly Slater

Martin Welch

George P. C. Salmond

University of Cambridge, Cambridge, United Kingdom

INTRODUCTION

Bacterial soft-rot diseases afflict a diverse range of crop plants, both in the field and in storage. Accurate figures for the economic impact of bacterial soft rots are not easy to acquire, but even two decades ago, the global impact of soft rots was estimated to be \$100 million. Although the veracity of such estimates is difficult to establish, it is undeniable that bacterial soft rots are economically important in a world stage.

A spectrum of saprophytic and pathogenic bacteria, including some *Xanthomonas* and *Ralstonia* species, can synthesize depolymerizing enzymes that degrade plant cell walls, but relatively few bacteria have been linked with the soft rotting of living plants or stored crops. Bacteria that have been associated with soft rots include some anaerobic clostridia, *Flavobacterium* species, various pseudomonads, and several species of *Bacillus*. However, the soft rotters par excellence are certain members of the genus *Erwinia* (now also known as *Pectobacterium*), which are gram-negative facultative anaerobes and members of the Enterobacteriaceae. The few species that induce soft rot are opportunistic phytopathogens, only causing disease under specific environmental conditions that encourage bacterial virulence and debilitation of the plant host.

The major *Erwinia* species that cause soft rot are *Erwinia carotovora* subsp. *carotovora* (Ecc), *E. carotovora* subsp. *atroseptica* (Eca), and *Erwinia chrysanthemi* (Echr). Ecc causes soft rot in a wide range of crop plants. Echr is also a significant soft-rotting bacterium, particularly in tropical and subtropical regions. Arguably, the most important crop plant threatened by soft rot due to *Erwinia* spp. is potato. Some soft-rotting erwinias show a degree of host plant predilection (e.g., Eca is the major etiological agent of potato blackleg), but this may be more related to the ecological distribution of *Erwinia* species, rather than bona fide plant specificity. Indeed, the notion of host plant specificity (as exemplified by the various phytopathogenic pseudomonads or xanthomonads) is highly contentious for any of the *Erwinia* soft-rot species.

ECOLOGY AND DISSEMINATION OF SOFT-ROT *ERWINIA* SPECIES

Despite the phytopathological and commercial importance of *Erwinia* soft rots, and some detailed studies on the transmission of Ecc and Eca in relation to potato infection,^[1–3] the ecology of the pathogens is still ill defined. As summarized in Fig. 1, there are multiple pathways known or predicted for the dissemination of soft-rot bacteria. Soft-rot erwinias are extracellular pathogens that gain entry to their hosts through wounds. Pathogen transmission can also occur when bacteria are in asymptomatic mother tubers (a latent infection) and can be transferred into the soil, and then to other plants from that location.^[1–3]

PLANT CELL WALL-DEGRADING ENZYMES, ENVIRONMENTAL FACTORS, AND DISEASE DEVELOPMENT

The main virulence factors are secreted plant cell wall-degrading enzymes, including cellulases, proteases, a nuclease, and a lipase.^[4,7–9] However, multiple secreted and periplasmic isoforms of pectinases (pectate lyases, pectin lyases, polygalacturonases, pectin methylesterases, and so on) are the key virulence factors.^[4,7–9] The phytopathological contribution of some enzymes, and their associated secretory machineries, have been demonstrated by genetic and biochemical analyses,^[1–9] and the details of the species-dependent spectrum of exoenzymes have been reported in considerable detail.^[4,7–9] It is important to appreciate that the type I and, particularly, type II secretory pathways that deliver the cell wall-degrading enzymes are vitally important in pathogenesis. Mutants defective in the type II system (Out mutants) show significantly reduced virulence.^[6]

Environmental conditions strongly influence the outcome of the plant–*Erwinia* spp. interaction. Temperature, oxygen tension, and humidity have been shown to act as environmental cues.^[1,2,4,8,9] Although some environmental factors affect the expression levels of the pectinase

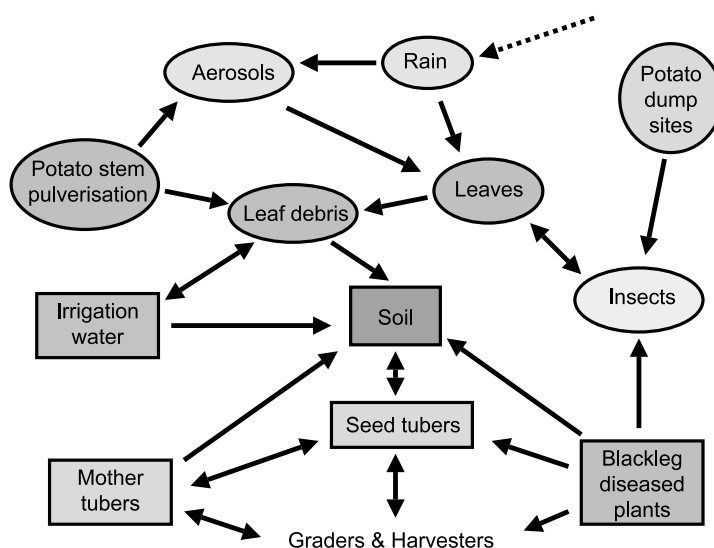

Fig. 1 Dissemination routes for infection of potato due to soft-rot *Erwinia* species. The figure outlines the complexities of possible *Erwinia* transfer pathways. These involve inputs from infected plants, seed tubers, soils, rain and irrigation waters, insects, and activities of potato harvesters and graders. Contaminated rainwater (dotted arrow) can arise as a natural consequence of the widespread ecological distribution of some soft-rot erwinias. (From Refs. [1] and [2].) Boxed categories represent activities that are mostly, or exclusively, underground, whereas categories within ovals represent largely surface/aerial activities. (View this art in color at www.dekker.com.)

genes,^[4,8,9] such factors do not act exclusively on the pathogen. For example, oxygen depletion also reduces the ability of the plant to mount a defense reaction and thereby increases the susceptibility of the plant to attack by *Erwinia* spp.^[1,2]

VIRULENCE FACTORS OTHER THAN EXOENZYMES

Although the exoenzymes are the main virulence determinants in soft-rotting phyto-bacteria, they are not the sole players in plant attack. The soft-rotting erwinias have the ability to elicit a defensive hypersensitive response (HR) in nonhost plants, and can make a necrosis-inducing “harpin” protein and deliver it via a type III secretion system. The precise role of harpin-like molecules in the rotting process is unclear, although it is likely to act at an early stage in pathogenesis. In addition to harpin, other factors thought to play a role in virulence of the soft rotters include motility, lipopolysaccharide integrity, iron-chelating siderophore production, toxin/elicitor production, and ability to respond to oxidative stress.^[1,2,4,6,10–12]

MOLECULAR ASPECTS OF EXOENZYME PRODUCTION

Soft-rot erwinias can respond to plant signals, but are also extremely responsive to various environmental cues such

as temperature, pH, oxygen tension, osmolarity, and carbon source.^[1–3,6–8,11,12] All of these physiological inputs have effects — often differential gene-specific or strain-specific effects — on the production of the exoenzymes. Therefore the controls over virulence factor production by soft-rotting erwinias are extremely flexible and — at a molecular level — complex. One of the main regulatory inputs is that of “quorum sensing” (for more information, see the chapter by Chakrabarty et al. in this volume; Ref. [13]).

The Quorum-Sensing System

Quorum sensing involves the sensing of bacterial cell population density by individual cells via titration of a diffusible signal molecule made by the bacteria.^[5] The *N*-acyl homoserine lactone (N-AHL) signal molecule is usually generated by an enzyme of the “LuxI” class and “sensed” by a protein of the “LuxR” class. The latter acts by binding the ligand and then activating or repressing a selection of target genes specific to the host bacterium.^[5,6,10] In this way, a bacterial population can activate and repress a spectrum of genes in response to cell density by using a small chemical as a diffusible intercellular communication signal.

Exoenzyme synthesis by *E. carotovora* is coordinately controlled by quorum sensing involving the diffusible signalling molecule *N*-3-(oxohexanoyl)-L-homoserine lactone (OHHL or 3-oxo-C6-HSL) made by the product of

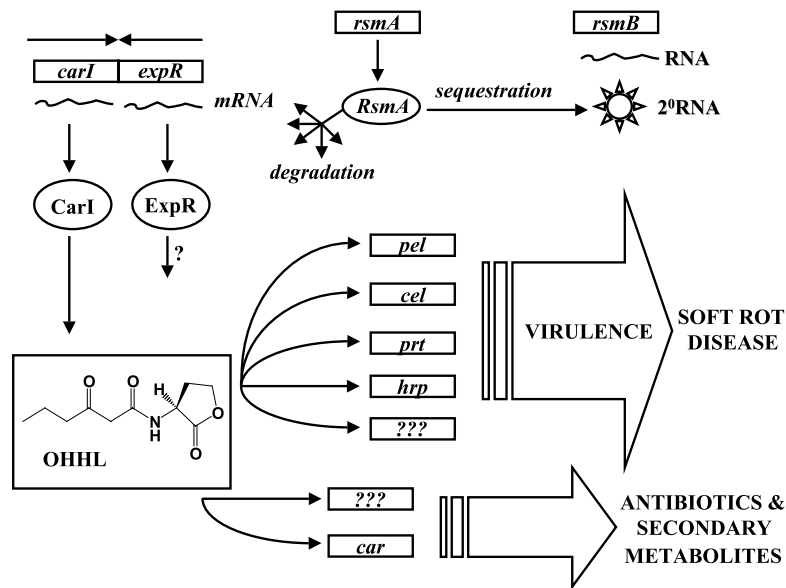

Fig. 2 Summary of quorum-sensing inputs to virulence and antibiotic regulation in *Ecc*. The *carI* gene encodes the OHHL synthase, and the signal molecule is involved in the regulation of multiple virulence factor genes, including pectinases (*pel*), cellulases (*cel*), proteases (*prt*), harpin (*hrp*), and other unknown factors (???). OHHL is also involved in the regulation of various secondary metabolites (???), including a carbapenem (*car*) antibiotic. (From Ref. [6].) The physiological role of ExpR is not clear (?). The Rsm system involves the RsmA protein and its ‘partner’ *rsmB* RNA. The *rsmB* RNA is thought to develop a secondary structure (2° RNA) and, in this format, sequesters the RsmA protein. Upregulation of *rsmA* (or downregulation of *rsmB*) leads to a stoichiometric imbalance such that excess RsmA protein can be targeted to degrade specific mRNA of the quorum sensing and virulence regulon. The figure does not include the wide range of other known regulators of virulence factor production in soft-rot *Erwinia* species. (From Refs. [4–10].)

the *carI* (also known as *expl* and *hslI*) gene.^[4,5,9] Induction of the exoenzymes (and therefore soft rotting) requires OHHL production, but connections between OHHL production and exoenzyme gene activation are not yet clear. The *carI* gene is convergently transcribed with *expR* (*rexR/eccR*), but although ExpR may play a repressive role in pectinase control for some strains, its physiological role is not proven (Fig. 2).

In *Echr*, the quorum-sensing system is slightly different because the *expl* gene encodes an enzyme responsible for 3-oxo-C6-HSL and C6-HSL production. As in *Ecc*, an *expR* gene, overlapping and transcribed convergently with *expl*, is present, but *expl* and *expR* mutants have no obvious defects in exoenzyme synthesis. Although the physiological function of the quorum-sensing system in *Echr* is not clear, it does interact with other regulators. For example, ExpR binds 5' of *pecS*, which encodes a global repressor, and *PecS* interacts with the *expl* promoter.

The Rsm Global Regulation System in *Ecc*

The *Ecc* quorum-sensing mechanisms act in concert with a complex network of global regulators. A key regulator is the Rsm system identified in elegant studies by Mukerjee

et al. (Ref. [14]; see Ref. [5] for review). *RsmA* mutants are hypervirulent and overproduce pectinases, cellulases, proteases, and harpin protein, which elicits the HR in ‘nonhost’ plants. *RsmA* is thought to bind RNA and act as a posttranscriptional regulator by reducing target mRNA stability (Fig. 2). In *Ecc*, *rsmB* enhances the expression of exoenzyme genes in a dose-dependent and plant extract-dependent fashion. *RsmB* exists both as a 479-base nucleotide transcript (*rsmB*) and as *rsmB'* — a processed 259-base nucleotide. High-copy *rsmB'* causes exoenzyme upregulation, probably through sequestration of *rsmA*. *RsmC* (HexY) represses expression of *rsmB*, while activating expression of *rsmA*. *RsmC* mutants are very pleiotropic and the mode of action of *rsmC* is not yet clear.

Other Regulatory Systems in Exoenzyme Production

A pectinolysis pathway repressor, KdgR, has been identified in *Echr* and multiple *Ecc* strains. KdgR represses the transcription of *rsmB* and several exoenzyme genes. KdgR binds to KdgR ‘boxes’ downstream of the *rsmB* transcriptional start site and 5' of some exoenzyme

genes. A homologue of KdgR (RexZ) is a positive regulator of exoenzyme synthesis in Ecc, although the mechanism of this activation is not understood.

Finally, in addition to the quorum-sensing system, the Rsm system, and the KdgR pectinolysis pathway repressor, several other regulatory genes that modulate exoenzyme biosynthesis in *Erwinia* have been identified (e.g., see Refs. [4,6–9] for reviews). However, it is still unclear as to what extent the various exoenzyme regulators act hierarchically, or within a complex neural network.

CONTROL/RESISTANCE

There are no effective chemical control methods available for soft-rot diseases. The opportunistic nature of *Erwinia* spp. infection and the key roles played by environmental conditions predisposing plants to disease mean that the best methods available for soft-rot control rely on good crop propagation and harvesting procedures (Fig. 1), coupled with adequate environmental storage conditions.^[1,2] Potato plants vary considerably in their susceptibility to *Erwinia* spp., and this has encouraged studies with somatic hybrids from stocks of wild potato species to generate soft-rot-resistant plants. Similarly, there has been interest in engineering transgenic plants expressing “plantibodies” or lysozyme.^[2] However, these studies have yet to yield a commercially viable disease-resistant potato.

Quorum Sensing as a Target for Pathogen Control

Mutants of Ecc that are defective in their quorum-sensing system show reduced virulence, confirming its phytopathological significance. Therefore disruption of the quorum-sensing system might enhance plant disease resistance. There are multiple targets for intervention (e.g., inhibiting *carI* homologue function, sequestering the N-AHL signal molecule, and molecular mimicry and competitive inhibition via furanone molecules).^[10] Transgenic plants that make an N-AHL mimic or an enzyme that degrades the signal have been made recently and shows some potential as a route toward soft-rot disease prevention.^[5,6,10]

CONCLUSION

We now have an extensive knowledge base on multiple aspects of the phytopathogenesis of soft-rot erwinias. However, the vast majority of our understanding of the

regulation of virulence factors in soft-rot diseases is derived from work in vitro or in laboratory culture.^[1,2,10,11] The current paucity of information on pathogen gene expression and corresponding product function, in planta, means that we have only a cursory view of the molecular bases of soft-rot pathogenesis. Nevertheless, imminent release of the full genomic sequences of Echr and Eca strains, plus advances in proteomic analysis of both genetically tractable species, will provide a platform for microarray technologies that could be used to investigate aspects of soft-rot pathogenesis from initial plant–pathogen interactions to full-blown rot. Such advances, coupled with the progress being made in transgenic approaches to intervention in the pathogen quorum-sensing system, may pave the way toward the eventual control of bacterial soft rot.

Bacterial Survival and Dissemination in Insects

Alexander H. Purcell

University of California, Berkeley, California, U.S.A.

INTRODUCTION

Most bacterial plant pathogens are spread from one plant to another by wind, rain, or human activities, but many of them infect plants only through the intervention of insect vectors. Non-vector insects may pick up microbial pathogens by feeding on infected plants and can retain large numbers of the microbes within their bodies, but only those insects that can transmit a pathogen or parasite to a host are vectors. The transmission process can be a simple mechanical transfer of a pathogen by an insect to a susceptible site on a plant. In these cases, insects are usually not the only means by which the pathogen can disperse and infect plants. At the other extreme, transmission can require a complex sequence of steps for the pathogen to circulate and multiply within specific locations before the vector can transmit the pathogen to a plant. Complex transmission processes confer considerable specificity as to which insects can serve as vectors.

PATHOGENS WITH NON-OBLIGATE VECTORS

Fireblight of apple, pear, and other pome fruits is an example of a disease where many kinds of insects can increase the spread of the causal bacterium (*Erwinia amylovora*) from plant to plant, but insects are not essential. For example, flower-visiting insects can transport *E. amylovora* to flowers and create tiny wounds that the bacterium can invade, but pruning tools and splashing rain are more important ways by which the bacterium spreads.^[1] Likewise, insects may be important in moving *E. carotovora* subsp. *carotovora* from potato cull piles into potato production fields, increasing the incidence of soft rot in the crop.^[2] Removal or burial of cull piles from field areas to deny insect access is an important disease control measure.

PATHOGENS WITH OBLIGATE VECTORS

Chewing Insects as Vectors

Bacterial wilt of cucurbits (caused by *Erwinia tracheiphila*) and Stewarts wilt of maize (caused by *Pantoea*

[*Erwinia*] *stewartii* subsp. *stewartii*) require chewing insect vectors to spread the causal bacteria from plant to plant. Cucumber beetles (family Chrysomelidae) that feed frequently on cucurbits are the most important vectors of *E. tracheiphila*. Flea beetles (Chrysomelidae, subfamily Alticinae) are the key vectors of the Stewarts wilt bacterium.^[3] Controlling the insect vectors is important for the management of both diseases. The beetle vectors of each of these pathogens harbor the bacteria within their guts during the winter and then establish new infections in plants the following growing season. The bacteria do not otherwise survive the winter in soil or plant debris. A winter cold severity index can predict the severity of Stewarts wilt, because cold temperatures lessen the survival of flea beetle vectors and disease severity depends on the number of independent bacterial infections per leaf, which originate in the margins of the small holes chewed by the flea beetle vectors. Not many details are known about how the beetle vectors transmit these two pathogens or why other, similar chewing insects cannot serve as vectors.

Sucking Insects as Vectors

Most insect vectors of plant pathogens are sucking insects that feed on plant sap or cell contents. Bacterial pathogens that are strict parasites of plant vascular systems (phloem or xylem) usually have specific sucking insect vectors. Pathogens with a high degree of vector specificity have only a single or few (but usually related) insects as vectors, although other insects may acquire but not transmit these pathogens from infected plants by feeding on infected tissues.

A major disadvantage of xylem or phloem sap as a primary food source is that it has low or unbalanced concentrations of nutrients.^[4,5] Consequently, all insects that feed on plant sap probably harbor one or more bacterial symbionts, housed inside the cells of specialized organs, that provide essential nutrients required for the host insect to develop and reproduce.^[4,5] The symbionts invade the developing eggs within the mother insect to ensure that all offspring have these essential bacteria.^[5] These codependent partnerships between insect and bacteria are ancient and may predispose plant sap-feeding

insects to be capable of supporting the multiplication and internal circulation of other bacteria within the host insect.

Noncirculative Transmission of Bacteria

The best known of the bacterial parasites of plants that are strictly limited to xylem is *Xylella fastidiosa*. This bacterium has a broad range of vectors, but they are all sucking insects that specialize on feeding on xylem sap.^[6] Vectors include spittlebugs (family Cercopidae) and leafhoppers (family Cicadellidae) in the subfamily Cicadellinae, which are commonly called sharpshooters. Clues as to how vectors transmit the bacteria are 1) that there is no delay between vector acquisition of the bacteria from infected plants and the vectors transmitting the bacterium to plants (called the latent period) and 2) that vectors stop transmitting after shedding their outer skin. These properties suggest that the vector transmits to plants bacteria that are attached to the lining of the mouth (the foregut, which is shed with molting of the outer skin), but the exact location in the foregut is still unclear.^[7] Bacteria can be seen attached to various parts of the vector foregut, where they experience flow velocities of more than 5 to 50 centimeters per second.

Circulative Transmission of Bacteria

Some insect vectors transmit bacterial parasites that are restricted to the plant's phloem cells. In contrast to the nutrient-dilute xylem sap, the food-conducting phloem contains sap that is high in sugars and other solutes. The lack of a rigid cell wall may be an advantage for phloem-inhabiting bacteria to counter the osmotic stresses of the high sugar environment of phloem sap, and the most commonly recognized bacterial parasites of phloem are Gram-positive bacteria (class Mollicutes) that lack a cell wall. The absence of a rigid cell wall also allows the small bacteria (0.2 to 0.5 microns wide, lengths variable to several microns) to deform and squeeze through the pores connecting phloem elements.

Two types of mollicutes are plant pathogens. Spiroplasmas are helical in shape, and phytoplasmas are spherical to filamentous in form (pleomorphic). To date, these mollicutes cannot be mechanically inoculated into plants, so vectors are essential for infection. Citrus stubborn disease and corn stunt are two important plant diseases caused by leafhopper-transmitted spiroplasmas. The number and diversity of phytoplasma diseases (at least 300) is much greater than that caused by spiroplasmas.

The mollicutes have a high degree of vector specificity because of the complex route within the vector that must be completed for transmission to occur. This requires

vector uptake of the mollicute by feeding in the phloem, passage of the mollicute through the vectors gut and its surrounding basement membrane, and multiplication in one or more sites or organs within the vectors body cavity (hemocoel), followed by movement to the interior of certain salivary gland cells and ejection into plant phloem in such a way as to establish a new mollicute population in the plant. All of these consecutive steps result in a latent period of many weeks until the vectors are able to first transmit. The principal mollicute vectors are leafhoppers, planthoppers, and psyllids. Spiroplasmas occur in great diversity in insects or nectar, but only a relative few are plant pathogens.

Grapevine yellows is the name of a complex of diseases with the same or very similar symptoms, but caused by a variety of phytoplasmas, each with different vectors.^[8] This complex provides an example of how different mollicute pathogens with specific vectors vary in how they spread and thus how they can be controlled. The flavescence dorée (FD) type of grapevine yellows is transmitted by a single leafhopper species (*Scaphoideus titanus*); the bois noir type is transmitted by a planthopper (*Hyalesthes obsoletus*). At least two other types of grapevine yellows caused by phytoplasmas are genetically unique from FD or bois noir and are presumed to be closely related to leafhopper-transmitted phytoplasmas. The FD phytoplasma can be transmitted to plant species other than grape, but the strong specificity of its vector for feeding and reproducing on grape limits the occurrence of FD in the field to grape. This vector feeding preference thus clearly target vineyards and wild grapes for controlling the vector with insecticides. In addition, eliminating FD-grapevines is an important part of control measures to reduce the percentage of remaining vectors that carry the FD phytoplasma. In contrast, the bois noir phytoplasma and its vector can be found in numerous weed and crop species in or near vineyards, complicating the control of the vector and making the elimination of plants harboring the phytoplasma very difficult.^[9]

The best known and most important example of a disease caused by phloem-limited bacteria that has a typical rigid cell wall is citrus greening disease.^[10] The milder, African version of greening disease is presumed to be caused by *Candidatus Liberobacter africanum* and the more severe Asian form (Huanglongbin) by *Candidatus Liberobacter asiaticum*. Each type of greening disease has its own species of psyllid (superfamily Psylloidea) vectors. Psyllid vectors begin to transmit the bacteria to plants after a latent period of many days to weeks, depending on temperature. This is presumably because the bacteria must pass through the vectors gut wall, multiply within the insects body cavity (hemocoel), and enter the salivary glands before they can be ejected out of the insect's body

into plants with saliva secreted by the insect during feeding. The occurrence of the psyllid vectors only on citrus may limit the greening bacterium to citrus.

VECTOR MOVEMENTS

The transmission efficiency of any vector species is only one factor in determining the effectiveness of that species in the spread of pathogens. Of equal importance are the vectors feeding preferences, population sizes, and movements. Vector species vary enormously in their capacity or inclination to disperse. Examples of long distance migrants are the beet leafhopper vector of *S. citri* and the aster leafhopper vector of aster yellows phytoplasma.^[11] Each of these leafhoppers can migrate many hundreds of kilometers during spring months to establish new vector populations that are more localized during summer. In contrast, the principal vectors of *X. fastidiosa* in California mainly disperse into vineyards that are only about 100 meters from their breeding habitats during the spring months that are critical for establishing chronic (permanent) infections that cause Pierce's disease of grapes.^[7,12]

CONCLUSION

The kinds of relationships that have evolved between insects, plant pathogenic bacteria, and plants are almost as diverse, but fortunately not as common, as insect relationships with nonpathogenic bacteria such as symbionts or gut-associated bacteria. All of the bacterial plant pathogens transmitted by obligate vectors persist in the vector, meaning that they can be transmitted for the lifetime of the vector (in the case of *X. fastidiosa*, for the length of a developmental stage). This increases the difficulty of using vector control to reduce the spread of these plant pathogens because infective vectors that survive long enough to disperse over long distances are still infective when they enter a crop field. In addition, the wide plant host ranges of many vector-borne bacterial pathogens means that sanitation by removing disease sources may have little effect on pathogen spread within a crop. As illustrated by two different pathogens of the grape yellows complex of phytoplasma diseases, what is effective for control of one disease may be ineffective for another. The specifics of pathogen, vector, and crop biology must be

understood to devise effective control strategies on a case-by-case basis.

Bacterial Survival and Dissemination in Natural Environments

Steven Lindow

University of California, Berkeley, California, U.S.A.

INTRODUCTION

A variety of different bacterial species attack all possible plant parts. The inoculum of such pathogens can survive in different ways, depending on the habitat in which infection occurs. Very often such inoculum comes from other plants, and can be removed from former hosts and arrive at new hosts in a variety of ways. The various survival methods exploited by plant pathogenic bacteria and the methods of inoculum dispersal will be explored, with an emphasis on those pathogens that attack above-ground plant parts.

SURVIVAL OF PLANT PATHOGENIC BACTERIA

Just as there are many different kinds of plant pathogenic bacteria attacking different plant parts, there are many different strategies for their survival during periods when either host plants are unavailable or environmental conditions required for infection are not conducive. Especially in the case of annual agricultural crop plants, pathogenic bacteria survive from one season to another on or within seed or propagative plant parts, such as tubers. Some pathogens also survive in or on living crop plants or weeds. For example, the fire blight pathogen *Erwinia amylovora* survives the winter in cankers in infected branches of pear and apple trees. Since survival in seed and planting material will be addressed in detail in another article, it will not be discussed here. Almost all bacterial plant pathogens can also survive in debris of infected plants,^[1] but because they are generally very poor saprophytes, this phase is unimportant in either maintaining or increasing pathogen abundance.^[1,2]

Many plant pathogens that attack foliar plant parts may exist in a “resident phase” on healthy shoots, buds, or roots.^[1–3] Termed epiphytes, such bacteria can colonize both susceptible host plants as well as nonhost plants. The resident phase of a crop pathogen on a weed species can be of consequence in the epidemiology of crop plants nearby. The significance of such epiphytic inoculum was first described for *Pseudomonas syringae* pv. *syringae*, which colonizes hairy vetch plants that survive winters under snow cover in the northern United States and can

subsequently be transferred to nearby bean crops in the spring.^[4] The epiphytic phase of many foliar plant pathogens has since been described on nonhost plants.^[1–6]

Because plant disease occurs only when suitable environmental conditions coincide with sufficient pathogen populations on a susceptible plant, the epiphytic phase is important in allowing the persistence of the pathogen on host plants during periods that are not conducive to infection. For example, inoculum of *P. syringae* pv. *syringae* on bean plants emerging from infested seed develops epiphytic populations on leaves.^[3,6] The epiphytic population can be redistributed across the susceptible plant parts, and more importantly, can persist for extended periods of time in the absence of disease. The population sizes of epiphytic bacteria can be very dynamic, with death of the epiphytes commonly occurring during periods of dry weather.^[5–7] The survival of epiphytes on leaves may be facilitated by the occurrence of at least some of the epiphytic cells in “protected locations” within leaves.^[5] Plant pathogens, unlike nonpathogens, may thus have some ability to escape stresses on plants. Such adaptations might, however, apply only to their colonization of susceptible plants, and may account for the fact that populations of plant pathogens are usually higher on host plants than on nonhost plants.^[5]

Additionally, physical stresses on the leaf may reduce the culturability of epiphytes without actually reducing their viability. Cells that enter a viable but nonculturable (VBNC) state are indistinguishable from dead cells by standard plate-count methods of estimating bacterial populations, but could still be available as a source of inoculum should conditions in which the cells are “revived” be encountered.^[8] The conditions, if any, under which epiphytes may become VBNC must be understood to better assess epiphytic populations as a means of cell survival on plants.

DISSEMINATION OF PLANT PATHOGENS FROM PLANTS

Bacterial cells can be removed from plants in at least two different ways. The most attention has been placed on rain as a vector to remove cells from leaves. Rain can wash off a substantial proportion (up to 50%) of bacteria from

leaves.^[9] However, a large variation in bacterial population sizes (although a little smaller overall) will remain among these leaves.^[6] In addition, the reductions in bacterial population that occur during some rain events^[4] are sometimes small compared to the magnitude of increases that occur following rain.^[6] The relatively small reductions in bacterial populations during rain may be due in part to their having become attached to the leaf surface.^[5] In addition, epiphytes that are dislodged during rain may reattach to other leaves before they are lost from the plant canopy. Some of the dislodged bacteria may instead become incorporated into small droplets of water that can be dispersed away from the original plant.^[10] Adjacent plants can recapture some of these aerosol droplets by impaction and sedimentation, thereby minimizing the loss of bacteria from plant canopies during rain.^[9-11]

Substantial numbers of epiphytic bacteria also leave the surface of plants in dry aerosol particles. A net upward flux of bacteria can occur above plant canopies, especially during mid-day when plants are dry and winds are at their maximum velocity.^[9,11] In fact, the upward flux of bacteria from dry plants is much greater than that from either wet plants or from bare soil.^[9,11] A net daily introduction to the atmosphere of about 5×10^6 particles bearing viable bacteria per square meter of plant canopy having large bacterial population sizes (approximately 10^6 cells/cm² of leaf) has been observed.^[11] This would represent an emigration of only about 0.0001% of the total epiphytic population each day.^[12] Only if a very high fraction of the emigrant cells lost viability or entered a VBNC state soon after removal from a plant canopy (and hence would not be counted) could the number of total emigrant cells approach even a few percent of the total bacterial population. Thus, emigration away from a plant appears to contribute little to the reduction of epiphytic bacterial populations on a plant. Other modes of removing of bacteria from plant surfaces, such as by insect vectoring or the physical abrasion of adjacent leaves, are probably inconsequential, but have not been quantified.

CAPTURE OF BACTERIA BY PLANTS

Immigration of bacteria to a leaf is coupled strongly with their emigration from another leaf, since most dispersed bacteria have foliar plant parts as their primary habitat. Immigration to a leaf may occur via several modes of transportation.

1. Many bacteria can be transported to a leaf via rain splash. Although rain deposits a large percentage of the bacteria released from plants onto the soil,^[4,9,11] substantial lateral movement of bacteria can occur during rain.^[10] In general, however, more bacteria are

removed from a plant with an established epiphytic microflora than are deposited from adjacent plants by rain.^[6,9]

2. A number of phytopathogenic bacteria can be transferred from infected plants to healthy plants by insect vectors. There are some bacterial pathogens that are disseminated due to intimate associations with an insect vector,^[10,12] but most bacteria are transmitted via insects that are contaminated during their foraging or nectar collecting activities.^[12] This latter phenomenon is most well studied in the case of the vectoring of *E. amylovora* from cankers or infected flowers of pear and apple trees to newly opened flowers where infection can occur.^[12] Although such transmission has been demonstrated, the number of cells that are transferred is unknown, but probably very small.
3. Plant pathogenic bacteria might be disseminated with infected leaves that become airborne. Since bacteria can survive for long periods of time on dead and/or dry infected leaves,^[1,7] it is likely that as leaf fragments are dispersed in the wind, cells of phytopathogens could be transferred to healthy leaves.^[10] Again, the prevalence of such a phenomenon and the number of bacteria that might potentially be transferred to new leaves by this process are unknown.
4. Many bacterial plant pathogens produce exopolysaccharides (slime). This slime can be quite substantial in the case of certain pathogens such as *E. amylovora*, whose slimes can produce strands that are as much as 10 cm long in infected tissues. It has been speculated that these strands could fragment as they dry and disperse as small particles to other plants.^[2]
5. The deposition of dry aerosol particles has been rather well studied. On average, about 10^3 particles containing viable bacteria were deposited in an area the size of a bean leaf (approximately 100 cm²) each day.^[2,6,9,11] Although many aerosol droplets are scrubbed from the air by other raindrops, some can disperse beyond the immediate site of release and potentially can be deposited onto other plants.^[2,6,9,11] The contribution of immigrant wet aerosol particles to the size of bacterial populations has not been well studied, but is probably less than that of dry particles.

CONCLUSION

Since the survival and dispersal of bacterial plant pathogens often involve relatively small numbers of cells, studying these processes has been hampered over the years due to inadequate methods to quantify and differentiate the cells. New molecular tools can detect very small numbers of cells, as well as cells that are not culturable, and should

prove very useful in epidemiological studies of plant pathogens. As in the case of human bacterial pathogens that commonly exist in a VBNC state but are still infectious, there may be many plant pathogens that survive undetected in an unculturable state. It will be important to examine this possibility with the new tools available. Although the epiphytic phase has become well accepted as a reservoir for plant pathogens, their endophytic phase in host and nonhost plants is largely unexplored and may also constitute a sizable reservoir of inoculum.

Bacterial Survival and Dissemination in Seeds and Planting Material

Diane A. Cuppels

Southern Crop Protection and Food Research Centre, London, Canada

INTRODUCTION

Many phytopathogenic bacteria can survive in or on the seed or other propagules of their host plant. Contaminated or infected planting material provides a major inoculum source for many of the economically important diseases of plants caused by bacteria. Often there are no visible symptoms or signs of infection on the seed. Provided that the association is not completely superficial, most bacteria survive as long as their host seeds. Seed and vegetatively propagated planting material frequently are produced at locations distant from their intended market; thus a pathogen may be introduced to regions where it had not previously existed. Because of this practice, we now have a worldwide distribution of diseases such as fire blight of apple and pear, bacterial wilt of potato and tomato, and bacterial leaf blight of rice. Also, diseases such as bacterial spot of tomato, whose causal agent does not overwinter in northern climates, may be reintroduced each year on seed or transplants that were produced in warmer regions. Preventing the spread of disease through seed and other propagating material requires the institution of quarantines and routine inspections, the use of disease-free production areas, and the eradication or reduction of seedborne inoculum.

BACTERIAL INVASION AND SURVIVAL ON PROPAGATIVE MATERIAL

Seed may carry phytopathogenic bacteria internally or externally. If the bacteria establish themselves within the seed, then it is considered an infection; if they are found adhering to the seed surface or mixed with seed, then it is considered an infestation or contamination. Bacteria usually are located in the seed coat, and are rarely seen in the generative tissues. Successful establishment of the pathogen in or on seed depends upon a number of factors, including the host and pathogen genotypes and environmental conditions. Invasion may occur by a number of different routes and a pathogen may not be limited to just one mode of entry.^[1] Only a few bacterial pathogens actually are known to be transmitted to the developing

seed through the tissues of the mother plant. Generally, these bacteria are vascular pathogens such as the cabbage black rot pathogen *Xanthomonas campestris* pv. *campestris*. Systemic infection of seed occurs through flower or fruit stalks (pedicels) or through ovule (seed) stalks (funiculi). If the black rot pathogen is present at flowering, then it may enter the xylem of the pedicels and travel through the suture vein of pods to the funiculi. The tomato pathogen *Clavibacter michiganensis* subsp. *michiganensis* invades the placenta via the calyx and then progresses to the funiculi. Some bacteria gain entry through lesions on fruit or pods (a dry and dehiscent form of fruit). *Pseudomonas syringae* pv. *phaseolicola* penetrates the pod wall of bean directly, whereas *Xanthomonas axonopodis* pv. *phaseoli* enters via the dorsal suture of pea pods. The hilum—which is the scar produced when the seed detaches from the funiculus—is a natural entry point for bacteria. Bacteria such as *X. axonopodis* pv. *phaseoli* also can penetrate seed through the micropyle (an integumentary opening of the ovule). Bacteria also may reside on the seed surface. Seed coats may be covered with cracks that provide an ideal sanctuary for bacteria, as do the substomatal chambers of the seed coat. Infected plant parts or small clumps of infested soil may become mixed with the seed during the harvesting, extraction, or cleaning of seed. Bacteria can be found loosely associated with individual seeds, bonded to the seed coat or lodged among the seed hairs. The rough and textured surface characteristic of some seed coats facilitates adherence by bacteria (Fig. 1). Although invaded seed typically do not show signs of infection, symptoms do occasionally develop and include watersoaking around the hilum, yellow or brown discolorations, wrinkling, and buttery deposits.

As mentioned, most phytopathogenic bacteria will remain viable as long as their host seed.^[2] The seed moisture content typically is low; thus the bacteria are in a state of dormancy. The bacterial speck pathogen *Pseudomonas syringae* pv. *tomato* has been recovered from twenty-year-old tomato seed, whereas *X. axonopodis* pv. *phaseoli* can survive on bean seed for at least 15 years. However, studies with the bean pathogens *P. syringae* pv. *phaseolicola* and *X. axonopodis* pv. *phaseoli* showed that bacterial populations will decline as their time in storage

Fig. 1 The effect of seed extraction and treatment on the seed coat surface of tomato seeds. (A) Fuzzy, untreated seed; (B) hydrochloric acid-treated seed; and (C) chlorine-treated seed. (View this art in color at www.dekker.com.)

increases. If the moisture content and temperature of the host seed are lowered, bacterial longevity will increase. Bacteria that are more deeply situated in seed tissue are better protected than those on the surface and thus have a better chance of survival. Many plant-associated bacteria produce exopolysaccharides that may shield them from desiccation and other harsh environmental conditions. The persistence of phytopathogenic bacteria on seed also is strongly influenced by the presence or absence of other microorganisms.

Phytopathogenic bacteria can be carried on vegetatively propagated planting material such as cuttings, grafts, transplants, tubers, rhizomes, corms, and bulbs. Frequently, these infections are latent with the host showing no visible signs of disease. The bacterial population associated with a latent infection is usually small and thus can be difficult to detect. The situation is particularly serious in nurseries of perennial crops such as grapevines and trees. If the nursery soil becomes infested with the crown gall pathogen *Agrobacterium tumefaciens* (see the article titled “[Crown Gall](#)” by T. Burr), it will very quickly spread among the young plants, which will often show no signs of disease until after they have been planted in destination vineyards or orchards. Likewise, symptomless greenhouse-grown tomato transplants often can be an inoculum source for diseases such as bacterial speck and bacterial canker on field tomatoes.^[3]

DISEASE TRANSMISSION THROUGH PROPAGATIVE MATERIAL

Although many phytopathogenic bacteria can infect or infest seed, systemic infection of young seedlings through infected seed does not occur frequently; nonsystemic transmission resulting in postemergence symptoms is more common.^[1] Again, vascular pathogens such as *X.*

campestris pv. *campestris* are most likely to be transmitted systemically. Many host and environmental factors influence pathogen movement from seed. High humidity and free moisture are required for primary cotyledon infection. Symptoms include leaf and stem spots, wilting, root rots, and blights. Initially, diseases caused by seed-borne pathogens may develop slowly. However, once established, pathogens can spread very quickly, particularly if the seedlings are grown in high density in transplant greenhouses or nurseries (Fig. 2). The clipping practices sometimes used to prepare a uniform and vigorous shipment of transplants will enhance pathogen transmission throughout the nursery. One contaminated seed in 10,000 may be enough to cause an epidemic and economic loss, depending upon the pathogen, host, and environmental conditions.

Fig. 2 Six-week-old tomato seedlings heavily infected with the bacterial spot pathogen *Xanthomonas vesicatoria*. These seedlings were grown in high density (288-well plug trays) in a tomato and pepper transplant greenhouse. (View this art in color at www.dekker.com.)

PREVENTION OF BACTERIAL DISSEMINATION ON PROPAGATIVE MATERIAL

Bacterial diseases carried on seed or vegetatively-propagated planting material are best controlled by an integrated approach, employing exclusion through quarantine measures, disease-free areas for production, resistant cultivars (if available), treatment to reduce bacterial contamination and routine seed health testing or certification. Most countries have plant quarantine laws and regulations based on the International Plant Protection Convention of the Food and Agriculture Organization (FAO) of the United Nations. The European and Mediterranean Plant Protection Organization (EPPO) has published two quarantine lists: A1 gives the quarantine pests not present in the area (includes 13 bacteria) and A2 records the quarantine pests present but officially controlled and not widely distributed (includes 21 bacteria).^[4] A list of regulated plant pests of concern in the United States is maintained by the U.S. Department of Agriculture Animal and Plant Health Inspection Service.^[5] In addition, the North American Plant Protection Organization (NAPPO) operates the Phytosanitary Alert System,^[6] which provides up-to-date information on pests of importance in North America.

Commonly used seed treatments to reduce or eliminate pathogenic bacteria include thermotherapy (hot water, dry heat, or aerated steam), acid dips, antibiotic soaks, and chlorination.^[2] Although there are several biological control-based products that target bacterial pathogens, most are not intended for seed application. The antibiotic most commonly used on seed is streptomycin (see the article titled “[Chemical Methods](#)” by D. Hopkins); unfortunately, it may have a phytotoxic effect depending upon the dosage and duration of treatment and the sensitivity of the host. Phytotoxicity can be a problem with other treatments as well; the dose that is effective at eradicating the pathogen may also reduce seed viability. Many of the sites on the seed-coat surface where bacteria might adhere are eliminated by acid or chlorine treatment (Fig. 1). For transplants or other vegetatively-propagated planting material, copper-based bactericide sprays are often used to reduce pathogen populations. Soil in tree nurseries may be disinfested using steam or solarization. Several biopesticides employing *Agrobacterium radiobacter* strains antagonistic to the crown gall pathogen are now commercially available for ornamental, fruit, and nut stock protection.^[7]

For seed health tests to be an effective tool in certification and quarantine programs, they must reliably detect and estimate the pathogen population present on seed.^[8] The inoculum threshold for a pathogen, defined as

the amount of seed infection/infestation that causes disease under field conditions and results in economic loss, is based upon such a test; unfortunately, inoculum thresholds have not been adequately established for many of the bacterial pathogens. Determining inoculum thresholds is a difficult process that is affected by numerous environmental and cultural practices. Because they can spread very quickly through a production field, bacteria usually have low inoculum thresholds.^[9] For crops started from transplants grown in high density, seed often is given a zero-tolerance level for bacterial contamination. One uncomplicated but relatively insensitive assay for bacteria on seed is the growing-on test, in which a large sample of seed is planted and the resulting seedlings are scored for the presence of disease. Other simple detection methods include direct planting on semi-selective media and host plant inoculation.^[2] Serological and nucleic acid-based methods have been developed for the identification of a number of bacterial plant pathogens.^[10] Although more expensive, these methods offer greater sensitivity and a shorter response time than conventional assays.

CONCLUSION

Although the International Seed Testing Association (ISTA) provides a standardized set of seed health testing methods,^[11] they are not universally accepted by the various agencies and laboratories responsible for screening seed. The situation is further complicated by the emergence of several new molecular detection methods. These new methods have great potential but they must first be evaluated and validated before they can be incorporated into any standardized set of recommendations. Such tests should be helpful not only in assessing the emerging new seed treatment technologies but also in determining inoculum thresholds and realistic tolerance levels for seed-borne diseases—one of the greatest challenges facing the seed industry today.

Bacterial Survival Strategies

Cindy E. Morris

Christine M. H. Riffaud

Institut National de la Recherche Agronomique, Montfavet, France

INTRODUCTION

Bacteria in the phyllosphere have significant roles in plant health and general plant biology, in the hygienic and market qualities of food products derived from plants, in global climatological processes, and in the recycling of elements. The phyllosphere is a heterogeneous environment that can engender stress due to UV radiation, temperature fluctuation, dehydration, osmotic and pH conditions, oxidizing agents and other antimicrobial compounds, starvation, predation, and parasites. Examples are given of the two types of strategies—stress avoidance and resistance to unavoidable stress—exploited by phyllosphere bacteria to survive in this habitat.

IMPORTANCE OF THE PHYLLOSHERE AS A HABITAT FOR BACTERIA

Plants inhabit over 90% of the 1.5×10^8 km² of terrestrial surface of the Earth, providing over 10⁸ km² of potential habitat for microorganisms in the form of leaf surfaces.^[1] Bacteria are generally the most abundant of the microbes associated with leaves. In temperate climates, bacteria attain population densities of at least 10⁴ cells cm⁻². It has been estimated that the global population size of bacteria in the phyllosphere is roughly 10²⁴ to 10²⁶.^[1] Many of the bacteria in the phyllosphere have well-described roles in environmental processes or in the biology of the host plant. These include plant pathogens; animal pathogens; ice nucleation-active bacteria; bacteria that produce active phytohormones, allergens, toxins, and aromatic compounds; and antagonists of plant pathogens. Phyllosphere bacteria probably also participate in global cycling of carbon and nitrogen and in the fossilization of plant material. Hence, leaves harbor bacteria that have significant roles in plant health and general plant biology, in the hygienic and market qualities of food products derived from plants, in global climatological processes, and in the recycling of elements. The importance and diversity of the roles of bacteria associated with leaves has prompted interest in understanding how bacteria persist and proliferate in this habitat.

STRATEGIES FOR ADAPTING TO STRESS

In light of the physical, chemical, and biological nature of the phyllosphere habitat,^[2] bacteria are likely to experience stresses due to UV radiation, temperature, dehydration, osmotic and pH conditions, oxidizing agents and other antimicrobial compounds, starvation, predation, and parasites. These stresses are accentuated by the ever-changing nature of the phyllosphere as leaves senesce, die, and fall to the ground thereby delivering the residing bacteria to a markedly different habitat. Furthermore, because leaves are generally in open environments, phyllosphere bacteria can be taken up by insects, become airborne or waterborne, be transported to inert surfaces, etc. The diversity of situations in which phyllosphere bacteria may be found suggests that they are capable of surviving an even broader range of conditions than those encountered in the phyllosphere.

For bacteria in general, much is known about the physiological alterations induced by the different sources of stress indicated above. Oxidizing agents, for example, damage membranes. Other antimicrobial compounds may cause denaturation of proteins. Temperature extremes can cause membranes to move out of the liquid crystalline phase essential for them to function correctly. UV radiation leads to DNA damage. Dehydration also can lead to DNA damage, protein denaturation, and an increase in the melting point of cell membranes, causing transition to the gel phase. However, bacteria in the phyllosphere as well as in other environments experience multiple forms of stress simultaneously. For example, drying of water on leaf surfaces would be accompanied by changes in osmotic conditions, pH, and availability of nutrient sources as solubilized nutrients become more and more concentrated and eventually crystallize. Furthermore, bacteria can turn on a common regulatory network in response to many different environmental stresses. Hence, in summarizing the mechanisms exploited by bacteria to survive stress, it is difficult to distinguish mechanisms that are specific to a given stress.

Mechanisms for survival exploited by bacteria in general can be grouped into categories describing the processes by which these mechanisms are expressed as listed in [Table 1](#). These processes reflect two overall

Table 1 Bacterial survival strategies

Type of stress response	Examples for bacteria in general	Examples for phyllosphere bacteria
Stress avoidance		
<i>Environmental modification by bacteria.</i>	Production of wetting agents, of mucus, and of enzymes and toxins causing tissue leakage or degradation of the colonized substrate leading to increased availability or improved sequestering of water and nutrients; induction of root nodules by rhizobacteria; induction of opine synthesis by genetic transformation of plant hosts by <i>Agrobacterium</i> spp.; production of exopolymeric-enrobed biofilms.	Production of biosurfactants, exopolysaccharides, pectolytic enzymes, toxins, phytohormones, and biofilms by a wide range of phyllosphere bacteria.
<i>Dispersal into heterogeneous niches.</i>	Coexistence of planktonic and attached components of bacterial populations in aquatic and other liquid-saturated systems.	Dissemination of bacteria by air, water, and insects; colonization of seeds; colonization of a range of leaf features (trichomes, grooves over veins, substomatal cavities, etc.); formation of biofilms.
<i>Coexistence with other microbial species having active stress-resistance mechanisms leading to protection of coinhabitants.</i>	Coexistence with bacteria producing extracellular enzymes capable of degrading or inactivating antibiotics or liberating nutrient sources.	Not yet described for phyllosphere bacteria.
Responses to unavoidable stress		
<i>Constitutive factors.</i>	Resistance to certain antimicrobial compounds and to certain parameters of the physical-chemical environment (temperature, salt, etc.).	Expression of the <i>uvrB</i> gene, involved in UV resistance in <i>Xanthomonas campestris</i> .
<i>Factors induced by physical-chemical environmental conditions.</i>	Enhanced resistance to acids and active oxygen species in response to low doses of these compounds; production of small cells with reduced metabolic activity in response to starvation; generalized stress resistance induced during starvation; changes in lipid content of membranes during nutrient stress leading to reduced permeability to antimicrobials; changes in cell hydrophobicity during nutritional stress leading to changes in capacity to adhere to surfaces; viable-but-not-culturable states; formation of biofilms.	Resistance to certain heavy metals that are constituents of pesticides (Cu^{2+} , etc.); osmoadaptation in <i>Erwinia carotovora</i> ; production of siderophores (an iron chelator) induced under conditions of iron limitation in <i>Pseudomonas</i> spp. and <i>Erwinia</i> spp.; induction of a viable-but-not-culturable state.
<i>Population density-dependent factors.</i>	Factors triggered by the process of quorum sensing.	Antibiosis against congenics induced at high population densities in <i>Erwinia carotovora</i> .
<i>Life cycle-dependent processes.</i>	Formation of spores; production of dense cell masses and microcysts during the life cycle of fruiting myxobacteria; production of flagellated swarming cells during the life cycle of sheathed bacteria; expression of metabolic processes specifically during stationary phase.	Formation of spores by <i>Bacillus</i> spp.
<i>Rapid generation of genetic diversity.</i>	Phase variation; appearance of hypermutators; horizontal gene transfer.	Development of antibiotic-resistant populations (<i>Erwinia</i> spp., <i>Pseudomonas</i> spp., <i>Xanthomonas</i> spp.) due to horizontal transfer of antibiotic resistance genes associated with conjugative plasmids and transposable elements.

strategies: 1) stress avoidance and 2) resistance of unavoidable stresses. Stress avoidance includes the following: 1) modification of environmental conditions by bacteria to ensure availability of water and nutrients; 2) dispersal of cells (passive or active) into a wide range of environmental conditions; and 3) coexistence with other microorganisms who ensure protection of coinhabitants by producing extracellular enzymes that inactivate antibiotics or liberate nutrient sources, for example. The following are responses to unavoidable stress: 1) constitutive expression of genes involved in resistance to antimicrobial compounds, to salt, to extremes of temperature, etc.; 2) induction of a wide range of traits by conditions of the physical or chemical environment; 3) expression of traits triggered by the population density-dependent process of quorum sensing; 4) development of cell types and cell states characteristic of specific phases of the life cycle (spores, swarming cells, etc.); and 5) rapid generation of genetic diversity. These processes are not exclusive. For example, environmental conditions may be involved in induction of different life-cycle phases such as spore production or swarming. Furthermore, population density may foster the environmental conditions leading to induction of these life-cycle phases via depletion of nutrients or accumulation of metabolites. Ultimately, the specific molecular signals triggering the processes listed above may be very limited in number and may explain why certain regulatory pathways are common to a wide range of stress responses.^[3]

Phyllosphere bacteria express many of the processes listed in Table 1. In some cases, the contribution of these processes to enhanced survival in the face of stress has been demonstrated, and in other cases data are not yet available to support their importance in survival. The production of toxins, phytohormones, and pectolytic enzymes by phyllosphere bacteria contributes to modification of local environmental conditions by causing the release of nutrients for bacterial growth.^[4] Bacterial-produced biosurfactants can enhance availability of free water on leaf surfaces. Numerous phyllosphere bacteria produce exopolysaccharides that protect them from desiccation. These exopolysaccharides might also contribute to the formation of microbial biofilms, ubiquitous on leaf surfaces.^[5] Biofilms, in general, foster the establishment of environmental conditions protecting bacteria from the harshness of the external environment. Although this may also be true for biofilms on leaf surfaces, it is not yet clear which, if any, phyllosphere bacteria gain significant survival advantages by residing in biofilms. Biofilms are also one of the diverse niches inhabited by phyllosphere bacteria. Other niches include the varied features of the leaf surface such as trichomes, grooves over leaf veins, hydathodes, and substomatal cavities. Viable phyllosphere bacteria have also been

found in irrigation waters, in lakes and rivers, and in air and have been associated with debris in soil. Widespread dissemination into a diversity of niches may lead bacteria to new, favorable sites for colonization, thereby maximizing survival for the population as a whole. It has been suggested that the ice nuclei produced by *Pseudomonas* spp., *Xanthomonas* spp., and *Erwinia* spp. play this very role. In the form of aerosols, these bacteria are transported from leaf surfaces into the stratosphere. By initiating ice formation and subsequent rainfall while in the stratosphere, ice nucleation-active bacteria ensure dissemination to new plants.^[6]

Few of the bacterial traits associated with survival on leaf surfaces are clearly expressed constitutively. Expression of the *uvrB* gene, involved in UV resistance in *Xanthomonas campestris*, is one example.^[7] On the other hand, the conditions of the physical-chemical environment can induce expression of a wide range of traits. Osmoadaptation, the production of iron scavengers (siderophores) and resistance to certain heavy metals that are constituents of pesticides can be induced by conditions of the chemical environment and are probably important in survival on leaf surfaces. Production of small cells manifesting generalized stress resistance is a common response of bacteria to oligotrophic conditions. Reduction in cell size has been observed for bacteria growing on leaf surfaces, but cell size per se is not clearly related to enhanced forms of resistance in these bacteria. Temperature influences the expression of numerous genes of certain plant pathogenic bacteria.^[8] To date, the genes described are involved in pathogenicity to plants. Although the expression of these genes confer enhanced fitness, the significance of temperature induction is not clear. In other bacteria, adaptation to cold or heat shock involves modification of membrane fluidity, nucleic acid conformation, protein flexibility, and repair of misfolded proteins.^[3] The temperature adaptations of plant pathogenic bacteria described above may be involved in reducing the cost of pathogenicity-related processes for the bacterial population.

Population density-dependent responses to stress are generally mediated by quorum sensing, enabling bacteria to mount a unified response that is advantageous to the population as a whole in the face of stress. Quorum-sensing operons appear to be typically found in bacterial species from fluctuating, heterogeneous environments and absent in bacteria from stable environments.^[9] Numerous species of phyllosphere bacteria produce pheromones that, upon accumulation, induce expression of, for example, pectolytic activity or production of bacteriocins active against congeners. Dense cell masses such as those found in biofilms or in substomatal cavities would be ideal sites for accumulation of bacterial pheromones. However, expression of quorum-sensing operons on leaves has not yet been demonstrated.

Little is known about the role of life cycle–dependent processes in the survival of bacteria on leaf surfaces and in particular those that occur during stationary phase. Another important survival strategy for a broad spectrum of bacteria involves increasing the genetic diversity of populations. One form of this strategy, referred to as phase variation, results in reversible, high-frequency genetic variation of specific contingency loci. Another common process of generating genetic diversity involves hypermutation. Among phyllosphere bacteria, hypermutation has not been described. Phase variation, observed in terms of changes in lipopolysaccharides or in pathogenicity to plants, is well-known for certain phyllosphere species, but its contribution to survival has not been elucidated. On the other hand, phyllosphere bacteria are known to benefit from gene acquisition via horizontal transfer. The development of antibiotic resistant populations of *Erwinia* spp., *Pseudomonas* spp., and *Xanthomonas* spp. occurs due to transfer of antibiotic resistance genes associated with conjugative plasmids and transposable elements.

CONCLUSION

Bacteria associated with leaves exploit numerous processes to survive the environmental stresses experienced in this habitat. The diversity of these processes reflects the complex ecology of bacteria associated with living tissue in open, heterogeneous environments. However, it is likely that these processes are aimed at a few primordial goals: protecting membranes, protein, and DNA from irreversible damage and preventing cells from being killed by predators and phages. The next frontier in the study of survival strategies of phyllosphere bacteria will be the search for the molecular mechanisms involved in protecting the vital functions of bacterial cells common to these different processes.

Bacteria-Plant Host Specificity Determinants

Alan Vivian

The University of the West of England, Bristol, U.K.

INTRODUCTION

Our understanding of the bacteria-plant interaction has grown rapidly since the pioneering work of H. H. Flor set the theoretical basis for its investigation. It seems that bacterial pathogens possess a battery of virulence (*vir*) determinants, some of which the plant has learned to recognize and respond strongly to (these are the products of avirulence (*avr*) genes)—a fact that has enabled their isolation. These virulence proteins are delivered inside plant cells by the type III secretion system—some likely to the nucleus and others to the cytosol—where they function as effectors to promote disease. If specific molecular recognition occurs, then programmed plant cell death—called the hypersensitive response (HR)—results in a localized necrotic lesion around the point of bacterial invasion that limits and curtails the infection.

PATHOGEN RACE DEFINITION

Races have been most clearly identified among pathogenic varieties (pathovars, pv.) of *Pseudomonas syringae* and *Xanthomonas campestris* by their interaction with host plants that have been bred to produce cultivated varieties (cultivar, cv.) differing in their resistance to the pathogen. Races are defined by their differential interactions with a set of cultivars for a given pathovar-host system. The most clearly defined race structures among pathogenic bacteria are those for *P. syringae* pv. *pisi* and pea (*Pisum sativum*), *P. syringae* pv. *phaseolicola* and bean (*Phaseolus* spp.), and for *P. syringae* pv. *glycinea* and soybean (*Glycine max*).^[1] The basis of this race structure is matching resistance (*R*) genes in the host and *avr* genes in the bacterium, represented in the classical quadratic check (Fig. 1). The *R*-gene content of cultivars has been determined by genetic crossing and testing of the reactions of the progeny to bacterial attack, and many *avr* genes have been cloned and their specificity confirmed. An example (Table 1) postulates a system based on five established gene pairs, together with a possible sixth pair.^[1] Races may not be genetically homogeneous: In *P. syringae* pv. *pisi*, races 3 and 4 include strains from two distinct genomic groups that appear to have evolved separately to parasitize pea.^[4]

RESISTANCE GENES AND THE HYPERSENSITIVE RESPONSE

R genes have been isolated from a number of plant species, including tomato (*Lycopersicon esculentum*) and *Arabidopsis thaliana*. They appear to encode protein receptors for signal transduction pathways that potentiate plant responses to bacterial attack. Six major classes of *R* proteins have been identified.^[5] These proteins often possess a leucine-rich repeat (LRR) domain, potentially involved in recognition, and domains for signal relay. A useful concept has been the guard hypothesis,^[6] which now appears to provide a molecular basis to account for how at least three pairs of *Avr/R* proteins interact.^[7] It proposes that an *R* protein acts as a guard to monitor the status of a go-between protein that interacts directly with both the *R* and *Avr* proteins. When the *Avr* protein binds to or modifies (for example, by peptide cleavage) the go-between protein, this somehow activates the *R* protein to initiate the phenotypic expression of a HR. The release of putative antimicrobial factors, which are thought to include active oxygen species and phytoalexins, limits the spread of the pathogen.

BACTERIAL TYPE III SECRETION OF EFFECTOR PROTEINS

Some bacterial pathogens of both animal and plant cells possess a specialized protein secretion system, called the type III system.^[8] In plant pathogens, the genes that are conserved from animal type III systems are designated *hrc*, and the remaining genes *hrp* (HR and pathogenicity). The system was originally recognized through the creation of bacterial mutations that resulted in the concomitant loss of the ability to cause disease in the usual host and induce a HR in a nonhost, such as tobacco (*Nicotiana tabacum*).^[9] Although direct observation of the delivery of proteins into plant cells via a type III system has not been reported, there is considerable circumstantial evidence to support this conclusion.^[10] Secretion of effector proteins is dependent on a functional type III system, and expression of the *hrc/hrp* genes is regulated coordinately with the secretion system. Some effector genes have been shown to have multiple functions. An example

Fig. 1 Gene-for-gene: The quadratic check. A simplified comparison of two races of *Pseudomonas syringae* pv. *pisi* inoculated on two pea cultivars. Specificity resides in the matching of the avirulence gene (here designated A2) with the resistance gene R2, resulting in resistance to disease. All other combinations of races and cultivars result in susceptibility and a disease outcome. (View this art in color at www.dekker.com.)

is *avrPphF*, a plasmidborne gene from the bean pathogen *P. syringae* pv. *phaseolicola*, which confers cultivar-specificity through its avirulence activity in bean cultivars carrying the *R1* resistance gene. In native races a second effector gene, *avrPphC*, blocks the virulence function of *avrPphF*. The presence of *avrPphF* in a nonpathogenic, plasmid-cured derivative of the bean pathogen lacking a number of effector genes, including *avrPphC*, confers an enhanced HR in cv. Canadian Wonder and virulence in cv. Tendergreen. This example and the failure to detect loss of virulence when individual effector genes are inactivated suggest that virulence is redundantly encoded and requires the concerted actions of a number of effector proteins.^[5]

Structurally, effector genes are of two kinds: those that resemble *avrBs3* (see Fig. 2) and those that do not. The *avrBs3*-like gene products appear to be targeted to the plant cell nucleus, where it is suggested they act (directly or indirectly) as transcription factors modulating host gene expression. Thus far, the *avrBs3*-like genes have only been found in *Xanthomonas* spp. and *Ralstonia solanacearum*. The specificity of these effector proteins appears to lie in centrally located repeats of 34 amino acids, which vary in number and precise sequence.^[10] The remaining group of *avr* genes (which are predominantly from *P. syringae*) are often clustered on the bacterial genome, tend to have low G+C content of their coding sequences, and appear to code for peptides that are hydrophilic and range

in size from 18 to 100 kiloDaltons (kDa). All known *P. syringae* effector genes are associated with Hrp box promoters, whose consensus sequence is 5'-GGAACC-NA-N₁₃₋₁₄-CCACNNA-3' and which lies upstream of the coding region of the gene. This appears to ensure that their regulation is coordinated with the expression of the type III secretion system. Other systems of regulation are found in other plant pathogenic bacteria.^[5,10]

CONCLUSION

Disease and host specificity are intimately linked and involve an interaction between two living organisms, in this case a bacterium and a plant host. A feature of such encounters is the concept of matching genes, the products of which interact in a very precise way. Pathogenic bacteria deliver effector proteins—the products of *avr* and *vir* genes—into plant cells via a specialized type III protein secretion system (in phytopathogens, called Hrp). Resistance genes in plants specify a surveillance system (which detects avirulence gene products), and the phenotypic outcome is seen as a HR in the plant. Disease occurs in the presence of appropriate virulence gene products, delivered by the Hrp machinery but conditioned on the absence of a functional avirulence gene product or resistance protein that can recognize the virulence protein.^[11,12]

The cloning of *R* genes has opened the potential for engineering disease resistance in susceptible plants. But the redundancy seen in bacterial effectors suggests that reliance on individual engineered *R* genes will be as unreliable as their introduction through classical breeding.^[12] Thus, it is vitally important to study genomes of both bacterium and plant to set all aspects of the bacterium–plant interaction in their true context. This in turn should enable us to gain insights into the global control mechanisms that drive pathogen evolution. The phenomenon of PAIs, which contain many effector genes, should be investigated together with their accompanying bacteriophage and insertion sequence neighbors to discover how their horizontal spread may be mediated and controlled.

INTRODUCTION

The poinsettia, *Euphorbia pulcherrima* Wild, a member of the family Euphorbiaceae, is native to southern Mexico and Central America. Poinsettia was first introduced into the United States from Mexico and named after Joel Robert Poinsett in 1825 while he served as the first U.S. Ambassador to Mexico. Unlike today's commercial cultivars, wild poinsettias grow into straight and tall shrubs (Fig. 1) that often can reach heights of ca. 3.5 m. In the early 1900s, most poinsettia plants were sold as fresh cut flowers, notably by the Ecke family in Southern California.^[1] Through selection and breeding by growers and scientists, many cultivars with desirable genetic traits such as stiff stems, shorter stature, larger bracts, new colors, and lasting indoor life span have been developed in the United States and Europe. The modern era of poinsettia culture characterized by free-branching, multi-flowered plants began in 1967, when a self-branching cultivar called Annette Hegg Red was introduced by Thormod Hegg of Lier, Norway.^[2] These free-branching cultivars comprise the majority of commercial cultivars propagated today. In the United States poinsettias are one of the most economically important floricultural crops with sales of approximately \$325 million per year. Over 65 million plants were sold in the United States alone in 2000.^[3] The branching factor has been a mystery to horticulturists for decades. Recent evidence has indicated that poinsettia branching is caused by a graft-transmissible biological agent, called a phytoplasma.

CHARACTERISTICS OF FREE-BRANCHING CULTIVARS

Two morphotypes of poinsettia cultivars are grown commercially^[4] (Fig. 2). One is a restricted-branching

morphotype characterized by strong apical dominance and its ability to produce one to three axillary shoots and "flowers" (actually modified leaves called bracts) through an excision of the apical bud (pinch) (Fig. 3). The other is a free-branching morphotype (e.g., the Hegg cultivars) characterized by weak apical dominance and its ability to produce five to eight axillary shoots and multiflowers after the removal of the apical bud (Fig. 3). Many free-branching cultivars were developed after Annette Hegg Red was introduced. In contrast to the restricted-branching morphotype, which has typical oak-leaf morphology, leaves of the free-branching cultivars are less lobed (Fig. 4).

DETECTION OF A PHYTOPLASMA RESPONSIBLE FOR THE INDUCTION OF FREE-BRANCHING IN POINSETTIA CULTIVARS

The presence of an endophytic biological agent was suspected when horticulturists noticed that the ability of free-branching cultivars to induce axillary shoots and to produce a desirable multiflowered canopy was lost after poinsettias were regenerated via true seed or had been subjected to heat treatment, meristem tissue culture, or somatic embryogenic tissue culture. The latter processes are traditionally used to eliminate potential pathogens including poinsettia mosaic virus (PnMV).^[5] The free-branching ability, however, could be restored when the treated plants were approach-grafted (both plants being grafted retain shoot and root systems) onto free-branching stock plants.^[4] Early attempts to identify the biological agent responsible for the induction of free-branching failed.^[6] The role of PnMV in the induction of free-branching was excluded because this virus was

Fig. 1 Wild poinsettia native to Costa Rica. Courtesy of William Villalobos Muller of the University of Costa Rica. (View this art in color at www.dekker.com.)

commonly found in both restricted and free-branching cultivars.

A phytoplasmal etiology of the free-branching morphotype was suspected because excessive branching of host plants is one of the characteristic symptoms induced

Fig. 3 Branching types: restricted- (left) and free-branching (right). (View this art in color at www.dekker.com.)

by phytoplasmal infections. In collaboration with Ball FloraPlant scientists (West Chicago, IL), Lee et al.^[7,8] conducted polymerase chain reaction (PCR) assays using phytoplasma-specific primers (developed based on phytoplasma 16S rRNA gene sequences) and detected the presence of phytoplasmas in all of the 20 commercial free-branching poinsettia cultivars, including a number of Annette Hegg cultivars.^[9] No phytoplasma was detected in restricted-branching cultivars or in poinsettia plants regenerated by somatic embryogenesis. Proof of a phytoplasmal etiology was achieved by a transmission study using dodder (*Cuscuta* spp.) as a bridge, connecting vascular tissues between poinsettia and periwinkle (*Catharanthus roseus*).^[8] Phytoplasmas from a free-branching poinsettia plant were transmitted, via dodder, into healthy periwinkle, a common host of phytoplasmas

Fig. 4 Leaf morphology of restricted- (right) and free-branching (left) poinsettias. (View this art in color at www.dekker.com.)

and a nonhost of PnMV. After 3–6 months, the periwinkle plants developed bushy growth characteristic of phytoplasmal infection, and phytoplasmas were detected via PCR. ELISA tests indicated that no detectable PnMV was present in these plants. Phytoplasmas from symptomatic periwinkle plants were then transmitted, via dodder, into PnMV-free restricted-branching poinsettias, which developed a free-branching form after 3–4 months. The phytoplasma, not the virus, was subsequently detected in the free-branching poinsettia. The presence of the same phytoplasma in all the tested plants was confirmed by restriction fragment length polymorphism (RFLP) analysis of the PCR-amplified phytoplasma 16S rDNA amplicons.^[8,10] Lee et al.^[8] concluded that the induction of free-branching in poinsettias was attributed to phytoplasmal infection. A tetracycline-mediated suppression study by Bradel et al.^[11] further supports the conclusion that phytoplasma is responsible for the induction of free-branching. Tetracycline treatment, which inhibited the growth of phytoplasma, caused remission of the free-branching phenotype in poinsettia cultivars.

MOLECULAR IDENTIFICATION OF PHYTOPLASMAS ASSOCIATED WITH FREE-BRANCHING POINSETTIAS

Phytoplasmas are cell wall-free plant pathogenic bacteria that cannot be cultured in cell-free media. They are phloem inhabitants. Phytoplasmal diseases are transmitted by insect vectors (primarily by leafhoppers) and grafting. Because of the inability to culture these organisms in the laboratory, the detection and identification of phytoplasmas associated with plants or insects can only be made by molecular-based procedures. Currently, phytoplasmas are detected by PCR using phytoplasma-specific primers based on 16S rRNA gene sequences. These primers are generic to phytoplasmas and can be used to detect a broad spectrum of known phytoplasma strains. RFLP analysis of PCR-amplified phytoplasma 16S rDNA sequences is used to differentiate and identify the phytoplasmas detected. It appears that phytoplasmas are present in relatively low concentrations. Often, a nested PCR assay, which requires two consecutive PCR amplifications using two different sets of generic primers, is used to detect the associated phytoplasmas from infected poinsettia tissues. The phytoplasma strain belonging to the peach X-disease phytoplasma group (16SrIII), subgroup H, was predominantly associated with all 20 free-branching poinsettia cultivars tested.^[8] Other phytoplasmas (related to members of the aster yellows phytoplasma group and to other members of

the peach X-disease group) occasionally co-infect with the major poinsettia phytoplasma.^[7,8,12]

CONCLUSION

Free-branching poinsettia cultivars that produce numerous axillary shoots are essential for propagating desirable multiflowered potted poinsettias. Many free-branching cultivars (>100) have been developed and propagated commercially in the last decade. There is evidence that the branching ability of the majority of commercial free-branching cultivars of today is not due to genetic traits selected through breeding but by the grafting of new seedlings (phytoplasma-free) to a free-branching rootstock that contains phytoplasma. The presence of phytoplasma causes the induction of free-branching in these infected poinsettias. Under proper management, the associated phytoplasma appears to do little harm to poinsettias but modifies their normal growth habits resulting in desirable branching patterns suitable for production of multiflowered potted poinsettias. This is the first reported example of a pathogenic phytoplasma as the causal agent of a desirable and economically important trait.

Biennial Crops

I. L. Goldman

University of Wisconsin, Madison, Wisconsin, U.S.A.

INTRODUCTION

The common environmental signals that regulate the processes of vegetative and reproductive growth cycles in plants are temperature and photoperiod. Mechanisms have evolved in many plants to synchronize reproductive development with a particular environmental cue or cues, thereby leading to improved reproductive success and, therefore, improved fitness. One such adaptation is spring flowering preceded by a season of vegetative growth. Plants with this particular adaptation, or those that require two seasons in order to complete reproductive growth, may be considered biennials.

WHAT ARE BIENNIALS?

Biennials typically consist of a root system, a compressed stem, and a rosette of leaves close to the soil surface following the first season of growth. Biennials generally do not become woody during the second season of growth; however, there are many examples in which root or hypocotyl tissues undergo secondary growth.^[1] In such cases, the swollen tissues resulting from this may be used as a crop, such as the hypocotyl and root that are present in the carrot or beet. In biennial plants, food reserves that accumulate in root tissues during the first season of growth are used to produce reproductive structures during the second season of growth. In addition, hormones such as gibberellins and cytokinins are produced in root meristems and transported via the xylem to the shoot, where cell growth and development will occur during this second season of growth.^[1]

A number of important crop plants are considered biennial, including cabbage and related *Brassica* crops, sugar beet, Swiss chard, table beet and related *Chenopodiaceae* crops, carrot and related *Apiaceae* crops, onion and related *Alliaceae* crops, and a wide variety of ornamental species. Although many of these plants are considered biennial from a horticultural standpoint, few of them are “true” biennials and instead represent genetic modifications for maximization of vegetative growth prior to reproduction. Certain grains that are sown in the fall and flower in the spring, such as winter wheat and rye, may be considered winter annuals. These plants possess a

facultative vernalization requirement. Therefore, they will flower more quickly with a cold treatment, but the cold treatment is not required for flowering. Biennials, by contrast, are obligate from a vernalization point of view.

Many cultivated vegetable crops are considered biennials. They are typically consumed after the first season of growth, and thus we usually consider them to be biennials that are cultivated as annuals. This article is largely focused on biennial vegetable crops. Cultivars of most winter annual grain crops are pure lines, and methods of breeding pure lines are discussed in another section. The term “vegetable” is problematic from a scientific point of view because it lacks biological meaning and instead refers only to a cultural phenomenon. Still, there are two important criteria for vegetables that allow us to place these crops into a particular category for classification: They are immature plant parts that are of high moisture content. For those vegetable crops that are biennials, the immature plant parts that form during the first season of growth are those that are desired. In fact, it is likely that these organs are the products of artificial selection for enhanced biomass in annual plants.

VEGETABLE CROPS

In the case of many vegetable crops, the large vegetative structures desired by human cultures necessitated longer periods of vegetative growth. Selection under the process of domestication likely modified the life cycle of such crops from annuals to biennials, thereby increasing the vegetative growth period and providing a substantial reserve for subsequent reproductive growth. Three common examples of this are cabbage, carrot, and beet, all of which were likely domesticated from annual ancestors and modified by European agriculturists to adhere to a biennial life cycle.

Cabbage (*Brassica oleracea*) was selected from leafy forms of *Brassica* into a headed form in order to allow for a storage form of this edible plant. Likely, this transition took place as the leafy forms moved from a warm to a cool climate during cabbage domestication. As selection for a headed form was carried out, the life cycle was lengthened to allow for maximal biomass production during the first season of growth. Thus, an annual ancestor was converted

into a biennial derivative by enhancing vegetative growth at the expense of reproductive growth. The late-summer flowering associated with the annual forms became early-spring flowering in the biennial forms, thereby allowing for only vegetative tissues to be produced during the first season of growth.

A similar evolutionary history took place for the biennial vegetable crops carrot (*Daucus carota*) and table beet (*Beta vulgaris*).^[2,3] Annual forms with small root systems were gradually converted to biennial forms as selection was practiced for enhanced root and hypocotyl growth. In the climates where this was practiced, the swollen-rooted forms could be stored for a longer period of time, thereby providing a substantial food source during the winter months.

Table beet has been cultivated for millennia as both a root and a leafy vegetable crop. Its origins trace back to the development of a leafy vegetable by the Romans from wild species of *Beta* growing in the Mediterranean region (reviewed in Ref. 3). As the crop moved into Northern Europe, the growing season was shorter and the winter was longer. This may have caused selection pressure to favor a transition toward a biennial life cycle by selecting a swollen hypocotyl or root as an overwintering propagule. Some have suggested that swollen roots may have been selected from leafy beets cultivated in Assyrian, Greek, and Roman gardens.^[4,5]

BIOLOGY OF BIENNIALISM

The term “vernalization” comes from the Latin “ver-nus,” which means spring. Vernalization is an adaptation to environments in which it is advantageous to flower in the spring, following a season of vegetative growth. Vernalization accelerates the ability of a plant to flower but is not responsible for the formation of flower primordia or for the breaking of dormancy.^[6] Vernalization can be obligate or facultative in plants; however, in biennial plants the vernalization requirement is obligate.^[6]

Typically, temperatures of 1–7°C are required for adequate vernalization, although many exceptions exist.^[6] The duration of the vernalization requirement varies; however, two to three months is average. For many crops, flowering may occur with a minimal period of vernalization, but maximal flowering may require additional time. Some species are sensitive to fluctuations in temperature during vernalization, while others are not.^[7] A vernalization treatment can be rendered ineffective with a heat treatment, and this process is known as devernalization. Although seed can be vernalized in some species, most plants must reach a more advanced developmental stage in order to be vernalized. The shoot apex is the most likely spot for the perception of vernalization.^[6,8] It is also

possible for vegetative tissues to be vernalized and ultimately regenerated into whole plants.

The hormone gibberellic acid (GA) is often implicated in regulating the flowering response in plants. Applications of GA to biennial plants can cause flowering in the absence of vernalization, and this may allow for seed production in a biennial plant during a single growing season. Michaels and Amasino^[9] found that the late-flowering vernalization-responsive *Arabidopsis* mutants respond normally to cold treatment in the presence of the *gal-3* allele, which is a deletion in kaurene synthase, a gene involved in GA biosynthesis. This finding suggests GA may not be involved directly in the vernalization pathway. Interestingly, the vernalization requirement of a biennial plant can be eliminated by grafting. Non-cold-treated plants can be grafted to cold-treated biennial plants and induced to flower.^[8] Lang suggested the possible presence of a vernalization hormone (vernalinalin) that might be produced constitutively in plants that do not require vernalization as well as in those that do; however, such a hormone has never been identified.

Bolting, or the appearance of a flower stalk during the vegetative growth stage, is detrimental to crop production. Bolting is a fairly common occurrence in early-planted biennial crops such as carrot and table beet, particularly in temperate environments. Significant yield losses can be expected when bolting has occurred, and selection against bolting is routinely practiced. Jaggard et al.^[10] reported that 50% of field-grown sugar beet plants bolted when temperatures were less than 12°C for 60 days during vegetative growth. Vernalization typically takes place for 12 weeks during the standard breeding cycle, during which time temperatures are maintained at approximately 2–5°C.

Although seemingly complex from a physiological point of view, biennialism is often controlled by relatively few loci. Both dominant and recessive alleles have been identified that control the biennial versus annual habit. *Hydrangea niger* has a single dominant allele conditioning biennialism, while sugar beet has a recessive allele, *b*, conditioning the biennial habit.^[11] Recent work by Michaels and Amasino^[12] points toward major regulatory genes controlling the response to vernalization and the transition from vegetative to reproductive growth in biennial plants, which is consistent with the finding of a relatively simple genetic control of biennialism.

CONCLUSION

Much of their recent molecular work has been conducted with *Arabidopsis*, a model plant that has shed much light on the biology of biennialism. *Arabidopsis* plants flower in response to long days and vernalization. Many

researchers use a rapid-cycling summer-annual ecotype of *Arabidopsis* in their genetic studies. However, many ecotypes of *Arabidopsis* are extremely late flowering unless vernalized, and thus they behave as winter annuals. Two loci, *frigida* and *flowering locus C* (FLC), are responsible for the vernalization-responsive late-flowering habit of these winter-annual ecotypes. The vernalization requirement for late-flowering ecotypes is created when the floral inhibitor FLC is up-regulated. After a cold treatment, FLC transcripts are down-regulated and remain low for the remainder of the plant's life cycle, and it is during this phase that flowering occurs.^[12] Interaction and expression of these genes may be responsible for conditioning the biennial habit, and it will be interesting to determine whether biennialism is conditioned by these genes in other species.

INTRODUCTION: MINING MOLECULAR SEQUENCE DATA

DNA sequences diverge over time because of the gradual accumulation of mutational differences. Mutations erode DNA coding information, and if sufficient time has elapsed since the separation of lineages, it may be difficult to discern any historical similarity between two DNA sequences that once shared a common ancestor. The bioinformatician is presented with DNA sequences, protein sequences, or derivative data such as DNA hybridization signals associated with microarrays. A major challenge is to detect regions of similarity between different DNA sequences (or surrogate measures) to test the inferences of a common history. A common origin implies a shared function, or a related function, and this provides important clues in the assignment of a preliminary function to raw sequence data from a new source. A second major challenge is the management and curation of the vast stores of new data originating from the genomics enterprise. A variety of computational tools are available to organize and retrieve useful results from these vast databases. Genomics data are maintained in a number of publicly available databases. Perhaps the most important of these is the NCBI database, which can be accessed via the World Wide Web (<http://www.ncbi.nlm.nih.gov>) and provides a number of data analysis tools.

Bioinformatics combines computer science, genetics, and statistics to meet the challenge of mining useful information from the vast stores of new molecular sequence data. In this article we will touch on a few of the issues that confront bioinformaticians with a specific focus on DNA sequence data.

Several computer scripting or programming languages are used to handle DNA and protein sequence data. Perl and Python scripting are both commonly used; example code from Bioperl is available at <http://bioperl.org/> and for Biopython at <http://biopython.org/>. Many tools that simulate DNA sequence evolution are written in C or C++. Dr. Richard Hudson and his colleagues have made source code to simulation-related tools available at <http://home.uchicago.edu/~rhudson1/source.html> and <http://molpopgen.org/>.

ANALYTICAL METHODS: THE CHALLENGE OF SEQUENCE ALIGNMENT

The proper alignment of molecular sequence data is fundamental to many aspects of bioinformatics. The raw data are usually strings of DNA, RNA, or protein sequences for a particular gene or protein drawn from a set of organisms. These data may also take the form of a position of a fragment on a gel (e.g., RFLPs or microsatellites) where identity in the location in the gel is assumed to imply identity in the underlying DNA or protein state. In what follows, we will restrict our discussion to DNA sequence data for simplicity. We use the term “string of nucleotides” to refer to the DNA sequence for a gene obtained from a particular organism (or a particular copy of a multigene family from within a genome). Thus, S_1 refers to the string from source 1, and S_n refers to the string from source n . The first analytical task is to align the strings of nucleotides (S_1, S_2, \dots, S_n) to minimize the number of nucleotide differences across the set $\{S\}$. This involves finding the minimum of a weighted function of the number of indel (insertion/deletion) events and nucleotide site differences over the set. The weights are assigned based on some prior assumptions about the likelihood of indels versus nucleotide site differences (Fig. 1). The final alignment is assumed to be the “best” representation of the number of mutational events that occurred over the evolutionary time spanned by the set $\{S\}$. We denote the aligned set as $\{A\}$. More sophisticated alignment algorithms use a tree-fitting iteration to generate a best alignment by simultaneously estimating the phylogeny and alignment (e.g., Clustal W). Various alignment algorithms are readily available from a wide variety of DNA sequence analysis packages.

When the sequences in $\{S\}$ are so diverged that it is difficult to obtain an alignment from DNA sequences, a translation into the derived amino acid sequence is useful. Protein change occurs at a slower rate than DNA sequence change, and alignment of a protein sequence may be relatively straightforward even when the underlying DNA sequences are highly diverged.

It should be clear from this limited discussion that the alignment step is a crucial operation, and all subsequent

Fig. 1 A nucleotide sequence alignment with two indels. Alternative alignments could include a single indel but would require a nucleotide substitution.

calculations (e.g., distance measures, see below) depend on the accuracy of this operation. An operation that assumes a very high penalty (weight) for indels will force a larger number of nucleotide site differences on the alignment; conversely, assuming a very low penalty for indels will force a large number of small indels at the expense of nucleotide site differences (Fig. 1). These distortions will affect all subsequent inferences based on the sequence data. Indels are much more common in noncoding regions. When they occur in coding sequence, they often involve nucleotide triplets and preserve the gene's reading frame (Fig. 2). As indels become superimposed on one another during the course of evolution (this is especially common in noncoding sequence), it is increasingly difficult to determine the boundaries of individual indel events. As a consequence, it is usually not possible to count the number of indels that separate two sequences, and because the process of insertion/deletion is not stochastically regular, it is also not feasible to construct mathematical models of the process to provide a basis for estimation of the number of events. One practical way out of this dilemma is to select a set $\{S\}$ where the time of separation between each S_i ($i = 1, 2, \dots, n$) is sufficiently small so that at most one indel event will

have occurred in a region. It is then possible to count the number of events across the set $\{S\}$.

ESTIMATION OF DISTANCE METRICS

Once an alignment is obtained, various calculations can be made on the aligned set $\{A\}$. One of the most common and useful calculations is to estimate the evolutionary distance between a pair of sequences (see Ref. 1 for a detailed discussion of distance metrics). The simplest distance measure is the percent divergence between two sequences, where divergence is measured as nucleotide site differences and indels are omitted from the calculation. This is a satisfactory measure for sequences that have been separated for a "sufficiently brief" period of evolutionary time. In operational terms, "sufficiently brief" means that the likelihood of two mutations hitting the same site is small enough to be neglected. Over longer periods of time, the likelihood of two or more hits at a site cannot be neglected, so a model of the substitution process must be introduced. Mathematical models permit estimation of the total number of events both observed and unobserved.

A number of mathematical models of nucleotide substitution have been introduced over the years. They all have the following fundamental assumptions in common: 1) The probability of a substitution event per site is assumed to be small so that multiple events per site have close to a zero probability over small intervals of time; 2) statistical independence of mutational events over time and over sites is assumed; and 3) an assumption must be made about the equilibrium frequency of nucleotides in the sequence (usually a uniform frequency of 25% per

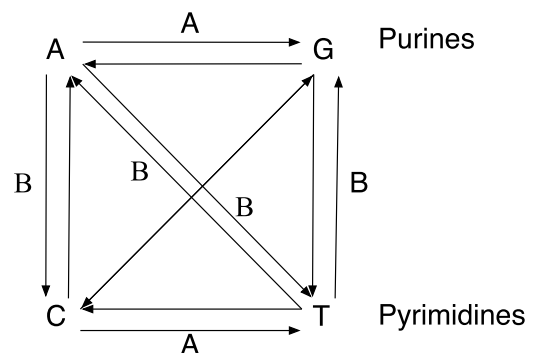

Fig. 3 Under the simplest (one-parameter) model of nucleotide substitution, the rate of change between any pair of nucleotides is equivalent. Under the two-parameter model (pictured here), the rate of transitions (A) may differ from the rate of transversions (B).

nucleotide type is assumed [$A = 0.25$, $T = 0.25$, $G = 0.25$, $C = 0.25$]). The simplest model of nucleotide change assumes that all possible nucleotide interchanges occur with an identical probability,^[2] which requires that only a single mutation parameter be estimated.

Other progressively more complex models are also available. For example, a slightly more complex model posits two mutation parameters—one for the probability of transition mutations and one for the probability of transversion mutations (a transition is an interchange of a purine for another purine or a pyrimidine for another pyrimidine and a transversion is a purine to pyrimidine interchange or the reverse) (Fig. 3). There are now computer programs available that allow researchers to choose the model of DNA substitution that best fits their data.^[3,4] A number of programs implement various distance calculations from aligned sequence sets; among the best known is the PHYLIP package,^[5] at <http://evolution.genetics.washington.edu/phylip.html>. The PHYLIP Web page provides links to many other computer programs useful for the study of sequence evolution.

At its simplest, the distance between two sequences (1 and 2), denoted $D_{1,2}$, is a function of the mutation rate μ and the time ($2t$) since the two sequences separated from a common ancestor (the factor 2 occurs because both sequences trace back t time units to their common ancestor). It follows that $D_{1,2}$ is approximately equal to $2\mu t$. This simple relation is very useful in many rough calculations such as obtaining time estimates based on a molecular clock assumption.

Molecular Clock Analyses: As noted previously, the time between separation of lineages can be estimated if mutation rates are constant per site per unit time and if no other forces intervene to alter the rate of accumulation of mutational change between molecules that trace back to a single common ancestor. The most likely force to affect the accumulation of nucleotide change is natural selection. Natural selection acts as a kind of editor of the sequence messages transmitted through time (see article on [population genetics](#)). Mutations that arise and are deleterious to function are edited out by selection because their carriers are less likely to survive and reproduce. Hence, it is important to attempt to use sequence regions that are less likely to be perceived by selection for clock calculations (see forthcoming section on partitions of DNA sequence data).

Another likely cause of rate variation is variation in generation time. Recall that we assumed that μ is constant per unit time. Our conventional measurement of time is in years (celestial time), but the more natural measure of time among organisms is in terms of generations. It seems likely that μ is closely correlated with replication cycles that in turn depend on generation time.

We must therefore regard molecular clock calculations as rough approximations.

INFERRING HISTORY: THE PROBLEM OF ESTIMATING PHYLOGENETIC TREES

The sequence alignment also provides the starting point for estimating a phylogeny. We will not delve into the technical details of phylogeny estimation, but rather give a brief outline of the major methods in common use (the interested reader is referred to Ref. 1 or Ref. 6 and the PHYLIP documentation (cited previously) for a detailed discussion of this topic). All methods assume that the elements of $\{A\}$ are connected through a dichotomous branching tree. The problem is to deduce the branching network from $\{A\}$ subject to some constraint or optimality criterion. There are three different approaches to tree estimation in common use: 1) parsimony; 2) maximum likelihood; and 3) distance-based methods.

Parsimony attempts to minimize the number of site changes over the tree (“character state changes” in the jargon of systematics). Thus, the parsimony optimality criterion is minimum evolution or minimum number of character state changes. Well-developed algorithms exist for parsimony calculations, and tree estimation is relatively fast for large data sets. This method tends to be the choice of workers in systematics because it conforms to a philosophy that emphasizes the importance of calculating phylogenetic trees from ancestrally derived characters. Parsimony does have at least two drawbacks. First, it does not provide a unique tree. Frequently a number of trees will give the same minimum number of character state changes (i.e., a number of trees may satisfy the optimality criterion). This is not a particularly important drawback as it is a simple consequence of the fact that the parsimony optimality criterion is based on a discrete measure (number of site or character state changes) rather than a continuous measure (as is the case with maximum likelihood and distance-based approaches discussed below). Second, parsimony can be biased when evolutionary rates differ substantially over the tree. This bias is manifested by a tendency for long edges (rapidly evolving branches) to be joined together when in fact they should join other branches on the tree. This is a more significant concern in view of the fact that rate variation appears to be common over long evolutionary distances.

Maximum likelihood is a statistically derived method that depends on a mathematical model of the nucleotide substitution process (analogous to the distance estimation models introduced above). This method has the virtue that the machinery of statistical hypothesis testing can be

implemented to discriminate among candidate trees. It also provides a direct statement about the uncertainty associated with any tree in terms of the variances of branch length estimates. Finally, assuming that the model is appropriate, maximum likelihood takes proper account of rate variation. It is possible to test the fit of various models to data (as discussed above); so, model validation is a feature of the method. Maximum likelihood has the serious drawback that it requires large amounts of computer time for moderate data sets (20–30 sequences), and larger data sets cannot be analyzed in reasonable lengths of time. Several maximum likelihood programs are available over the World Wide Web for tree estimation, and faster versions are under development (see the PHYLIP Web site).

Distance-based methods, as the name implies, begin by estimating a matrix of distances from $\{A\}$ (denoted $D_{i,j}$) using the estimation methods introduced in the section on evolutionary distances. The optimality criterion seeks to minimize the total distance over the tree. A number of different algorithms have been introduced to estimate a tree from the $[D_{i,j}]$ or from some transformation of the $[D_{i,j}]$ that attempts to adjust for variation in evolutionary rates. Distance-based methods are computationally fast and can be very useful for data exploration. In the case of both parsimony and distance methods, it is easy to use resampling methods (such as the bootstrap) to evaluate the statistical support for a particular tree. Because the various estimation methods differ in assumptions and methodologies, many workers view consistency among methods as an indication that a particular phylogeny is robust to these variations.

A phylogenetic tree is the fundamental starting point for much analytical work in genomics because it provides our best estimate of the pattern of historical relationships among a set of sequences and hence among the set of organisms that donated those sequences. A wide variety of questions are addressed by using the phylogeny as an organizing framework. To illustrate this point, we mention a few important problems that rest on a phylogenetic analysis.

1. For many purposes, it is useful to deduce the pattern of duplication among members of a multigene family. This is accomplished by estimating a gene family phylogeny.
2. An important question is whether the pattern of transposon evolution is consistent with vertical transmission (and hence consistent with a phylogenetic tree).
3. Phylogenetic analysis allows us to ask which partitions of sequence along a chromosome are allelic and share a common history of transmission (inconsistent combinations of mutations that distinguish alleles

might indicate intralocus recombination in the gene phylogeny).

4. It is often desirable to map other molecular or phenotypic changes on a tree to determine their time of origin and the temporal order in which major evolutionary events occurred.

ANALYSIS OF SEQUENCE DATA: PARTITIONS OF DATA SETS

It is often informative to divide $\{S\}$ into various subsets that reflect natural partitions of the data. A natural partition might be untranslated regions and exons; a further partition could be 5' untranslated regions, introns, exons, and 3' untranslated regions. In addition, exon regions can be further partitioned into codons, and codons can be partitioned into synonymous versus replacement sites. Finally, synonymous sites can be partitioned into twofold, fourfold, and sixfold degenerate sites based on codon degeneracy patterns. All the calculations introduced above can be performed on various partitions of the data.

One partition that is especially informative is the partition of exon regions into replacement sites (sites where a substitution induces an amino acid change) and synonymous sites (sites where a substitution does not induce an amino acid change). Because synonymous changes do not change the protein, they are thought to be approximately neutral to natural selection. Let us denote D_s as the distance estimated from the synonymous partition of $\{A\}$ and D_n as the distance estimated from the replacement partition of $\{A\}$. Then, the ratio D_s / D_n measures the average strength of selective constraint on amino acid change as compared to synonymous change. The ratio is one when replacement sites change with the same frequency as synonymous sites. Typically this ratio is observed to be approximately 10, indicating a tenfold selective retardation in protein change relative to the assumed mutational input. (This follows because if synonymous changes are neutral, then D_s approximates $2t\mu$ and $2t$ cancels in the ratio.) It is possible to plot this ratio on branches of a phylogenetic tree to search for indications of acceleration or retardation of protein evolution on particular branches of the tree. A plot of this kind allows the detection of regions of the tree where evolutionary patterns have shifted. A ratio of one or greater indicates an acceleration of protein evolution, which may be an indicator of an adaptive shift. For example, Jia et al.^[7] have used this approach to identify regions of accelerated protein evolution for the Myb family of plant transcription factors. A D_s / D_n ratio of one or greater in population data can also indicate a balanced polymorphism as is evidently the case with the major histocompatibility polymorphism of humans.

A different partition is a moving average of the D_s / D_n ratio across the sequence graphed as a function of a sliding window. For example, a window of 100 nucleotides may be chosen, and the averages of D_n and D_s are calculated for this window beginning with nucleotide 1 to 100 in the sequence. The window is then moved one nucleotide to the right (2 to 101), and the averages are recalculated and so forth until the end of the sequence is reached. Large changes in the plots may indicate regions of the sequence that are subject to differing evolutionary forces.

Bioinformatics is a relatively new and rapidly evolving area of research, but there are several excellent books that provide either a detailed introduction to the field^[8–11] or a more in-depth exploration of particular problems.^[12]

CONCLUSIONS

The mining and analysis of genomics data is still in an early phase. Only a few of the large number of potential applications have been touched on in this article. During the 1990s the technology for producing molecular sequence data grew faster than our ability to extract all useful knowledge from these data sets. Despite this lag, there has been a fortuitous correspondence between the growth of computational power and the growth of genomics databases. There is every reason to expect that the combination of increasing computational power, new analytical techniques, and the expansion of databases will lead to a continuing stream of new discoveries that will have a revolutionary impact on biology, medicine, agriculture, and environmental management during the next quarter century.

Biological Control in the Phyllosphere

John H. Andrews

University of Wisconsin, Madison, Wisconsin, U.S.A.

INTRODUCTION

This article addresses biological control of plant disease in the aerial environment—construed broadly to mean the use or facilitation of organisms, genes, or gene products to disfavor a pathogen. Thus, this discussion may be taken to include manipulation of a host plant genetically or in other ways, but the emphasis is on microorganisms (antagonists) that are introduced and interfere directly or indirectly with pathogens. This article considers 1) the status of biological control efforts in the phyllosphere; 2) key aspects of microbial and phyllosphere ecology that influence the likelihood of success; and 3) future prospects and directions.

THE STATUS OF PHYLLOSHERE BIOCONTROL

Since the first attempts to control disease by applying antagonists to forest soil in the 1920s, there have been hundreds if not thousands of reports on microbial antagonism and biocontrol. A tangible product of this wealth of information is eight biocontrol products currently registered in the United States for application in the phyllosphere (Table 1), and approximately twice this number for use in the rhizosphere or elsewhere.^[1] These are underestimates because they exclude agents not registered in the United States, or that are under development, or that are developed but not yet registered. Of the eight formulations, one product is based on the fungal hyperparasite *Ampelomyces quisqualis* (AQ-10 Biofungicide™); five are based on bacteria (three *Pseudomonas* spp. and two *Bacillus subtilis* strains); and two are chemicals (a protein and a benzothiadiazole) that activate host defenses. In addition to these commercial products, one benefit of decades of research on biocontrol has been the significantly increased understanding of microbial ecology and plant-microbe interactions.

PHYLLOSHERE ECOLOGY

The main science underpinning biological control is applied ecology pertaining to the antagonist, the pathogen, the plant, and the abiotic and biotic environment in which

the antagonist must function. It remains debatable whether the optimal approach is to use relevant ecological information in advance to screen candidates and then introduce what is supposedly the best among them to a particular crop ecosystem, or to operate empirically by using field releases at the outset to select the best among unscreened candidates. Ultimately, the success or failure of an introduced agent will depend on the existing ecological milieu.

Occasionally a biocontrol agent functions relatively inertly—essentially as a pesticide—in which case it is typically released in repeated, inundative fashion. The best example is *Bacillus thuringiensis* (BT) for insect control, although there are also some cases in plant pathology.^[2] Much more commonly, the antagonist must colonize the habitat to be effective, i.e., it must be ecologically competent. Colonization of an introduced biological control agent is analogous to successful invasion of a foreign species, and similar ecological concepts should apply.^[3–5] However, because invasiveness (or competitiveness) is a complex phenotype, it is likely that multiple genes and interactions will almost always be involved. This will make genetic analysis—a key step in one line of efforts to understand and improve biocontrol—complicated and refractory.

What are the determinants of competency in the phyllosphere and success as a control agent? Important intrinsic (biological) factors include the following: 1) pathogen vulnerability to attack at a weak link in its life cycle, typically at the preinfectious stage; 2) a mode of antagonism effective against, and preferably specific to, the pathogen in question; and 3) antagonist growth dynamics that are compatible with constraints imposed by the phyllosphere environment. Important extrinsic (commercial) factors include the type of crop and the economics of producing it; the economic significance of the pathogen; and the feasibility of mass culturing, formulating, and delivering the biocontrol agent to the site where it is needed. That there are not more registered biocontrol agents is testimony to the difficulty in meeting the dual stringent demands of biology and commerce. The need for biocontrol to be comparable to pesticides in being cheap, effective, reliable, and adaptable will be mitigated to the extent to which agriculture moves away from the profitability paradigm toward one based on sustainability.

Much has been written about the phyllosphere and, more broadly, the aerial environment of plants,^[6,7] including

Table 1 Commercial biocontrol products for phyllosphere diseases in the United States^{a,b}

Organism or agent	Category	Brand name	Pathogens or diseases controlled	Host plants
<i>Ampelomyces quisqualis</i> M-10	Fungus	AQ-10 Biofungicide (Ecogen, Inc.)	Powdery mildews	Fruits, vegetables, and ornamentals
<i>Pseudomonas aureofaciens</i> TX-1	Bacterium	Bioject Spot-less (Eco Soil Systems, Inc.)	Anthraxnose and soilborne pathogens	Turf
<i>Pseudomonas fluorescens</i> A506	Bacterium	BlightBan 506 (NuFarm, Inc.)	Frost damage, fireblight, fruit russetting	Tree fruits, small fruits, vegetables
<i>Pseudomonas chlororaphis</i>	Bacterium	Cedomon (BioAgri AB)	<i>Drechslera</i> spp, <i>Bipolaris sorokiniana</i> , <i>Ustilago hordei</i>	Barley, oats
<i>Bacillus subtilis</i> QST713	Bacterium	Serenade (AgraQuest, Inc.)	Powdery and downy mildews; leaf spots and blights	Diverse crops
<i>B. subtilis</i> MBI600	Bacterium	MBI600 Foliar (Becker Underwood, Inc.)	<i>Botrytis</i> , powdery mildew, leaf spot, eyespot, blotch	Cereals, fruits, vegetables, ornamentals
Hrp N harpin protein from <i>Erwinia amylovora</i>	Plant defense activator	Messenger (EDEN Bioscience Corp.)	Diverse fungal, viral, and bacterial pathogens	Ornamentals, fruits, vegetables, field crops
Acibenzolar-S-methyl	Plant defense activator	Actigard 50WP (Syngenta Crop Protection)	Downy mildew, tobacco blue mold, bacterial leaf spots	Leafy vegetables, tobacco, tomato

Based on Ref. 1 and manufacturers' Websites.

^bCertain of these products may also be used to control soilborne diseases, or may be considered primarily as chemicals rather than biologicals (plant defense activators).

the proceedings of seven international phyllosphere microbiology conferences since 1970. Microbial population levels in the phyllosphere can reach an average of about 10^6 – 10^7 cells per cm^2 , but densities range over several orders of magnitude among leaves as well as over time. Spatial variation in populations on the surface of a given leaf is likewise high, with some features—such as veins—densely colonized while the majority of the leaf remains relatively unoccupied. Epiphytic bacterial and yeast populations are highly responsive to environmental changes. Many (>100) species of filamentous fungi have been isolated from the phylloplane, but most of these are represented by quiescent propagules deposited from the air spora rather than as actively growing members of the community. Leaf surfaces are a unique and highly variable habitat that differ, for example, from root surfaces in their longevity, topography, aeration, nutrient flux, continuity of moisture, and microclimate. These characteristics influence the microbial inhabitants, including any natural or introduced biocontrol agents. Moreover, unlike roots, leaves do not reside in a medium that can be managed over time to promote antagonism. This implies that the potential for biocontrol will be different in the two habitats.

FUTURE PROSPECTS AND DIRECTIONS

Modification of plants, by conventional breeding or through genetic engineering, to resist pathogens or to favor beneficial microbes is a major future direction. A recent notable example is the transgenic resistance conferred by virus coat protein expressed in papaya to *Papaya ringspot virus*.^[8] Transgenic papaya varieties have been established in Hawaii in commercial quantity since 1998; the fruit is widely marketed. As another example, transgenic sugarcane expressing the albicidin detoxifying gene from the leaf scald pathogen *Xanthomonas albilineans* was resistant to the disease and to multiplication of *Xanthomonas*.^[9] This suggests that, through plant gene expression approaches founded on knowledge of molecular genetics and developmental biology, it may be possible to disrupt pathogenesis factors or key stages in the pathogen's life cycle (e.g., sclerotia production). However, to date the release of genetically modified organisms and the sale of such foods have generally been met with consumer skepticism and opposition. The prospects of this strategy for the immediate future are thus clouded and reinforce the earlier comment that an intrinsically effective biocontrol agent alone can not ensure commercial success.

Efforts to discover natural products from microorganisms, and other sources are intensifying.^[10] Such compounds may have activity against plant pathogens or serve as models for laboratory synthesis of related chemicals of

higher potency. For example, the fungicide fludioxonil, which is structurally related to the natural antifungal metabolite pyrrolnitrin from *Pseudomonas* spp, has been recently introduced.^[10] Other compounds that show potential in biocontrol are the cercropins, small antimicrobial peptides with lytic activity.^[11] An antifungal cercropin has been expressed in *Saccharomyces cerevisiae*; the transformed yeast cells, when coinoculated into wounded tomato fruit with spores of *Colletotrichum coccodes*, inhibited growth of the pathogen and decay.^[11] In principle, a similar method could be used in the phyllosphere, where the goal would be to transform a competitive yeast colonist.

Two recently introduced products are at the vanguard of a new era in control strategy based on activation of the plant's resistance response. The active ingredient of one such product, Messenger™, is the harpin protein produced by *Erwinia amylovora* (Table 1). Harpin induces host gene expression and the generalized response is effective against several categories of pathogens, evidently with minimal impact on non-target organisms. Actigard™, based on the chemical inducer benzothiadiazole, acts similarly to trigger a systemic acquired resistance-like response (Table 1) and there are other examples.^[12] Preliminary evidence from many laboratories is emerging that the silencing of specific genes at the messenger RNA (mRNA) level by the phenomenon known as RNA interference (RNAi) may be in part a plant defense mechanism. Knowledge of the mechanism may lead to novel biological means to control disease.

One final route to improved biocontrol is through a more insightful strategy based on microbial antagonists. Countless failed experiments on field release of putative biocontrol agents testify starkly to the need for refinements and a more judicious approach. There are some circumstances and environments (evidently including greenhouses)^[13] wherein antagonists can perform effectively and reproducibly. However, the hallmark of microbial biocontrol is its variability,^[14] although this may be offset by combinations of agents^[15] and likely by more attention to matching the agent to the local environment in which it must function. An encouraging note is that, given a mode of antagonism amenable to improvement by targeted genetic modification, substantial improvement in control can result.^[10]

CONCLUSION

Several commercial products with diverse modes of action are now available for biocontrol of foliar diseases. In general, these hold relatively small, “niche” markets, but nevertheless demonstrate that biocontrol in the phyllosphere is a commercial reality in some situations. Future

research in microbial ecology, molecular biology, and plant physiology will provide new insights, and ultimately new products, for biocontrol. It is likely that the real and lasting contribution of biocontrol in the phyllosphere, as is the case in soil systems, will be as one component in integrated programs that are a part of good crop production practice.

Biological Control of Nematodes

Brian R. Kerry

Rothamsted Research, Herts, U.K.

INTRODUCTION

Nematode populations are regulated by a wide range of natural enemies, including predators, antagonists, parasites, and pathogens.^[1] Although predatory protozoa, nematodes, turbellarians, tardigrades, mites, and insects are common, especially in uncultivated soils, little is known of their impact on nematode communities, and most research has concentrated on microbial agents that attack specific nematode parasites. In some soils, nematophagous fungi and bacteria have been reported to control the multiplication of pest species on nematode-susceptible crops (Table 1), but despite the commercialization of a few organisms, none is in widespread use. Continued economic, environmental, and health concerns over the use of nematicides have resulted in the development of control strategies that depend less on the use of these chemicals. However, biocontrol agents are yet to play a significant role in the integrated pest management of nematodes and they have proved difficult to exploit.

MICROBIAL NATURAL ENEMIES

Antagonists

Several bacteria, actinomycetes, and fungi produce bioactive compounds that are toxic or affect the behavior of nematodes without infecting them.^[2] Bacteria such as *Pseudomonas fluorescens* may reduce nematode hatch and invasion of roots by affecting their exudates, whereas *Agrobacterium radiobacter* and *Bacillus sphaericus* induce plant resistance.^[3] Endophytic fungi may compete for resources in roots or may produce systemic effects that reduce nematode development.

The toxin produced by the actinomycete *Streptomyces avermitilis* and the metabolites of the fungus *Myrothecium verrucaria* have been used in commercial anthelmintics and a nematicide, respectively. Antagonists may be a valuable source of biorational nematicidal compounds, but the production of toxins on nutrient media in vitro is no indication of an organism's ability to produce such compounds in situ. Some leguminous crops encourage nematode-antagonistic bacterial communities in their rhizospheres, which could be used in pest control strategies.^[4]

Parasites and Pathogens

Most research on the biocontrol of nematodes has been done on parasitic or pathogenic microorganisms. Those bacteria and fungi that parasitize active stages of nematodes produce adhesive spores or specialist traps. The Gram-negative bacteria *Pasteuria* spp., have a wide host range among plant parasitic nematodes, but individual isolates may be highly specific.^[5] Host recognition appears to reside in spore hydrophobin interactions with protein receptors on the nematode cuticle. Spores of *Pasteuria* spp. that parasitize cyst and root-knot nematodes usually do not germinate until the infective second-stage juveniles have invaded the roots. The bacteria spread throughout the body and significantly reduce or prevent egg production, completing their life cycle in 20–30 days at 30°C. *Pasteuria penetrans* and *P. nishizawae* have been associated with the natural control of root-knot and cyst nematodes, respectively. However, problems in the in vitro production of these bacteria have limited their exploitation as biocontrol agents.

Nematophagous species occur in most fungal groups. The much-studied trapping fungi produce adhesive or constricting traps that ensnare their hosts. In *Arthrobotrys oligospora*, host recognition is thought to depend on lectin carbohydrate interactions. Although host–parasite interactions influence trap production and rate of capture, nematode trapping fungi do not depend on nematode prey for their nutrition. The extent of the saprophytic phase in soil is unclear and differs between species. *Duddingtonia flagrans*, which produces adhesive trap networks, is being evaluated for the biocontrol of nematode parasites of domestic animals, but the use of trapping fungi for the control of plant parasitic nematodes has had limited success.

Some fungi, such as *Catenaria anguillulae*, infect their nematode hosts with zoospores that aggregate around natural openings, encyst on the cuticle, and produce a germ tube that penetrates the host, whereas both *Hirsutiella rhossiliensis* and *Drechmeria coniospora* produce adhesive spores on conidiophores that develop from infected cadavers. Although *H. rhossiliensis* is associated with the decline of *Criconomella xenoplax* populations on peaches, it requires large numbers of spores in soil to maintain small host populations, and this has limited its potential as a biocontrol agent.

Table 1 Some examples of nematode-suppressive soils and their general characteristics

Examples			
Nematode pest	Host crop	Country	Causal agent(s) of suppression
<i>Heterodera avenae</i>	Temperate cereal monocultures	N. Europe	<i>Nematophthora gyrophila</i> <i>Pochonia chlamydosporia</i>
<i>Meloidogyne</i> spp.	Peaches	California	<i>Dactylella oviparasitica</i>
<i>Criconebella xenoplax</i>	Peaches	S. Carolina	<i>Hirsutella rhossiliensis</i> <i>Pseudomonas aureofaciens</i>
<i>M. arenaria</i>	Peanuts	Florida	<i>Pasteuria penetrans</i>
<i>Meloidogyne</i> spp.	Vegetables	W. Africa	<i>P. penetrans</i>
<i>Meloidogyne</i> spp.	Vines	Australia	<i>P. penetrans</i>

Characteristics
<ul style="list-style-type: none"> • Suppression of nematode populations occurs only after 4–5 years of susceptible crops and may be specific to a single pest species. • Monocultures of nematode-susceptible crops or perennial crops are usually needed to support the development of a nematophagous microflora. • Nematode damage may be severe in the early stages of the cropping cycle, and control strategies that reduce nematode populations may delay the onset of suppression. • Soil amendments and crops may be used to manipulate the natural enemy community in the rhizosphere and increase biocontrol. • Sustainable management usually depends on a diverse (intra- or interspecific) microbial community. • Suppressiveness can be removed by biological treatments.

(From Ref. 2.)

Fungi that attack the sedentary stages (eggs and saccate females) of nematodes are generally rhizosphere colonizers that do not produce special infection structures other than an appressorium. More than 250 species of fungi have been isolated from the females and eggs of cyst and root-knot nematodes; *Paecilomyces lilacinus* and *Pochonia chlamydosporia* have been most studied. Both are facultative parasites that colonize the rhizosphere. Infection of eggs is associated with the production of an alkaline serine protease in both species, which may be a virulence and host-range determinant. These fungi are readily cultured in vitro and are being evaluated as potential commercial agents. *Pochonia chlamydosporia* is a key species in soils suppressive to the cereal cyst nematode in many soils in northern Europe.

DYNAMICS OF MICROBIAL AGENTS IN SOIL

There is much intraspecific variation among species of fungi and bacteria in suppressive soils, but the importance of such variation in the regulation of host populations is unknown. Those bacteria and fungi that occur in the rhizosphere are much affected by interactions between the plant and the nematode host.^[6] Density-dependent interactions with hosts have been reported for both obligate and

facultative parasites, but the dearth of quantitative methods to estimate parasite/pathogen populations has made observations beyond microcosms in controlled conditions difficult. However, it is clear that the dynamics of individual microorganisms differ greatly and have a profound influence on the potential of such agents for biocontrol.^[7,8]

BIOCONTROL APPROACHES

Relatively few natural enemies have been evaluated as biocontrol agents for nematodes, but of those tested, none is likely to provide rapid and effective levels of pest control if applied alone. Biocontrol strategies have been extensively reviewed.^[1,2] Although suppressive soils have provided the most sustainable method of nematode management for a few pest species in some soils, applying selected agents must be integrated with other control measures. Application of microbial agents following solarization or the addition of soil amendments, or in combination with nematicides or resistant hosts, has improved their performance. However, work on optimizing production and formulation methods remains to be done for most microbial natural enemies that have potential for biocontrol.

CONCLUSION

Nematode pests are obligate parasites on plants and spend different amounts of time in the rhizosphere, depending on their mode of parasitism. A detailed understanding of interactions between nematodes and their natural enemies in the rhizosphere is essential for the development of rational biocontrol strategies. Molecular biological and immunological techniques that discriminate and quantify individual isolates of microbial agents are needed to help understand the host–parasite dynamics in soil. Also, in combination with biochemical methods they would provide powerful tools for studies of the multitrophic interactions that occur in the rhizosphere, especially the factors that affect the switch from the saprophytic to the parasitic state in facultative parasitic fungi. Natural enemies may also provide novel bioactive compounds that could be developed as new nematicides or be incorporated in a transgenic approach to nematode management.

Biological Control of Oomycetes and Fungal Pathogens

Eric B. Nelson

Cornell University, Ithaca, New York, U.S.A.

INTRODUCTION

Oomycetes and fungi are economically damaging plant pathogens whose presence and activities invoke the use of repeated fungicide applications to minimize losses in plant yield, quality, or aesthetics. Increasing environmental and human health concerns associated with widespread fungicide use has prompted scientists and plant producers to explore biological methods of disease control.

Biological control strategies make use of microorganisms to mitigate disease losses. Such disease suppressive microorganisms are commonly found in many different habitats. Biological control strategies attempt to enhance the activities of these disease-suppressive microorganisms either by introducing high populations of specific microorganisms or by enhancing the conditions that enable microorganisms in their natural habitats to suppress diseases. Common strategies for manipulation of biological control microbes will be discussed along with the commercialization potential of biological disease control strategies in agriculture.

MICROBIAL INOCULANTS

Microbial inoculation strategies attempt to increase soil or foliar populations of specific disease-suppressive microbes temporarily and dramatically. Microorganisms commonly studied and deployed for control of oomycete and fungal diseases include species of bacteria in the genera *Bacillus*, *Pseudomonas*, and *Streptomyces* and fungi in the genera *Coniothyrium*, *Gliocladium*, and *Trichoderma*.^[1] Several organisms have served as model systems for generating many of our concepts of biological disease control. These include specific strains of *Bacillus cereus* and *B. subtilis*, *Enterobacter cloacae*, *Pseudomonas fluorescens*, and *Trichoderma harzianum*. Often specific strains of bacteria and fungi are deployed for biological control. Many times such strains, operating under rather narrow modes of action, have relatively narrow ranges of pathogen species for which they are effective.

The processes and traits expressed by biocontrol microbes result in reduced disease development by either directly disrupting stages of the pathogen's life cycle or

by indirectly altering the biochemistry of the leaf surface, spermosphere, or rhizosphere such that pathogenesis is disrupted. This can be accomplished by producing antibiotic compounds active against the target pathogen, by competing with the target pathogen for specific resources such as iron or carbon, or by parasitizing hyphae or reproductive structures of the target pathogen. Both fungal and bacterial biocontrol microbes can also induce the expression of resistance responses in the host plant, making the host less susceptible to infection or disease development.

Various formulations of *Trichoderma harzianum* have been the most widely commercialized and efficacious inoculants used for the control of oomycete and fungal diseases. Of particular importance is strain T-22 of *T. harzianum* sold under the trade names RootShield™, PlantShield™, and TurfShield™ (Table 1). This inoculant is sold in the U.S. to the greenhouse, row crop, and turf industries. During 1999, retail sales of T-22 products totaled around \$3 million^[2] and were expected to increase in the next years.

COMMERCIALIZATION HURDLES

Despite decades of research on the biological control of oomycete and fungal plant diseases, there remain few widely adopted and commercially successful microbial inoculants. Fewer than 25 microbial species have been commercialized worldwide (Table 1). There are a number of reasons for the lack of development and grower adoption. Among the more important are problems in formulation and delivery, variability in performance, and problems with poor efficacy under optimum conditions for disease development. There are countless examples of biological control organisms that perform effectively under defined laboratory conditions but fail when introduced on different crops under varying field conditions. Still others might perform effectively in the field, but exhibit strong year-to-year or site-to-site variability. Additionally, the economics and level of biological knowledge necessary for growers to implement biological control strategies is still not favorable for many cropping systems, making adoption levels low.

Table 1 Commercial microbial inoculants used worldwide for control of oomycete and fungal plant diseases

Table 2 Examples of soils suppressive to oomycete and fungal plant diseases

Pathogen	Disease	Microorganisms responsible
<i>Aphanomyces euteiches</i>	Root rot of pea	Unknown
<i>Armillaria mellea</i>	Root rot of conifers	Unknown
<i>Cephalosporium graminearum</i>	Stripe of wheat	Unknown
<i>Didymella lycopersici</i>	Stem rot of tomato	Unknown
<i>Fusarium oxysporum</i>	Wilts of various crops	Nonpathogenic <i>Fusarium</i> spp.; <i>Pseudomonas</i> spp.
<i>Fusarium solani</i>	Root rot of bean	Unknown
<i>Fusarium culmorum</i>	Foot rot of barley	Unknown
<i>Gaeumannomyces graminis</i>	Take-all of cereals	<i>Pseudomonas</i> spp.
<i>Phytophthora capsici</i>	Damping-off of tomato	Unknown
<i>Phytophthora cinnamomi</i>	Root rots of various crops	Various bacteria
<i>Phytophthora sojae</i>	Root rot of soybean	Unknown
<i>Poria weirii</i>	Root rot of conifers	Unknown
<i>Pseudocercospora herpotrichoides</i>	Root rot of cereals	Unknown
<i>Pythium aphanidermatum</i>	Root rot of many crops	Unknown
<i>Pythium splendens</i>	Damping-off of cucumber	Unknown
<i>Pythium ultimum</i>	Damping-off of cotton	Seed-colonizing bacteria
<i>Rhizoctonia solani</i>	Root rot of many crops	Unknown
<i>Sclerotium rolfsii</i>	Rot of tomato	Unknown
<i>Thielaviopsis basicola</i>	Root rot of tobacco	Unknown
<i>Verticillium albo-atrum</i>	Wilt of potato	Unknown

(From Ref. 8.)

SUPPRESSIVE SOILS

Disease and pathogen suppressive soils have been known for over a century and identified from many parts of the world (Table 2).^[3] They occur naturally or may be induced either through continuous monoculture or through the addition of organic amendments. Among the best-known are those suppressive to diseases caused by oomycetes and fungi such as *Pythium*, *Phytophthora*, *Fusarium*, *Rhizoctonia*, and *Gaeumannomyces*. The level of disease control is related predominantly and directly to unique microbiological properties associated with the soils themselves or, more importantly, with the sphere or rhizosphere of plants grown in these soils.^[4] Although the specific microorganisms providing the disease control are generally not known, suppressive soils provide some of the best examples of effective biological control where they can serve as models for understanding how microorganisms in their natural habitats might be manipulated to reduce plant disease losses.

Among the best examples of naturally suppressive soils are those suppressive to *Fusarium* wilt diseases of various crops.^[5] These soils are characterized by elevated populations of nonpathogenic *Fusarium* and fluorescent *Pseudomonas* species. These organisms compete with pathogenic species of *Fusarium* for carbon and iron, resulting in reduced plant infection.

Suppressiveness can be induced in soils either through the introduction of organic amendments or, in some cases, from crop monoculture. Organic soil amendments, particularly composts, have been studied extensively for their ability to induce suppressiveness to many oomycete and fungal diseases.^[6] These studies confirm the involvement of compost-associated and soil-enhanced microbial communities in the suppressive properties of amended soils. The identities of the specific microorganisms contributing to this suppressiveness remain elusive.

The most widely studied example of induced disease suppressiveness in soils is the take-all decline phenomenon following cereal monoculture. Continuous cereal monoculture has been observed worldwide to result in the gradual decline in the severity of take-all disease caused by *Gaeumannomyces graminis* var. *tritici* (*Ggt*). The natural selection provided by monoculture results in the buildup of specific antibiotic producing *Pseudomonas* species on and in *Ggt* lesions on cereal roots that suppress root infection by *Ggt*.^[7] If this cropping strategy is interrupted, disease suppression is lost.

CONCLUSION

The unpredictable nature of biological control systems has plagued research in this field for over 80 years and to date,

no clear means of overcoming this variability has been discovered. Insights into how individual or communities of biological control organisms succeed and how they fail can come only from a detailed understanding of how these organisms function during their interaction with the pathogen, the plant, and the environment in which they are placed.

Knowledge of specific microbial traits essential for biological control activity and the important regulatory role played by the plant, whether it be in eliciting pre-infection developmental responses of pathogens, or in regulating the pathogen-suppressive behavior of introduced biological control microorganisms, is crucial to the ultimate success of biological control strategies. By understanding how the host, pathogen, and associated microbes contribute to biological control processes, we will be able to predict better and manipulate microbial behavior with the goal of enhancing biological disease control.

Biological Control of Weeds

Linda M. Wilson

Mark Schwarzlaender

University of Idaho, Moscow, Idaho, U.S.A.

INTRODUCTION

Biological control of weeds is the deliberate introduction and release of a weed's natural enemies with the goal of reducing the weed infestation. To date, biocontrol of weeds has been limited to nonindigenous, exotic weeds. Insects are the most widely used organisms in weed biological control programs worldwide. Other natural enemies include mites, nematodes, and plant pathogens. Biological control of terrestrial and aquatic weeds using insects is described, and important approaches, strategies, and considerations in biological weed control are discussed.

DEVELOPING A BIOLOGICAL CONTROL OF WEEDS PROGRAM

Through global commerce and tourism, humans have traveled the world, consciously or unconsciously accompanied by plants. Non-indigenous plant species have been intentionally or accidentally introduced into many, if not most, countries around the world. Examples of introductions are purple loosestrife (*Lythrum salicaria*) and toadflax (*Linaria* spp.); both are valued as ornamental plants in Europe, but are major weeds in North America. Exotic plant species become invasive in the new location because they encounter favorable environments, adequate disturbance, and reduced competition, and they also lack their specialized natural enemies. In their native plant communities, these plant species do not attain pest densities; their natural enemies, a system of insects, mites, nematodes, and pathogens, regulate their population density.^[1]

Nearly all of the terrestrial and aquatic weeds targeted for biological control worldwide are exotic, nonindigenous, perennial plants.^[2] Uncontrolled expansion of invasive plants into large, monospecific stands of weeds, on relatively low-value land, rendered conventional weed control methods impractical; it is in these situations that biological weed control has been most effective. One approach, classical biological control, is the introduction and release of one or more natural enemies that are expected to establish, multiply, disperse, and damage their

host weed with little or no manipulation following introduction and release into the environment.

Since the late 18th century, biological control has become a useful and important tool in pest management. The first record of an intentional biological control of weeds program was the introduction of a cochineal scale insect (*Dactylopius ceylonicus*) into India in 1795 from Brazil to control an introduced cactus (*Opuntia vulgaris*).^[3] Successful, large-scale biological control of weeds began in the 1920s with the importation of the moth *Cactoblastis cactorum* from Argentina for the control of prickly pear cactus (*Opuntia* spp.) in Australia. The first use of biological weed control in the United States was in 1903 with the importation of natural enemies into Hawaii for the control of lantana (*Lantana camara*), followed in 1939 with the importation of two leaf-feeding beetles (*Chrysolina* spp.) for the control of St. Johnswort (*Hypericum perforatum*).^[4] Between 1950 and 1998, programs were initiated for over 130 additional terrestrial and aquatic weeds in 57 countries worldwide, involving 490 species of natural enemies.^[4] The major regions in which biological control is used include North America, South America, Australia and New Zealand, Central and Southern Africa, and Indonesia and the Pacific Islands.^[5]

When successful, biological control is cost-effective, environmentally safe, and sustainable. Limitations to biological control include the time required to develop programs, and the fact that effects are not immediate and not always adequate. Biological control has a good record of environmental safety, but it is not without risks. These risks include threats to non-target plant species and resulting indirect ecological effects to the environment.^[6] Careful selection, screening, and monitoring of potential biological control agents is imperative to minimize risks to native and other non-target plants. To emphasize safety, foreign exploration, quarantine, rearing, release, and host specificity testing all follow a comprehensive set of protocols. In considering a biological control program for any given weed, researchers evaluate the extent of the weed problem and its suitability for biological control, the potential natural enemies, the feeding range of the potential organisms, and their general suitability as biological control agents.

Table 1 Selected terrestrial and aquatic weeds, their most commonly used biological control agents, and location

Target weed	Natural enemy	Type	Location
Alligatorweed	<i>Agasicles hygrophila</i>	flea beetle	Australia, China,
<i>Alternanthera philoxeroides</i>	<i>Vogtia malloi</i>	stem borer	New Zealand, U.S.A.
Giant salvinia	<i>Cyrtobagous salviniae</i>	root weevil	Australia, Southern Africa, Ghana,
<i>Salvinia molesta</i>			South Pacific Islands, India
Gorse	<i>Apion ulicis</i>	seed weevil	Australia, New Zealand, U.S.A.
<i>Ulex europaeus</i>	<i>Agonopterix ulicit</i>	soft shoot moth	
	<i>Tetranychus lintearius</i>	spider mite	
	<i>Sericothrips staphylinus</i>	thrips	
	<i>Agonopterix nervosa</i>	tip moth	
Hawkweeds	<i>Aulacidea subterminalis</i>	gall wasp	New Zealand
<i>Hieracium</i> spp.	<i>Microlabis pilosellae</i>	gall midge	
	<i>Chelosia urbana</i>	root-feeding hover fly	
Houndstongue	<i>Mogolones cruciger</i>	root weevil	Canada
<i>Cynoglossum officinale</i>	<i>Longitarsus quadriguttatus</i>	root-feeding flea beetle	
Knapweeds	<i>Agapeta zoegana</i>	root moth	Canada, U.S.A.
<i>Centaurea</i> spp.	<i>Cyphocleonus achates</i>	root weevil	
	<i>Larinus minutus, Larinus obtusus</i>	seed head weevil	
	<i>Metzneria paucipunctella</i>	seed head moth	
	<i>Sphenoptera jugoslavica</i>	root gall beetle	
	<i>Urophora affinis,</i>	seed head gall fly	
	<i>Urophora quadrifasciata</i>		
	<i>Chaetorellia acrolophi</i>	seed head fly	
	<i>Bangasternus fausti</i>	seed head weevil	
	<i>Pterolonche inspersa</i>	root moth	
Leafy spurge	<i>Aphthona</i> spp. (6 species)	root beetle	Canada, U.S.A.
<i>Euphorbia esula</i>	<i>Chamaesphacia hungarica</i>	root moth	
	<i>Hyles euphorbiae</i>	defoliating moth	
	<i>Oberea erythrocephala</i>	root beetle	
	<i>Spurgia esulae</i>	bud gall midge	
	<i>Pegomya curticornis</i>	root fly	
Mediterranean sage	<i>Phrydiuchus tau</i>	root weevil	U.S.A.
<i>Salvia aethiopsis</i>			
Parthenium weed	<i>Zygogramma bicolorata</i>	leaf beetle	Australia, India
<i>Parthenium hysterophorus</i>	<i>Epiblema strenuana</i>	stem-galling moth	
	<i>Bucculatrix parthenica</i>	leaf-mining moth	
	<i>Listronotus setosipennis</i>	stem-boring weevil	
Paterson's Curse	<i>Longitarsus echii</i>	flea beetle	Australia, South Africa
<i>Echium plantagineum</i>	<i>Meligethes planiusculus</i>	pollen beetle	
	<i>Dialectica scalariella</i>	leaf-mining moth	
	<i>Mogolones larvatus</i>	crown weevil	
	<i>Mogolones geographicus</i>	root weevil	
Prickly pear and other cacti	<i>Cactoblastis</i> spp.	stem-boring moth	Australia, India, Indonesia,
<i>Opuntia</i> spp.	<i>Dactylopius</i> spp.	scale insect	New Zealand, U.S.A.
	<i>Chelinidea tabulata</i>	leaf-sucking bug	
Purple loosestrife	<i>Galerucella californiensis,</i>	defoliating weevil	U.S.A.
	<i>Galerucella pusilla</i>		
<i>Lythrum salicaria</i>	<i>Hylobius transversovittatus</i>	root weevil	
	<i>Nanophyes marmoratus</i>	root weevil	
Rush skeletonweed	<i>Bradyrrhoa gilveolella</i>	root moth	Australia, U.S.A.
<i>Chondrilla juncea</i>	<i>Cystiphora schmidti</i>	gall midge	
	<i>Eriophyes chondrillae</i>	gall mite

BIOLOGICAL WEED CONTROL AGENTS

Phytophagous arthropods (insects and mites) comprise over 70% of the species imported for biological control of terrestrial and aquatic weeds worldwide.^[5] Insects are often selected as biological control agents because they are relatively easy to study, and many species exhibit a high degree of host specificity, feeding on only a few plant species closely related to the target weed. Host range is the set of plant species on which a natural enemy can feed, develop, and complete its life cycle. Those selected for biological control must have a very narrow host range; ideally, they survive only on the target weed. Insects that feed inside the plant are more likely to be host-specific and have a more highly evolved association with the target weed than do externally feeding insects.^[1] In addition, a number of insect species may occur on a single plant or within the same part of the plant. For example, spotted knapweed (*Centaurea stoebe*) root feeders include three moth and two beetle species.^[7] Table 1 provides a partial

list of the major groups of biological control agents established on weeds worldwide.

Insects damage weeds either directly or indirectly. Direct feeding can severely injure or kill the plant. For example, insects suck out plant fluids, defoliate, bore into roots, shoots, and stems, and eat flowers or seeds. Indirect damage, resulting from secondary pathogen infections, can also weaken or kill the plant.

The insect orders most commonly used in weed biological control are beetles (Coleoptera), flies (Diptera), and moths (Lepidoptera) and to a lesser degree wasps (Hymenoptera), true bugs (Hemiptera), and thrips (Thysanoptera). Beetles have been the most effective and successful insects used in terrestrial and aquatic weed biocontrol.^[5] Families of beetles used in biological control are weevils (Curculionidae), leaf beetles (Chrysomelidae), long-horn beetles (Cerambycidae), wood-boring beetles (Buprestidae), and seed beetles (Bruchidae). Beetles may feed on seed heads, bore in stems and roots, or defoliate plants.

Flies such as gall midges (Cecidomyiidae) or fruit flies (Tephritidae) are used in many terrestrial weed biocontrol programs. Examples of gall midges include the rush skeletonweed stem and leaf gall midge (*Cystiphora schmidti*) and the leafy spurge shoot tip gall midge (*Spurgia esulae*). Examples of seed-feeding fruit flies are the knapweed gall flies (*Urophora* spp. and *Terellia virens*) and the yellow starthistle seed flies (*Chaetorellia* spp.). Moths are also widely used in weed biocontrol programs; they are typically seed-feeders or root-borers. Examples of moths include the leafy spurge root moth (*Chamesphecica* spp.), the parthenium weed stem boring moth (*Epiblema strenuana*), and the ragwort defoliating moth (*Tyria jacobaeae*). Examples of less commonly used types of insects in weed biological control include the hawkweed gall wasp (*Aulacidea subterminalis*), the prickly pear defoliating bug (*Dactylopius opuntiae*), and the gorse shoot thrips (*Seriothrips staphylinus*).

Although not insects, mites, with their two body regions, four pairs of legs, and microscopic size, are also used in weed biocontrol programs. Both gall mites and spider mites damage the plant by sucking valuable fluids from the stems and leaves; gall mites also cause plants to develop galls. Examples are the rush skeletonweed gall mite (*Eriophyes chondrillae*) and the gorse spider mite (*Tetranychus linearis*).

When initiating a weed biological control program, researchers survey natural enemies associated with the target weed in its native range. Candidate insect species are selected depending on their degree of specificity with the host, their ease of collecting and rearing, and their impact on the weed.^[8] Extensive host specificity studies are conducted over several years to determine that the insects attack only the target weed and a few closely related species, and do not pose a threat to species unrelated to the target plant, commercial or horticultural species, or threatened and endangered species located in the area where the insect is intended for introduction. Accurate identification of the selected insects and the host plant is vitally important in biological control of weeds.

The success of biological control of weeds programs historically has been based on the degree to which the weed population declined following the introduction of the biological control agent(s). Harris^[9] proposed a sequential, four-step process for evaluating the success of a biological control release, which includes establishment success, biological success, host impact, and control success. Cullen^[10] further proposed that the ultimate success of an insect in weed biological control is a result of a combination of three major factors: 1) the damage an individual insect can do to a plant, 2) the ecology of the insect in determining its density, and therefore, the total damage produced, and 3) the ecology of the weed in

determining if the damage is significant in reducing its population. These categories of success provide evaluation of biological weed control within a practical context. Objective assessment in weed biological control programs using manipulative experiments^[10] and economic cost-benefit analyses^[11] are also being applied to evaluate weed biocontrol programs.

CONCLUSION

The aim of biological control of weeds is not to eradicate weed, but rather to suppress the weed to a more acceptable density level. Biological control insects can affect weeds in plant communities by killing them or suppressing their competitive ability in the community. Land managers should note that successful biological suppression of a weed is not strictly the weed management end point. Without further management and intervention, the successional vegetation may be as undesirable. Very likely the opening created by suppression of one weed will be filled with an unrelated, potentially more invasive weed that, after gaining dominance, may eventually become a future target for biological control. Care must be taken to avoid this "biological control treadmill"^[12] and to prevent the need for and expense of introducing new organisms into the environment. In the most successful integrated weed management programs, biological weed control has combined together with competition from perennial grasses, prescribed grazing, and herbicides to achieve successful weed suppression and restoration of desirable, perennial plant communities.

Biosafety Applications in the Plant Sciences: Expanding Notions About

Emily E. Pullins

University of Minnesota, St. Paul, Minnesota, U.S.A.

INTRODUCTION

The expanding and evolving definition of biosafety has important implications for efforts to manage and safely use plants that are modified using modern molecular methods (biotechnology). The concept of biosafety has evolved over forty years, beginning with the recognition of hazards derived from biological science activities. Biohazards were defined as early as 1965 as a “risk to mankind or the environment, especially, one arising out of biological or medical work.”^[1] This definition included hazardous living microorganisms such as bacteria, non-living hazardous biological matter such as viruses or prions, as well as human error and material waste by-products that could facilitate the agency of these hazards, such as the improper disposal of used syringes.

WHAT IS BIOSAFETY?

The term biosafety, coined in 1977, was defined as processes that assured the safe use of potential biohazards through the systematic and system-wide implementation of safety programs, most often within the context of a laboratory or clinical setting.^[2] With the advent of modern molecular methods, some scientists raised concerns about novel hazards in organisms altered with these methods, such as recombinant DNA technology.^[3] Thirty years of public debate about the likelihood and assessment of these organisms as potential hazards have entered the plant sciences as plants have been altered through these same techniques. Some microbiologists take issue with the inclusion of plants and animals derived using biotechnology in the formal biosafety definition, because this may cause the public to unnecessarily doubt the safety of these products, and may distract from occupational or public safety concerns about traditionally recognized biohazards.^[4]

Debates among plant scientists have pivoted on what constitutes an appropriate biosafety evaluation and management process, particularly focusing on the extent to which gaps in information and unanticipated effects of these organisms should govern their use.^[5] Narrower definitions of biosafety science tend to focus primarily on

risk assessment and management tasks related to a single trait within a single species derived using biotechnological methods; these may be limited further by the temporal and spatial aspects of assessment. For example, risk assessments may occur prior to commercialization, focused on risk issues related to approved and expected use of the trait, and within a spatial range smaller than that after commercial release of the product. Some biologists argue that, based on existing scientific evidence from these risk assessments, there are no “immediate or significant risks” to environmental and food biosafety in the case of the array of plants most recently modified by biotechnological methods.^[6]

Broader definitions of biosafety consider additional risk issues, such as when genetic material, related traits, living organisms, or their nonliving products developed using biotechnological methods transcend anticipated physical or biological boundaries, temporal or spatial scales, or particular political jurisdictions.^[7] The settings in which safety evaluation and management of plants derived from modern molecular methods as potential hazards has been expanded by some to include both inside and outside controlled laboratory settings; in the trade of products across international borders; and in public, occupational, and environmental spheres. Broader biosafety concepts may also include a proactive safety program approach, in which risk assessment and management are tools used within a comprehensive safety prioritization framework;^[8] additional activities may include the formation of safety standards to govern the development, use, testing, and monitoring of these products.

These various notions of biosafety have been used for over a decade in vernacular and professional settings and are prominent in international and national policy documents. There is now political support for the notion that “[e]very country that wants to use GM [genetic modification] technology also needs to establish a strong biosafety system to ensure that any risks that these new crops might bring can be handled safely.”^[9] As a result, considerable efforts are being made to develop and use new scientific, technological, and political safety evaluation and management methods to address potentially hazardous aspects of these organisms in use.^[10–12] Recent critiques of some national policies related to the safety of

transgenic plants reveal that governance of these organisms tends to consist of a patchwork of risk-focused government regulations that, in some instances, do not comprehensively address present or future safety concerns.^[13–15] Several organizations have initiated institutional-capacity building activities in developing countries to facilitate biosafety research and governance programs;^[16,17] concerns about funding for national and international biosafety programs is a consistent theme in reports on these activities. The U.N.'s Convention on Biological Diversity is responding to such critiques by moving toward the establishment and support of formal biosafety programs based on the broader definition of biosafety, which include setting standards for acceptable risks, validation of scientific information related to risks such as post-commercialization testing and monitoring of products for safety, and training for safe management of biotechnologies.^[18,19] Most notable among the international policy activities addressed by this convention was the development of the Cartagena Protocol on Biosafety, which sought to “contribute to ensuring an adequate level of protection in the field of the safe transfer, handling, and use of living modified organisms resulting from modern biotechnology that may have adverse effects on the conservation and sustainable use of biological diversity, taking also into account risks to human health, and specifically focusing on transboundary movements.”^[18] This protocol was adopted by consensus at the Extraordinary Conference of the Parties to the Convention on Biological Diversity, January 29, 2000, and has been ratified by 23 countries.^[20] Substantive support for recommendations made in the protocol has come from The Global Environment Facility through the United Nations Environment Program, which has contributed over 3.6 million dollars to pilot national biosafety frameworks and to sponsor related activities worldwide.^[21,22]

LOOKING AHEAD

Biosafety presents new challenges to thinking about safe practices in the relatively new agricultural biotechnology industry, not the least of which are the myriad safety evaluations necessary for use of or exposure to such products in multiple spheres, including occupational and worker safety, environmental toxicology and chemical safety, environmental ecological safety, food safety, consumer safety, and medical or pharmaceutical safety. Assuring biosafety across these spheres may require more than expanded definitions and policy change. Effective and efficient safety evaluations for products that are derived from new biological technologies may require both a coordination of existing, diverse safety expertise, and the construction of new formal safety programs that

prioritize novel safety issues related to these products. This approach puts safety as a singular priority in the process of engineering—thinking systematically about the conception, implementation, and use of an engineered design in order to prevent harm; this includes, and goes beyond, risk assessment and management activities.^[23] The rich history of formal safety program advocacy and development in the previous century, which was in part motivated by intense social and philosophical debates, resembles current controversies that have fueled the expansion of the biosafety concept.^[24] Therefore, future activities that may provide governance and direction to biosafety programs in the agricultural biotechnology industry may closely resemble the formation of safety programs in other industries. For the agricultural biotechnology industry, the adoption of the expanded notion of biosafety principles and practices would represent an historical opportunity to contribute to new developments and discoveries in the safety engineering sciences.

Formal safety engineering programs in other industries that serve as models are those that work to establish safety standards and a framework for an industry-wide safety program for products using a process that utilizes the elements of criteria setting, verification, follow-up, and safety leadership.^a In criteria setting, safety criteria are developed to systematically analyze the possible harm of a product. This involves the rigorous identification of hazards, the assessment of risk, and planning to reduce risk. Establishing a complete and scientifically reliable set of safety design criteria rests on two requirements: establishing rigorous criteria at the outset of development of a new product and independently validating those criteria before they are used. Verification is the design of rigorous tests to fully challenge the product and credibly demonstrate that it meets the pre-set and government-approved safety criteria. Designing these tests requires the application of the best available scientific methodologies and information from all relevant fields. Follow up efforts require the setting of criteria and conducting of tests that verify the product continues to meet its safety criteria in commercial use. Open-minded and scrupulous monitoring of the product in all its uses is also required for effective follow-up; the discovery of problems needs to be followed up with meaningful and timely corrective action. Safety leadership assures the consistent and proper implementation of the criteria setting, verification, and follow-up procedures.

Safety leadership needs to occur in three areas. The first area is the establishment of rigorously trained and independently certified safety engineers who are valued employees of industry firms. The second area is the

^aFrom Ref. 23.

encouragement of a company management style that fosters broad thinking, application of the best scientific methodologies and information, self-imposed responsibility to make safe products, responsiveness to evidence of real hazards and problems, and independent review of all aspects of the product safety program. The third area is the creation of a framework for managing the application of industry-wide safety standards, including an independent audit function. Assuming that the trend toward safety-oriented management programs for plants derived using new biological technologies continues, the life science industries may adopt these elements of safety programs to form a more extensive framework for biosafety. By wedding such programs to a transparent, public deliberation process, we may better address the fundamental fears of consumers and achieve successful negotiations about when products are safe enough.

CONCLUSION

This section is an introductory review of the science and policy efforts that inform biosafety science and policies for plant crops derived from agricultural biotechnology, and includes speculation regarding future directions for this trend. Topics covered in this section include an overview of scientific research on risk issues specific to transgenic or genetically engineered crop plants, such as gene flow between such plants, the persistence of pesticides in soils that contain transgenic crop plant residue, management for insect resistance to pest-protected crop plants, and considerations for management of disease-resistant transgenic crop plants. In addition, a review of adaptive biosafety assessment and management principles and practices provides a model for biosafety management of transgenic crop plants that incorporates lessons learned from a wide array of scientific and political specializations.

Biosafety Approaches to Transgenic Crop Plant Gene Flow

Terrie Klinger

University of Washington, Seattle, Washington, U.S.A.

INTRODUCTION

Gene flow from transgenic (or GMO) crops to wild relatives will introduce transgenes into wild plant populations at rates in excess of those in the absence of the commercial release of GMO crops. Unintended introduction of transgenes confers potential hazard to agricultural ecosystems and to wild populations and the ecosystems in which they exist. Hazards associated with transgene introduction by gene flow can be eliminated only when the likelihood of crop-to-wild hybridization is zero. When the likelihood of hybridization is greater than zero, precautionary management approaches require the implementation of risk-averse strategies that appropriately minimize potential negative impacts to populations and the environment. Effective management strategies will take into account socially acceptable levels of risk, will incorporate uncertainty due to spatial and temporal variability in gene flow and to error associated with the estimation of gene flow, and will become increasingly precautionary as levels of uncertainty increase.

HYBRIDIZATION AND INTROGRESSION

Conventional crop plants are known to hybridize with their wild relatives where they occur within mating distance.^[1,2] That some transgenic (or GMO) crops are or will be capable of effecting similar crop-to-wild matings is undisputed. Only where hybridization is impossible (e.g., where crops and wild relatives do not co-occur) can the risks of hybridization and introgression be assumed to be nil. In all other cases, development of risk-averse strategies for the management of hybridization and its associated impacts is appropriate. It is important to note in this context that the apparent inability to hybridize (e.g., due to apparent incompatibility or sterility) does not necessarily confer an absolute or permanent inability to hybridize.

Hybridization between crops and wild relatives can lead to gene introgression and spread through wild populations. Introgression and spread are most likely to occur when the introduced traits confer a selective advantage, for example by increasing fitness due to higher

rates of reproduction or survival. Introgression can alter genetic structure within recipient populations, and in extreme cases can increase the risk of extinction in small populations.^[3] Where GMO crops are capable of hybridizing with weedy or wild plants, their introduction can lead to the introgression and spread of transgenes through non-target populations. Some traits introduced by transgenes are likely to be undesirable in wild populations. For example, the generation of herbicide-resistant weeds could negatively impact both wild and agricultural populations by altering competitive interactions in favor of hybrids. Other environmentally relevant traits could be conferred to wild plants through hybridization with GMOs, including traits such as increased drought or salt tolerance, or changes in mating success, life history traits, or competitive abilities. The accelerating use of GMO crops and the growing number of genetic constructs borne by individual GMOs increases the likelihood that multiple engineered genes will be introduced simultaneously or sequentially into wild populations. The occurrence of multiple introductions will substantially reduce our ability to predict the outcome of such introductions, because the complexity of the problem grows with the number of new introductions, and because interactions between multiple engineered genes in wild-type backgrounds are difficult or impossible to anticipate.

While hybridization does not always constitute a limiting step in gene introgression among plants, it does constitute an important first step in the introgression and spread of transgenes, and therefore is an important factor to consider in the development of risk-averse management strategies that seek to minimize the negative impacts of transgenes released into the environment. One essential element of such management strategies is the incorporation of uncertainty into the estimation of gene flow between transgenic crops and wild relatives.

FACTORS AFFECTING RATES OF HYBRIDIZATION

Numerous factors are known to affect rates of hybridization in plants. Genetic factors (genotype, mating system,

and compatibility between mates) and biological and physical aspects of populations and the local environment (size, shape, number, density and distance between donor and recipient populations, pollinator behavior and abundance, and spatial and temporal variability in physical factors such as temperature and rainfall) all can affect hybridization rates.^[4] Consequently, spatial and temporal variability in rates of hybridization can be quite high, hindering confident estimation of distance-dependent gene flow.

Distance-dependent hybridization rates typically are reported as estimated average values.^[5] However, high levels of variability in rates of gene flow render average measures inappropriate for management purposes, because average measures can dramatically underestimate maximum rates of hybridization,^[4] leading to substantial underestimation of risk and of potential adverse effects.

Several studies have described “hot spots” of hybridization among crop plants or between crops and wild relatives that could not have been predicted from average rates of hybridization (e.g., Refs. 4 and 6). Significantly, discrepancies between average and maximum rates of hybridization have been found to increase with distance between donor and recipient populations. For one case in which hybridization between cultivated and wild radish (*Raphanus sativus*) was studied in an agricultural field setting, observed maximum rates of crop-to-wild hybridization at 1000 m distance from the crop exceeded average hybridization rates by a factor of about 30.^[4] The same study found that the observed number of hybrid progeny at 1000 m distance from the crop exceeded the expected number of hybrids by a factor of about 315. These findings imply that actual rates of hybridization can exceed average rates by a substantial amount. Therefore, the use of average rates of hybridization in risk assessment is decidedly not risk-averse.

USING MODELS TO DESCRIBE HYBRIDIZATION

Numerical models have been used to describe the expected decay of hybridization rates with distance.^[7,8] For example, maximum likelihood techniques have been applied to problems of distance-dependent dispersal of pollen from source populations.^[9,10] However, these models require large amounts of case-specific data for adequate parameterization, and such data are unlikely to be available in most instances. Numerical models have yet to be successfully applied to situations in which multiple source populations contribute transgenes to one or more recipient populations, nor are they adequate to describe low-frequency but high-magnitude hybridization events that can lead to hot-spots of hybridization. Models might better be

used to help design monitoring programs than to predict hybridization rates; however, the choice of inappropriate models could bias the distribution of monitoring effort, leading to undetected impacts due to sampling error. Adequate management strategies require that policy decisions be made regarding levels of risk that are acceptable to society. Models used to develop management strategies must incorporate these policy decisions in addition to incorporating uncertainty in all model parameters.

RISK-AVERSE STRATEGIES

It must be assumed that crop-to-wild hybridization will occur wherever crops and wild relatives grow within mating distance. Hybridization between transgenic crops and wild populations will impose some degree of hazard, for example, through the displacement or extirpation of native species, or the alteration or loss of ecosystem function. Depending on their individual probabilities of occurrence, these potential hazards will confer risk to wild populations and the environment. Consequently, the most risk-averse strategy is to avoid planting transgenic crops in regions where they co-occur with wild relatives. Where this is impractical or undesirable for economic or social reasons, risk-averse strategies must be developed to account for uncertainty in rates of hybridization and introgression. In particular, it is important that management strategies become increasingly conservative as the amount of uncertainty increases, as the hazard posed by individual or aggregate engineered traits increases, and as the number of engineered traits or donor populations increases. Examples of risk-averse strategies include changes in cropping practices to decrease the potential for hybridization and changes in genetic engineering techniques to decrease the likelihood of gene transfer by pollen.

CONCLUSION

In a world where the human population is expected to increase by 50% over the next 75 years, the expanded use of GMOs to enhance crop production is extremely likely. Changes in human land use practices combined with the effects of global change will place additional and increasing stress on already burdened agricultural and wild ecosystems. These ecosystems will be highly susceptible to further disruption caused by the introduction of transgenic constructs into wild populations, and effects may intensify as the number and magnitude of interacting stressors grows.

Under these conditions, the management of risks associated with transgenic crops and other agricultural

products will become extremely important in protecting ecosystem function. A precautionary approach to management requires that management practices become adequately risk-averse *before* substantial negative effects are manifest in agricultural or wild ecosystems. Risk-averse management requires the development of policies that take into account socially-acceptable levels of risk concerning the function of agricultural and wild ecosystems. In addition, risk-averse management strategies must incorporate uncertainty in all parameters used to predict the likelihood of adverse effects of the use of GMOs in crop production.

INTRODUCTION

Transgenic insecticidal plants produce proteins that are toxic to particular groups of insects. In addition to killing pest insects feeding directly on the crop, they may affect non-target organisms that feed on litter from the crop or on nectar or pollen that expresses the toxins. Detrimental effects on non-target species have been documented, but no immediate catastrophic impacts have been identified. Although protocols have been developed to quantify impacts on non-target biodiversity, complete assessment of non-target effects will necessitate determination of changes in the ability of non-target organisms to perform ecological functions such as weed suppression, decomposition, and pollination. Losey et al. (this volume) focus on predators or parasitoids, and in this entry we discuss effects on direct consumers.

BACKGROUND

A wide variety of crops have been modified to produce insecticidal proteins derived from genes transferred from the bacterium *Bacillus thuringiensis* (Bt). Transformed corn, known as "Bt corn," is the most widely planted transgenic insecticidal crop in the world. Genetic material from different strains of *B. thuringiensis* produces toxins effective against different groups of insects. Currently, the only commercially available hybrids are derived from the Bt *kurtstakii* strain (Btk corn) and were developed for selected lepidopteran species that feed on aboveground portions of the corn plant.^[1] By 1999 over 6 million hectares of Bt corn was planted, and adoption reached at least this level in 2000 and 2001.^[2] Transgenic Bt corn is now the most common management tactic for the European corn borer, *Ostrinia nubilalis*, throughout the

United States. Corn hybrids transformed with genetic material from the Bt *tenebrionis* strain, which is active against coleoptera (beetles), are in the final stages of registration. If the new hybrids are approved, they appear destined for widespread use because corn rootworms (*Diabrotica* spp.) cause more damage than European corn borer and are the target of considerably more total kilograms of insecticide.

The potential benefits of transgenic insecticidal corn include reduction of resources devoted to scouting for pests, reduction in broad-spectrum insecticide applications, increased or protected yields due to season-long control of *O. nubilalis*,^[3] protection of stored corn from lepidopteran pests,^[4] and lower mycotoxin levels due to a reduction in fungal plant pathogens associated with *O. nubilalis* feeding.^[5] The varying magnitude of these benefits is discussed in.^[6]

Balanced against these potential benefits are possible negative aspects of growing these crops.^[6] In general, negative effects of genetically modified crops could include selection for resistance among populations of the target pest, exchange of genetic material between the transgenic crop and related plant species, and impact on non-target species. The negative impact on non-target species can be separated into direct effects on organisms that feed on living or dead corn tissue (e.g., herbivores, pollenivores, detritivores) and indirect effects on organisms that primarily prey upon those direct consumers (predators). The existence of these four functional groups illustrates the often underestimated complexity of the many agroecosystems and the multiple mechanisms for potential impact (Fig. 1). It is important to note that direct consumers provide invaluable ecological services including weed suppression, pollination, and decomposition, while indirect feeders contribute greatly to suppression of insect pests. Interference with these processes could lead to

Fig. 1 Functional groups to be considered for assessment of risk from Bt corn and their relationship to Bt corn. (Adapted from Ref. 6.)

increased competition from weeds or delayed breakdown in plant material, both of which could lead to lower yields.

INSECT HERBIVORES

Currently commercialized hybrids of Bt corn and cotton express toxins that are active against lepidoptera, and many herbivorous non-target species are likely to be directly susceptible. There are two major crops that express a beetle toxin: *Bt* corn and *Bt* potatoes. Since *Bt* corn is not commercially available and *Bt* potatoes have not been widely adopted as of this writing, we will focus primarily on effects on lepidopteran non-targets. However, it is important to note that many families of beetles contain species that may directly consume living or dead corn tissue. Many of the same protocols used to identify which species of butterflies and moths are most at risk may be effective for beetles as well.

Since lepidopteran herbivores that feed on corn plant tissue within the cornfield are considered “target pests,” we will consider non-target herbivores to be those species that may contact corn pollen on weedy plant species within fields or on plants outside of fields. Since cotton is not wind-pollinated, the small amount and low mobility of the pollen produced minimizes the potential of impact through pollen drift. It is important to note that different events of Bt corn produce variable amounts of toxin in their pollen, with some events expressing very little. The lepidopteran species most likely affected by Bt corn pollen can be determined by examining their distribution and phenology.^[7] Factors that will determine which lepidopteran species are most likely to be affected by pollen from *Bt* corn include the following: 1) which plant species grow in and around corn; 2) which lepidopteran species feed on those plant species; 3) temporal overlap

of corn pollen shed and larval feeding by the non-target lepidoptera; and 4) susceptibility of potentially affected species to the Bt toxin.^[7] Integrating distribution, phenology, and susceptibility can allow a ranking of the risk to specific lepidopteran species. Species that may be at particularly high risk could then be identified for further testing.

The monarch butterfly, *Danaus plexippus*, provides one example of how a species might be evaluated after it has been determined to be potentially at risk from *Bt* corn pollen. Observations that the monarchs’ host plant, milkweed, was common in cornfields and often exposed to pollen led to initial studies that confirmed the toxicity of the pollen to monarch larvae.^[8,9] Further studies determined that the risk of a short-term catastrophic impact on monarch populations was negligible based on the level of pollen on milkweed leaves and the temporal overlap of pollen shed and larval feeding.^[10] However, this study also points out the importance of assessing longer-term, more subtle impacts on monarch populations.^[10] Using a “coarse filter” such as the four-point one we propose above, other species that warrant more detailed ecological studies like those done for the monarch butterfly could be identified.

POLLINATORS

An assessment of the impact of each Bt corn hybrid on pollinators is required for EPA registration.^[11] Although the toxins expressed in Bt corn pollen are specific for lepidoptera, several studies raise questions about its effects on pollinators, i.e., domesticated and wild bees. In the registration documentation, pollen from Bt corn is reported to have no effect on survival of either larval or adult domesticated bees.^[11] However, unexpected effects of transgenic plants on domesticated bees have been reported. For example, a preparation of *Bt*, reported to be specific for coleoptera, caused significant mortality in domesticated bees.^[11] Proteins, other than Bt, produced in transgenic rapeseed pollen, targeted for coleoptera and lepidoptera, interfered with learning by domesticated bees.^[12] When toxins are not expressed in the pollen, the process of transforming a plant may reduce pollen output, lowering availability of an important food source to pollinators.^[13] These studies raise concerns about the precision of genetic transformations and unintended side effects of genetic transfers. In addition, although wild bees provide a substantial amount of the pollination in many systems, they apparently were not tested for Bt corn registration, and we are not aware of any studies that examined the impact of Bt pollen on wild bees.

DECOMPOSERS

The insecticidal toxin (CryIA(b)) found in one type of transgenic corn (event 176) caused significant mortality and reduced reproduction in the soil-dwelling collembolan, *Folsomia candida*.^[1] A previous study had shown no effects of feeding on transgenic cotton leaves by *F. candida*.^[14] The same insecticidal protein was present in both transgenic crops (cotton and corn); however, the higher dose in the corn appears to have caused the adverse effects. Even though the EPA reports this adverse non-target effect, they conclude that there is a 200-fold safety factor in the levels of toxin that would occur in the field.^[1] In addition, because no buildup of corn stalk residues have been observed following use of soil insecticides in cornfields, which presumably would have a negative effect on collembola, “an observable deleterious effect on the soil ecosystem is not expected to result from the growing of CryIA(b)-endotoxin-containing corn plants.”^[1] This conclusion may need to be reconsidered, because there are potentially important differences in the seasonal occurrence of soil insecticides (at planting) to that of transgenic Bt toxins (from roots,^[15] pollen deposition, and stalk residues at harvest) relative to the seasonal life cycles of collembola.

CONCLUSIONS

The results of studies on the direct effects of Bt crops on organisms that feed on crop tissues (e.g., living tissue, litter, pollen) are mixed. While no short-term catastrophic impacts have been identified, several impacts that warrant further study have been documented. Research up to this point has focused solely on relatively simple measures of the biodiversity of non-target organisms. The rapid adoption of Btk corn and the predicted equally rapid adoption rate for Bt corn as well as other transgenic plants make a complete assessment of both positive and negative impacts on non-target organisms imperative. A complete assessment of non-target impacts needs to include measures of how ecological functions (e.g., weed suppression, pollination, decomposition) are impacted by transgenic crops in comparison to how they are impacted by conventional pest management tactics.

INTRODUCTION

The range of transgenic insecticidal crops grown in the United States and the potential benefits associated with those crops have been outlined in Losey et al. (this volume). As noted by Losey et al., the negative impact on non-target species can be separated into direct effects on insects that feed on living or dead corn tissue (e.g., herbivores, pollenivores, detritivores) and indirect effects on organisms that are primarily predaceous or parasitic on those direct consumers. Losey et al. focus on direct consumers, and in this entry we focus on predators and parasitoids.

BACKGROUND

Transgenic insecticidal plants produce proteins that are toxic to particular groups of insects. In addition to their toxicity to herbivorous insects feeding directly on plant tissues, the engineered plants may affect predator and parasitoid species. The proteins may be directly toxic to predators and parasitoids that supplement their diet with pollen, nectar, or tissues such as roots. Simply feeding upon prey or hosts that have consumed insecticidal plant tissue also may be detrimental to both predators and parasitoids. Finally, reductions in predator and parasitoid populations may be linked to reductions in prey and host populations associated with insecticidal plants. The few empirical studies to date bearing on these issues have reported mixed results.

Previous research showing some negative effects of microbial insecticide formulations of *Bacillus thuringiensis* on natural enemy species^[1] indicates a need to assess the impact of Bt corn on populations of insect predators and parasitoids in the corn ecosystem.^[2] Numerous species of insect natural enemies attack both the European

corn borer, *Ostrinia nubilalis*, and the corn rootworm, *Diabrotica* spp., in North America. *O. nubilalis* natural enemies include several predatory species that tend to have relatively broad host ranges and several specific insect parasitoids.^[3] Although there are no significant parasitoids of corn rootworms, there are several important soil- and litter-dwelling predators that may be affected by transgenic Bt corn including carabid and staphylinid beetles, ants, spiders, and mites.^[3] In addition to preying upon corn rootworm, carabid and staphylinid beetles are also known to consume the lepidopteran corn pests: black cutworm, armyworm, fall armyworm, common stalk borer, and European corn borer.^[3] Transgenic corn may affect natural enemies via three modes: 1) direct feeding on corn tissues, e.g., pollen, roots; 2) feeding on hosts that have fed on corn; and 3) through reductions in host populations.^[4] Data submitted for governmental registration of transgenic crops appear to focus primarily on the first mode.^[5]

INSECT PREDATORS

Several species of insect predators that attack the corn borer also feed on corn pollen (Table 1). Direct consumption of transgenic corn pollen by immature stages of three predatory species commonly found in cornfields did not affect development or survival.^[6] However, increased mortality of lacewing (*Chrysoperla carnea*) larvae, which may consume pollen, was observed when *C. carnea* larvae fed on artificial diet containing Bt toxin.^[7] Predator species may consume other corn tissues as well. Many carabid species which are primarily predators, such as *Stenolophus comma* and *Clivina impressifrons*, also feed directly on plant roots and tissues.^a However, there

<i>Erioborus terebrans</i>	F	0	Parasitism of larval hosts on non-transgenic plants within transgenic plots	10

(Adapted from Ref. 2)

are no data bearing on the effects of Bt corn tissues on these organisms.

There is also little data on indirect consumption of Bt toxins through prey or hosts that have fed on Bt corn. Lacewing larvae that preyed upon corn borers or other lepidopteran larvae that had fed on transgenic corn show increased mortality,^[7] but similar developmental times and survival rates were observed when the predator *Ori-*

usmajusculus was fed a thrips species that had been reared on either Bt or non-Bt corn.^[8]

Negative effects on invertebrate predators have not been documented in the field (Table 1); sampling from transgenic and non-transgenic cornfields has detected no differences in predator abundance.^[9,10] In one field study, higher numbers of predators were observed in Bt cornfields (Table 1). However, in a two-year field study,

abundance of the parasitoid species *Macrocentrusciculum* (previously *Macrocentrusgrandii*), specific to corn borer larvae, was lower in Bt cornfields in Iowa^[10] (Table 1). This reduction is expected because of significant reductions of larval hosts in Bt corn. The abundance of a second parasitoid species, *Erioborusterrebrans*, may also decline in transgenic fields due to the lack of corn borer hosts, although a field study reported no effects of transgenic corn on *E. terrebrans* parasitism.^[9] In Orr & Landis,^[9] relatively small non-transgenic plots, were planted within larger transgenic plots, and *O. nubilalis* larval hosts were parasitized in these non-transgenic plants. Effects of Bt corn on *E. terrebrans* parasitism may only be detectable in field studies conducted on a larger scale.

The potential trophic-level effects of Bt corn on vertebrate predators also should be considered in an ecological assessment of this biotechnology because bats and birds are known to prey on larvae and adults of several lepidopteran corn pests. Feeding Bt toxin directly to bobwhite quail for 14 days showed no effect on the quail.^[5] We are not aware of any studies that have considered the indirect effects on bird populations resulting from declines in *O. nubilalis* densities following use of transgenic corn. However, if lepidoptera and their predators and parasitoids are significantly reduced in Bt cornfields and adjacent margins, we might expect the insect prey available for birds, rodents, and amphibians to decrease (see Ref. 11 for a simulation of the potential effects of herbicide-tolerant crops on seed-eating birds).

Long-term field studies are needed to determine if the widespread planting of transgenic corn creates an “ecological desert” with relatively few hosts for natural enemies. This type of ecological pattern has been observed following the overuse of insecticides or regional planting of highly resistant crop varieties.^[12] The interactions among natural enemy and pest populations will likely occur within a mosaic of transgenic and non-transgenic cornfields, due to the current requirement for non-transgenic corn refugia to maintain susceptible corn borer populations. If corn borer densities are significantly suppressed by the use of transgenic corn, it might follow that significant reductions in natural enemy densities will occur, which may influence the rate of development of resistant pest populations.^[13] Natural enemies currently cause substantial levels of mortality of the corn borer.^[14] If this level of mortality were reduced and corn borer populations developed resistance, the result could be higher densities of the corn borer. Thus, negative impacts on natural enemies raise the possibility that overuse of transgenic corn could lead to the types of resurgence and secondary pest outbreaks that are associated with misuse of synthetic broad-spectrum insecticides.

CONCLUSIONS AND RECOMMENDATIONS—CONSIDERATIONS OF THE RISKS AND BENEFITS OF Bt CORN

Clearly more data are needed on the potential impact of Btk and Bt corn on predators and parasitoids. Studies on direct consumption of corn tissues are the simplest to carry out, but impacts mediated through the consumption of toxic prey or reductions in prey densities may have equal or greater importance in the field. Predicting the impact of future transgenic crops is difficult based on current studies because virtually all available data regarding impacts on predators come from Btk corn, which targets butterflies and moths (Lepidoptera), essentially none of which are predaceous. Impacts seem more likely in Bt corn since the toxin affects beetles, the largest and most important group of predators. The greater risk to predators associated with Bt corn highlights the need for a functional approach to assessment of non-target impacts. Important aspects of a functional assessment of predator impact would include field-level measures of predation rate and pest population suppression. Understanding the interaction between biological control and biotechnology will greatly facilitate the integration of these two important pest management strategies and increase the probability of avoiding the problems associated with the rapid adoption of pesticides.

Biosafety Programs for Genetically Engineered Plants: An Adaptive Approach

Anne R. Kapuscinski

Emily E. Pullins

University of Minnesota, St. Paul, Minnesota, U.S.A.

INTRODUCTION

Biotechnologists are rapidly diversifying the kinds of genetically engineered plants under development and production, thus offering a range of potential benefits to farmers and consumers. Approaches to the characterization, analysis, and deliberation of risks associated with genetically engineered plants have steadily improved with the development of the technologies and products themselves. This chapter reviews how lessons learned in environmental management, as well as in recent deployments of genetically engineered crops, are motivating a shift from single-plant risk assessment and management to more comprehensive and adaptive biosafety programs, within which traditional risk assessment and management tools are embedded.

ADAPTIVE BIOSAFETY PROGRAMS

Biosafety programs for genetically engineered plants should employ recent advances in environmental management of living organisms, such as grasslands, forests, and fisheries. According to recent reviews,^[1,2] environmental management programs that have failed to meet their economic and environmental objectives have made four major errors. They: 1) largely ignored critical ecological interactions, 2) assumed that surrounding environmental conditions would remain fairly constant, 3) did not undertake long-term monitoring, and 4) considered only very narrow temporal and spatial scales. Biosafety management programs for genetically engineered plants can avoid these errors, many of which were recognized in a report on the environmental effects of transgenic plants.^[3]

The carefully examined cases of failure in environmental management of living organisms show that the responsible institutions and the users were sometimes blind-sided by surprising social and ecological feedbacks in the system or, to use the terminology of Senge,^[4] “fixes that backfire.” Analyses of such failures have led to a major rethinking of the problems that environmental policies attempt to solve^[5] and have contributed to the shaping of adaptive management or adaptive environ-

mental assessment and management approaches promulgated by Holling^[6] and developed by Lee,^[7] Walters,^[8] and others.

These approaches are “adaptive” because they are designed to increase the chances that users and managers of a resource will consider all the relevant knowledge and experience before approving a proposed action and will detect and learn from expected and unexpected effects, which could be beneficial or harmful effects, as rapidly as possible even when there is a time lag in manifestation of the effects. These approaches are “adaptive” also because they include mechanisms to increase the ability of the responsible institutions and users to revise decisions in light of what they learn. In our case, the resource under management would be a particular genetically engineered plant produced in one or more kinds of agroecosystems, followed by the harvested whole plant, plant parts, or processed products being distributed through various public and marketing channels. The responsible institutions and users would be groups such as biotechnology companies, seed companies, farmers, food processors and retailers, government regulators, consumer groups, and environmental and other public interest groups. Implementation of an adaptive biosafety program could confirm the predicted environmental safety of producing the genetically engineered plant in a particular agro-ecosystem. This suggests it may be possible to reduce safety management controls over its production. Alternatively, the adaptive biosafety program might detect an unexpected environmental harm, triggering the need to revise controls over its production or, in the few cases where the harm may be severe and irreversible, to halt its production.

STEPS OF ADAPTIVE BIOSAFETY ASSESSMENT

Figure 1 represents the basic steps involved in adaptive biosafety assessment and management. These are summarized below and more fully elaborated in a proposed framework of adaptive biosafety assessment and management by Kapuscinski et al.^[2] This framework builds on

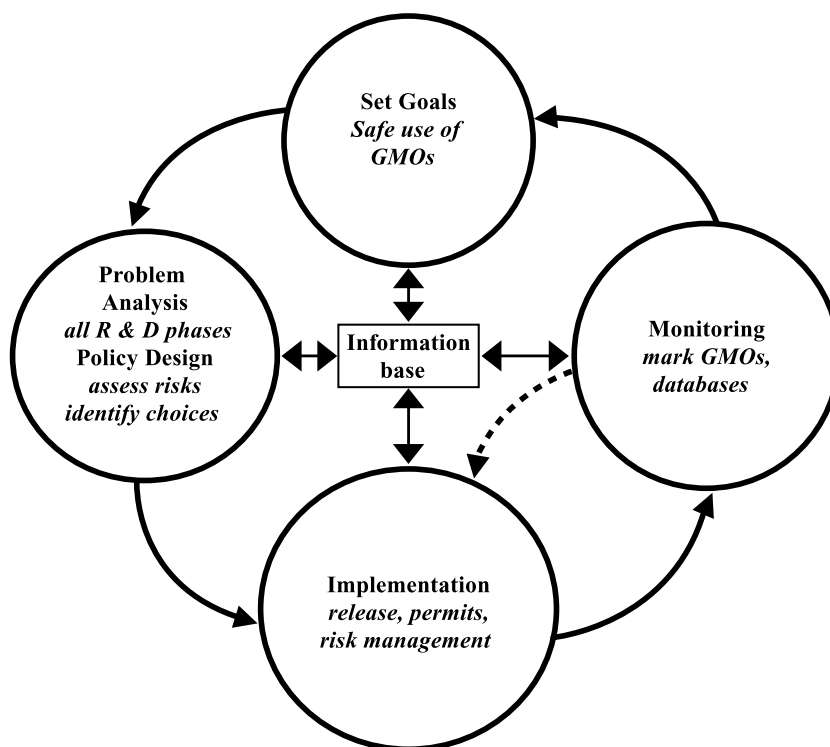

Fig. 1 The interconnected phases of adaptive biosafety assessment and management for uses of genetically engineered organisms (GEOs) in diverse societal-environmental systems. These phases should be applied iteratively and across multiple spatial scales from the local to global, with adequate provisions for information exchange among people implementing biosafety policies at different scales. (From *Genetically Engineered Organisms: Assessing Environmental and Human Health Effects*, CRC Press, New York, 2002.)

the essential, systematic steps of risk assessment and risk management that are part of biosafety assessment of genetically engineered organisms (GEOs).^[9]

Goals

Adaptive biosafety assessment and management begins with clear identification and statement of biosafety goals. At a minimum, goals should aim to anticipate/determine ecological risks posed by a given GEO and discern whether the GEO will yield the benefits it was designed to provide.

Problem Analysis and Policy Design

This stage of the adaptive biosafety framework involves clear definition of the ecological and social problems associated with attempts to meet stated goals. It involves bringing together disciplinary specialists and theorists and resource users, with knowledge about the social and environmental contexts of the problems. This group considers a range of objectives, from unchecked release to a complete ban on uses of specific GEOs. Though these extremes may be unrealistic, they nonetheless provide the

limits within which any realistic objective would fall; thus, they help the group to choose among policy options for testing.

Implementation

The biosafety policy action chosen for a particular kind of plant GEO should be implemented at the spatial and political scales likely to be impacted by the GEOs at issue. Local, national, and regional laws and regulations and international agreements, such as the Cartagena Protocol on Biosafety, may come into play to govern release and trade of specific GEOs. A comprehensive set of biosafety policies with coordination between the international and national scale would include measures for management of risks that cross spatial and political boundaries (following assessment of these risks at the problem analysis phase), biosafety capacity building programs, national permitting of trade and uses of GEOs (based on assessment and management of risks that might occur at the national or subnational scale), advanced informed agreements on transnational trade of GEOs, and an international system of liability and compensation for addressing cases in which harms occur.

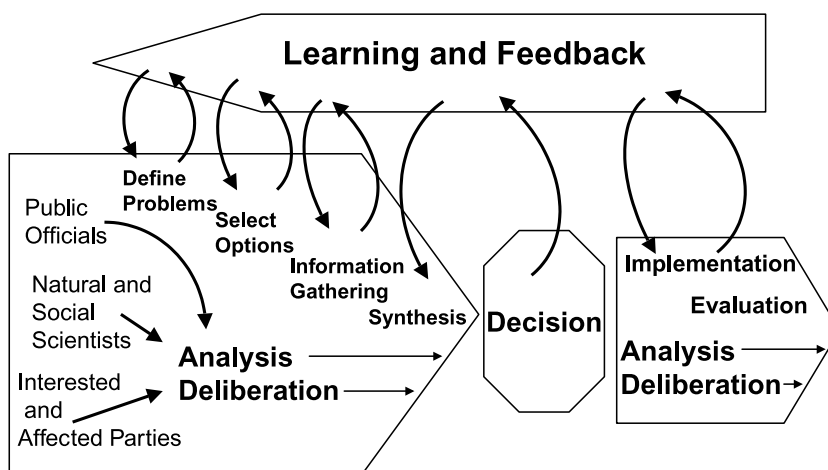

Fig. 2 The risk decision process. (From Ref. 15.)

Monitoring

An adaptive approach requires that, once a GEO is approved for large-scale use, there is a systematic, technically and financially feasible plan in place for postrelease monitoring. The plan would stipulate indicators and variables to be monitored, as well as agreed upon threshold limits of ecological change, derived from the biosafety objectives for case-by-case combinations of the genetically engineered plant and agro-ecosystems where it may end up.^[4] Planning should include the selection of sampling designs for the monitoring of GEOs that reduce statistical errors that over- or underestimate the risks of a GEO, including estimating the costs of such improved sampling designs, and the selection of identification technologies for GEOs and their products, potentially at the molecular level (e.g., Ref. 10). A project to measure the effects on nontarget grassland bird species of changes in patterns of herbicide applications in fields planted with herbicide-tolerant soybeans exemplifies monitoring for indirect ecological effects of genetically engineered plants.^[11]

As long as monitoring data indicate “normal” system behavior, the adaptive cycle runs between implementation and monitoring (depicted by the dotted line in Fig. 1). When monitoring indicates “abnormal” system behavior, the resulting data are used to review and, if deemed necessary, redefine goals, then to reanalyze problems, next to review and revise implementation, and finally to revise monitoring accordingly.

Information Base

The information base serves as a “source and sink” of the best available knowledge for each phase of the adaptive biosafety cycle. Continual updating and consultation of the information base also helps to bypass or shorten the time spent at each phase by ensuring that lessons learned

from past experiences are incorporated into revised policies and by highlighting what remains unknown. Through continual interaction with the information base, adaptive biosafety programs can continually unravel uncertainties and adaptively reformulate policies. This kind of actively adaptive biosafety assessment and management provides the most effective way for humans to address the uncertainty inherent to the interconnected natural and social systems.^[1,7] A recent example is the inclusion of new information in the assessment and management of risks of particular Bt corn varieties in interaction with Monarch butterflies; innovative research methods and varieties with altered trait expression resulted in the identification of commercial varieties that have improved environmental biosafety.^a

CONCLUSION

The above five steps serve to strengthen the scientific reliability, technical efficacy, and institutional responsiveness of a biosafety program. But the success of biosafety programs depends equally on winning and sustaining public trust in decisions made under them. Thus, adaptive biosafety programs need to utilize transparent decision-making processes and involve deliberation among potentially affected and interested parties at critical points in decision-making (Fig. 2). Implementation of the various stages of the adaptive cycle should involve political and regulatory decision makers, appropriate disciplinary specialists, methodologists, people with experiential knowledge about the social and environmental conditions, and all affected parties (e.g., Ref. 13). This kind of civic engagement in the development of the

^aSee five articles in Special Edition Section of Ref. 12.

knowledge base and implementation of biosafety policies can ensure that all phases of adaptive biosafety are broadly understood, built upon all relevant knowledge, and responsive to the concerns of the affected parties.^[14] Although even the best designed analytic-deliberative process cannot eliminate all controversy, this kind of transparency has been shown to increase the public's trust in diverse cases of risk decision-making.^[15]

Biosafety Science: Overview of Plant Risk Issues

L. L. Wolfenbarger

University of Nebraska, Omaha, Nebraska, U.S.A.

P. R. Phifer

U.S. Fish and Wildlife Service, Portland, Oregon, U.S.A.

INTRODUCTION

Biosafety science endeavors to assess the human health and environmental risks associated with the creation and release of a genetically engineered organism into the environment.^[1] Plant risk issues associated with the introduction of genetically engineered crops have been discussed extensively,^[2-4] and these generally focus on how engineered crops may impact biodiversity and biotic interactions in ecosystems as well as genetic diversity within populations and species. There are three broad categories of risks that might cause adverse changes in biodiversity and in biotic interactions in ecosystems: potential invasiveness, non-target effects, and new viral diseases. The likelihood of these risks will vary according to the trait engineered, the crop variety, the environmental conditions, and the surrounding ecosystem.

POTENTIAL INVASIVENESS

Humans have a long history of introducing plants for horticultural or agricultural purposes. Sometimes these practices include introducing species into non-native habitats or introducing new varieties or cultivars into an existing range. The vast majority of the nonindigenous species and novel cultivars are benign or beneficial when introduced. A small percentage of these, however, known as invasive species, spread widely in their non-native ecosystems and cause substantial environmental harm.^[5] Invasive species can degrade natural ecosystem functions and structure and are categorized as one of three most pressing environmental problems, along with global climate change and habitat loss,^[6] that cost an estimated \$137 billion annually in the United States alone.^[7]

A novel trait introduced into plants through artificial selection or genetic engineering has the potential to produce changes that enhance an organism's ability to become an invasive species. Ultimately, it is the individual plant's novel phenotype(s) and its interactions with the surrounding biotic and abiotic environment that determine whether it will become invasive. These interactions involve existing opportunities within the environment for

unintended establishment (e.g., a currently stressed ecosystem may be more susceptible to invasion), and the persistence and gene flow of the introduced organism. Each interaction, in turn, depends on various components of survival and reproduction of the organism or its hybrids. Given the multiple elements involved in the establishment of a new invasive species, it is difficult to predict with significant confidence whether an introduced organism will become invasive.

NON-TARGET EFFECTS

Direct Effects on Survivorship and Reproduction

Like other potential stressors introduced into the environment, genetically engineered crops have the potential to affect the survival and reproduction of non-target species. For example, transgenic crops with insecticidal properties may have lethal or sublethal effects on non-target insects. Peer-reviewed studies have focused on the effects of Bt corn on a small number of insect species,^[8] particularly two species of butterflies: the monarch (*Danaus plexippus*) and the black swallowtail (*Papilio polyxenes*). The work on butterflies indicated that effects on survivorship and larval growth vary according to the transformation event (type of Bt corn) and species.^[9,10] Some genetically engineered crops and microorganisms have been shown to affect soil ecosystems.^[11,12] No published studies have examined the significance (if any) of these differences or transient changes with an experimental design that mimics standard practices used with a transgenic organism compared to nontransgenic alternatives. However, lethal and even sublethal effects at the individual level can destabilize the population dynamics of species and the function and structure of ecosystems.^[13]

Non-target effects have traditionally been identified using laboratory tests on representative organisms to identify standard measures of toxicity (e.g., LD50, the dose at which 50% of subject organisms die). However, these laboratory tests may not always accurately represent

complex ecological systems, creating the need for extensive field studies.^[18]

Indirect Effects Caused by Bioaccumulation

Genetically engineered crops have the potential to indirectly impact populations of species whose survival or reproduction depends on the pests or weeds controlled. For example, population models suggest that more effective control of weeds by using herbicide-tolerant crops could lead to lower food availability for birds specializing on seeds.^[14]

Large-scale use of insecticidal pesticides is known to disrupt ecological interactions within naturally occurring biological control systems^[15] and a similar risk exists for genetically engineered crops that produce proteins with insecticidal properties. Specifically, genetically engineered crops with insecticidal properties may cause indirect non-target effects if bioaccumulation of pesticidal proteins can occur as predators consume prey items that contain these proteins. Such negative tri-trophic-level effects in the laboratory have been reported for the green lacewing (*Chrysoperla carnea*) reared on prey that have fed on Bt corn,^[16] but field studies have not been conducted to quantify what typical exposures to such prey items may be. Knowing the effects of pesticidal proteins on the survivorship and reproduction of organisms at multiple trophic levels of the food chain as well as understanding the fate and transport of these proteins are key components to understanding the potential for non-target effects.

While the detailed discussion here has focused on transgenic plants with insecticidal properties, any biologically active transgenic product will have the potential to have lethal or sublethal, direct or indirect effects on non-target organisms. In the future these could include crops that produce pharmaceuticals, vitamins, nutrients or micronutrients, or compounds that are novel for plants used for industrial purposes (e.g., polymer or oil production).

NEW VIRAL DISEASES

Viruses with new biological characteristics could potentially arise in transgenic virus-resistant plants through recombination and heteroencapsidation. Recombination dominates viral evolution^[17] and has been observed in a wide range of viruses, including regions encoding the capsid protein,^[18] which is a commonly engineered product for transgenic plants. The presence of viral coat protein genes in transgenic plants offers the opportunity for recombination between incoming viruses and RNA transcribed by viral coat protein genes. Recombination between the transgene's mRNAs and RNA of "challenge

viruses" can drive the development of chimeric genomes that contain segments of two distinct RNA species. Such events may generate a virus with properties that differ from either progenitor virus.

Laboratory studies show that recombination does occur between a viral genome and RNA from viral sequences present in transgenic plants.^[18] Yet, researchers have noted the uncertainty in predicting the effects of recombination on symptomatology and on alterations of host ranges,^[19] as well as the need for broad field experimentation to provide realistic assessments about the types of recombinants that might emerge, the frequency of emergence of novel viruses, and what steps can be taken to minimize the appearance of virulent recombinant.^[20]

Heteroencapsidation of viral nucleic acids by transgenic coat proteins could also create new viral strains, but they would not propagate because the genome would not code for the transgenic coat protein.

The actual ecological significance of any viral change depends on what impacts it causes in natural habitats and communities. Impacts could occur directly if new ecological niches for viruses change plant communities in a negative way, or indirectly if these viruses create epidemics that alter agricultural practices that increase negative ecological effects.

CONCLUSION

The risks associated with genetically engineered plants will vary spatially, temporally, and according to species and cultivar and to the ecosystem encountered. These risks include risks from potential invasiveness, non-target effects, and new viral diseases. As more organisms, including genetically engineered organisms, are introduced into non-native environments around the globe, the possibility increases that these organisms will come in contact with sensitive or susceptible plant species or habitats, thereby, elevating risk. Our ability to determine the risks plant species and communities face from the products of genetic engineering, however, is similar to our ability to predict the risks associated with the introduction of a novel, conventionally produced organism. This ability is imprecise, given the complexity of the organism and the environment into which it is introduced, and further efforts to improve these risk assessment abilities are needed.

Boron

Patrick H. Brown

University of California, Davis, California, U.S.A.

INTRODUCTION

Though boron (B) has been recognized as an essential plant element for 80 years, it was only in the late 1990s that significant advances were made in understanding the metabolism of B in plants. Primary among these advances has been the determination of the chemical form and function of B in plant cell walls, the identification of the role of polyhydric alcohols in transport of B in the phloem, and the characterization of the processes of transport of B across membranes. Boron is now known to be essential for cell wall structure and function, probably through its role as a stabilizer of the cell wall pectic network and subsequent regulation of cell wall pore size. Boron uptake and transport is unique among the essential plant nutrients. At adequate levels in the soil B passively permeates the plasma membrane through aquaporin type channels and direct membrane diffusion. At low levels of B supply, carrier-mediated transport may occur. The transport of B within a plant is unique in that species differ markedly in mobility of B in the phloem. This phenomenon is now well understood and has resulted in novel molecular approaches to enhance plant tolerance of environments that are deficient in B. The discovery that B is essential for animals (which lack a cellulose-rich cell wall) suggests that B has additional, undetermined, functions in biology. Careful consideration of the physical and chemical properties of B in biological systems, and of the experimental data from both plants and animals suggests that B plays a critical role in membrane structure and hence function.

UPTAKE

Boron is essential for plant growth. Even brief reductions in availability of B to roots, particularly during reproductive growth, have a profound effect on plant growth and productivity. Boron is also present at toxic levels in many arid soils, and many agricultural species are sensitive to high levels of B in soils and waters. Understanding the biology of B uptake by plants is therefore critical to the management of B in natural and agricultural systems. Boron is present in the environment and acquired by plants, as the uncharged molecule H_3BO_3 , for which there is no useful radioisotope. B also rapidly forms variably

stable complexes with a wide range of biological molecules. These characteristics have long hampered research into the mechanism of B uptake. It was only in 2000 that new methodology and experimentation provided the first direct measurement of membrane permeability of B and demonstrated that B permeates passively through aquaporin-type channels and directly through the plasma membrane. Theoretical calculations suggest that passive B permeation can satisfy plant B needs at adequate levels of B supply but would be inadequate at conditions of marginal B supply. The hypothesis that an active, carrier-mediated process is involved in B uptake at low B supply is supported by considerable experimentation; however, no specific carrier proteins have been characterized and no genetic mutants lacking in B uptake have been identified.

A model of B acquisition by plants is provided in Fig. 1. At adequate to excessive levels of B supply, both passive transmembrane permeation and channel proteins provide B uptake. Small differences in membrane permeability coefficients probably contribute to species variation in B uptake. At lower levels of B supply ($<1.0 \mu M$), passive B permeation appears to be inadequate to satisfy B demand, and uptake may be facilitated by an inducible, active carrier system.

PHLOEM TRANSLOCATION

Boron is unique in that species differ dramatically in their capacity for transport in the phloem. In the majority of plants, B has restricted phloem mobility, while in species that produce polyols (sorbitol, mannitol, dulcitol, etc.), B is readily translocated in the phloem to satisfy the demands for B in growth.^[1] Due to these differences in phloem transport, B toxicity symptoms are also fundamentally different among these plants. Non-polyol-producing plants show burning of the tip and margin of old leaves under B toxicity, while in the polyol-producing species these symptoms are absent and toxicity is expressed as meristematic dieback.^[2] The ability to remobilize B from old to young leaves in polyol-producing species reduces the occurrence of transient B deficiencies and provides remarkable tolerance of short term B deprivation. Species that do not transport B in the phloem are very sensitive to short term B deprivation. Tobacco plants genetically

Fig. 1 Model of H_3BO_3 across plant membranes. 1. Passive B transport by transmembrane diffusion. Undissociated boric acid diffuses directly through the plasma membrane and is influenced by the permeability coefficient, membrane source (plasma membrane, tonoplast membrane) and the concentration gradient. 2. Channel-mediated B transport through porin-type channels. Evidence for B transport through channel proteins was derived from experiments with channel blocking mercurials and from experiments in which the porin-type channel proteins (PIP 1, 1a, 2a, 2b) expressed in the *Xenopus* oocyte system resulted in a 30–40% stimulation in B uptake. 3. Proposed inducible carrier-mediated transport. Preculture in the presence of $1\mu M$ H_3BO_3 stimulates synthesis of carrier-mediated H_3BO_3 transport. Km values for H_3BO_3 transport of $2\mu M$ (*Chara nitella*) and $15\mu M$ (*Helianthus annuus*) have been determined. (View this art in color at www.dekker.com.)

engineered to produce sorbitol exhibit a marked increase in within-plant B mobility and a resultant tolerance of B deficient conditions. The development of enhanced tolerance of B deficiency in transgenic tobacco was the first effective manipulation of a plant nutrition character.^[3]

BORON FUNCTION AND DEFICIENCY SYMPTOMS

Boron deficiencies occur widely and have a significant agronomic impact throughout the world. Deficiency symptoms include the inhibition of apical and extension growth, necrosis of terminal buds, cracking and breaking of stems and petioles, abortion of flower initials, and shedding of fruits. Boron deficiency also causes many physiological and biochemical changes including altered cell wall structure, altered membrane integrity and function, changes in enzyme activity, and altered production of a wide range of plant metabolites. The essential function of B in plants was not established until 2001, when it was demonstrated

that B is critical for the formation of the plant cell wall and hence essential for plant growth.^[4] Though B's role in plant cell walls is inadequate to explain all of the observed effects of B deficiency seen in plants, there is currently no definitive evidence to suggest that B plays a specific role in any other metabolic function in plants.

A role for B in the cell wall of plants has long been predicted on the basis of several historical observations and broad interpretations of anatomical observations under B deficiency. It is well known that B is essential for organisms with carbohydrate-rich cell walls and symptoms of B deficiency suggest that B plays an important role in the cell wall. A B-polysaccharide complex was isolated from radish roots in 1993 and subsequently identified as rhamnogalacturonan-II (RG-II). In plant cell walls, RG-II is present predominantly as a dimeric molecule (dB-RG-II), in which two chains of monomeric RG-II (mRG-II) are cross-linked by a 1:2 borate ester with two of the four apiosyl residues of RG-II side chains. There is no compelling evidence to suggest that B is directly involved in the synthesis of cell wall material because no decrease in the production of pectic substances or cell wall precursors is observed under B deficient conditions. Experimental evidence does suggest, however, that B influences the incorporation of proteins, pectins, and/or precursors into the existing and extending cell wall.

A hypothetical scheme for the role of B in cell walls is provided in Fig. 2. In this hypothesis the formation of dB-RG-II influences plant growth and metabolism through its effect on wall pore size. Under adequate B conditions, the formation of dB-RG-II is critical for optimal pore formation. The pore size in the cell wall affects the passage of large molecules such as proteins (including wall-modifying enzymes), influences the transport of precursors to sites of cell wall deposition, and optimizes the environment that is probably critical for normal processes of wall development and cell growth. In the absence of adequate B, pore size is increased and the processes of cell wall deposition and growth are disrupted.

A function for B in cell walls is inadequate to explain all observed effects of B deficiency. Evidence now suggests that B probably plays a role in membrane structure and function. This hypothesis is supported by the observation that B deficiency disrupts membrane transport processes and alters the composition of the cell membrane. Boron deficiency in animals disrupts processes that are highly membrane-specific or that require synthesis of new membranes. It has been proposed that B plays a specific function in cellular membranes through its role in the formation and function of membrane rafts, as illustrated in Fig. 3.

Plant membranes contain a variety of hydroxyl- and amine-containing constituents with the potential to form complexes with borate. These include sugars (e.g., galactose and mannose) and amino acids (e.g., serine and

Fig. 2 Hypothetical scheme illustrating the role of B on cell wall pore size and function. Under adequate B conditions (+B in diagram), the formation of dB-RG-II is critical for optimal pore size formation and as a consequence affects the normal cell wall passage of large molecules including proteins (wall-modifying enzymes), influences the transport of cell wall precursors to sites of cell wall deposition, and optimizes the cell wall environment critical for normal processes of wall development and cellular growth. In the absence of adequate B (-B in diagram), pore size is increased and the normal processes of cell wall deposition and growth are disrupted. (View this art in color at www.dekker.com.)

tyrosine). These potential B-binding molecules are particularly abundant in membrane rafts, which are functionally discrete and physiologically active membrane subdomains. Membrane rafts are thought to have a specific physiological role in membrane signal transduction and to serve as the sites for glycosylphosphatidyl-inositol (GPI)

protein association. Boron deficiency disrupts the incorporation of GPI proteins into the cell membrane. Boron may therefore have a specific function in cellular membranes through its role in the formation, stability, and function of membrane rafts.^[6] Perhaps the most significant finding of recent years does not relate to the role of B

Fig. 3 Model indicating proposed function of boron (B) in cell membrane structure and function. The liquid ordered phase of a membrane raft is delineated by the black line. The exoplasmic leaflet is enriched in glycosphingolipids (G), sphingomyelin (S), and glucosylphosphatidyl-inositol (GPI) anchored proteins. The inner leaflet is shown to contain glycerolipids (L). It is hypothesized that B may attach to mannose-rich domains (M) of GPI proteins or to sugars in the glycolipid headgroups, thereby influencing chemical or physical membrane characteristics. (Adapted from Ref. 5.) (View this art in color at www.dekker.com.)

in plants but rather the observation that B is essential for animals. This discovery clearly implies a broader role for B in biology that has yet to be determined.

CONCLUSION

Though our understanding of the biology of B has developed dramatically, much still remains uncertain. Of all the effects of B on plant biology, none is more significant, or more puzzling, than the unique sensitivity of all species to B deficiency during reproductive growth. This is particularly significant since 80% of all agricultural production is based on reproductive structures. Recent advances in our understanding of B uptake by roots, B function in cell walls, and B transport within the plant provide a framework within which we can now attempt to discern the role of B in reproductive growth. Advances in quantification of B and in the use of stable isotopes will facilitate this research, as will breakthroughs in the molecular regulation of flowering. These approaches provide researchers with a means to induce flowering in a predictable pattern and to dissect the possible role of B through careful utilization of the host of available flowering mutants and molecular techniques.

Breeding Biennial Crops

I. L. Goldman

University of Wisconsin, Madison, Wisconsin, U.S.A.

INTRODUCTION

Biennial plants require two seasons of growth to complete their life cycle. The breeding of biennial crops typically involves crop or propagule production during the first season of growth, followed by a vernalization period in controlled environment and a subsequent flowering and hybridization period in either controlled environment or the open field. Thus, breeders of biennial crops have at least two opportunities to evaluate the quality of the crop: at the end of the first season's growth and after the vernalization period. In this way, biennial crop breeding allows breeders to evaluate crop quality and productivity in the field and to further refine their selections after evaluating storage traits during the vernalization phase. Biennial crop breeding may be compressed into an annual cycle if controlled environments are used; however, in many cases two full seasons are required for a single breeding cycle, making it a more time-consuming process than the breeding of annual crops.

BREEDING METHODS FOR BIENNIALS

Perhaps the most important innovation for breeding biennial crops was the introduction of controlled environments. The use of greenhouses and growth chambers, beginning in the early part of the 20th century, allowed plant breeders to compress the two-season life cycle of a biennial plant into a calendar year. This, in turn, greatly facilitated breeding procedures and allowed for greater gains from selection as well as enhanced precision in hybridization. One of the first uses of this procedure was in the cabbage breeding program of J.C. Walker at the University of Wisconsin. Dr. Walker made use of greenhouses during the winter months to allow for the flowering and hybridization of cabbage plants during the development of yellows-resistant cabbage.^[1] The use of greenhouses for breeding allowed Walker to reduce the amount of time it took to develop improved cabbage germplasm by one-half. Furthermore, the use of a controlled environment such as a greenhouse allowed for precise pollen control and improved seed set, which are crucial to the success of any breeding program.

Breeding programs for biennial crops, such as those for vegetable crops, use the first season of growth to produce the crop or propagule. In this discussion, propagule is synonymous with crop because the crop itself is later used as the propagule for seed production. For example, in the case of a crop such as carrot, the crop and the propagule are one and the same. In temperate regions, crop production may take place during the spring and summer months, so that by the end of summer or the beginning of autumn the crop is harvested and ready to be vernalized. Vernalization then takes place under controlled environment for a specified period, often coinciding with autumn. Following a suitable period of vernalization, plant propagules are brought into growth chambers or greenhouses where they are placed under long days and allowed to flower. Hybridization and seed production take place during this period, usually coinciding with winter and early spring. Thus, by the end of the pollination and seed production season, the biennial life cycle has been compressed into a single calendar year for the purpose of efficiency.

This scheme requires a vernalization chamber or access to a climate in which propagules can successfully overwinter outside, as well as access to greenhouses or growth chambers for reproduction. Therefore, while it is very efficient from a calendar point of view, the scheme requires large inputs of energy and resources in order to accomplish the compression of the life cycle. This program has been highly successful with many biennial crops, although not all biennial crops can be bred in such a way. Onion (*Allium cepa*), for example, requires a long vegetative period and long vernalization period, which typically do not allow its life cycle to be compressed into a single calendar year. In such cases, the vernalized propagules are held in cold storage for a longer period of time, perhaps as long as five months, during which time it is possible that they will have become de-vernalized. These propagules are planted as quickly as possible in the spring, where elongation of the flower stalk and flowering commences immediately.

Unlike the breeding of annual crops, the breeding of biennial crops allows for at least two primary opportunities to evaluate crop performance and quality. This is true whether the biennial cycle is compressed into a calendar year or whether two full seasons are used to

complete the life cycle. The reason for these two opportunities is that the propagules harvested for vernalization must be handled at first to prepare them for vernalization and then again after vernalization and prior to planting for reproductive purposes. For example, the breeding of table beet follows an annual cycle with two opportunities for selection.^[2] Seed is sown in May in the field. After approximately 70–90 days, plants are harvested and roots are separated from leaves with a scissors. Roots are selected, washed, trimmed, and placed in paper bags containing wood shavings. These paper bags are placed in plastic bags that are then sealed. The microclimate inside the paper bag where the propagules are placed is humid enough to prevent desiccation but dry enough to reduce damage caused by plant pathogens. Following a period of vernalization that typically lasts 10–12 weeks, roots are removed from the vernalization chamber and reselected.

Performance in storage is as crucial a trait for a biennial crop as yield performance during the first season of growth. The reason for this is that the biennial crop must be vernalized for an extended period of time, and therefore traits associated with high quality during this period are of great value in a crop cultivar. In addition, breeders of biennial crops realize that many of these same traits are those preferred by consumers for these same crops sold out of storage. For example, carrot germplasm that has been selected for superior traits during vernalization (retention of color and flavor, resistance to storage pathogens, inhibition of sprouting) will be more valuable in a breeding program as well as in a supermarket. Thus, selection for traits associated with quality factors during vernalization will serve the dual purpose of being valuable at a commercial level once a cultivar is produced.

In this way, biennial crops are often selected twice: once in the field following the harvest of the first season's growth and again following the vernalization period. Both of these opportunities for selection allow the breeder a chance to improve the crop for characteristics such as field performance and storability, which are both of great value in determining the success of a cultivar.

Following this second selection, propagules may be planted under controlled environment conditions, such as a greenhouse, where they will bolt and begin to flower. Typically, greenhouse conditions for hybridization and seed production are under long days, which will promote flowering in biennial plants.

Breeders of biennial crops have made use of genes that alter crop life cycles and thereby enhance the efficiency of breeding. One such example is the use of the *B* allele, which conditions an annual habit in *Beta vulgaris*. Plants carrying *bb* are biennial; however, a single *B* allele will result in an annual growth habit. W.H. Gabelman obtained the *B* allele conditioning annual flowering habit from

sugar beet breeding material from Dr. V.F. Savitsky.^[2,3] In general, the *B* allele allows for efficient development of sterile inbreds since spring-sown plants carrying *Bb* flower in the midwestern United States by mid-August. A cross of the constitution *Bb* × *bb* will give rise to 50% annual (*Bb*) progeny, which, because they are flowering, can be classified for sterility and other floral traits in the field. These annual sterile plants can then be decapitated, vernalized, and reflowered in winter in the greenhouse nursery, ensuring continuous inbreeding of the sterile line with its maintainer line.^[2]

When biennial plants carrying sterile cytoplasm are desired, such as during the latter stages of an inbred development program, the remaining 50% of the segregating progeny from the above-described cross that were not flowering can be chosen for appropriate test crosses or commercial use.^[3] These are of the desired genotype *bb*. In practice, use of the *B* allele in table beet breeding allows for greater flexibility and precision in inbred development because one can choose annual or biennial (or both) plants in the field and more accurately choose and plan the crosses to be made during winter months.

CONCLUSION

Biennial crop breeding, like much of modern scientific plant breeding in the United States during the 20th century, has followed a path toward the inbred-hybrid method. The inbred-hybrid method of breeding, which was developed in maize during the early decades of the 20th century, set the pattern for breeding techniques in many crops.^[4] The inbred-hybrid method allowed for the development of F₁ hybrids, which offered superiority in terms of early season vigor, productivity, and uniformity. Procedures similar to those used in annual crops have been used to apply the inbred-hybrid method to the breeding of biennial crops. The primary difference found in biennial crops bred using this method is the increased length of time required for each cycle of breeding, although as discussed above this can be greatly shortened with controlled environment nurseries.

Breeding Clones

Rodomiño Ortiz

International Institute of Tropical Agriculture, Ibadan, Nigeria

INTRODUCTION

Clones are propagules arising from asexual (or vegetative) propagation. The most important vegetatively propagated food crops are potato, cassava, sweet potato, yam, plantain/banana, sugar cane, and fruit trees. Other crops with asexual propagations are some ornamentals, grasses, and forages. Among the most common planting materials are tubers (e.g., potatoes and yams), vines (sweet potatoes), stem cuttings (cassava), and suckers (plantains and bananas). In vegetatively propagated crops the common origin of planting materials is crucial to having uniform trials. Tissue culture-derived plantlets are also promising planting materials to achieve propagule uniformity in some of these food crops.

CROSSBREEDING

Crossbreeding methods for vegetatively propagated crops rely on sexual hybridization, i.e., seeds are needed for producing new genotypes after crossing selected parents. Hence, special protocols are used to maximize flowering in some vegetatively propagated crops. Time (i.e., photoperiod) and intensity of light are among the most important factors affecting flowering in these crops.

The main goal of breeding clones will be to obtain genotypes that are phenotypically uniform (homogeneous) but often highly heterozygous, particularly if nonadditive gene action controls the commercial trait(s) of interest. Nonadditive gene action may arise from intra- or inter-allelic (epistasis) interactions. The conventional plan for breeding clones consists of: 1) selecting appropriate parents for crossing schemes; 2) early or late selection in clonal generations, which will be determined by the heritability of the targeted trait(s); and 3) adequate environmental sampling (i.e., number of locations and years) for testing advanced breeding materials leading to cultivar development. The steps in the most common breeding scheme are given in Fig. 1.

ANALYTICAL BREEDING

Genetic manipulations of complete chromosome sets are called ploidy manipulations: scaling up and down chromosome numbers of a species within a polyploid series. The most important vegetatively propagated food crops (potato, sweetpotato, yam, plantain/banana, and some fruit trees) possess well-endowed genetic resources from their wild species, which are often of lower ploidy.^[1] Chromosome sets are manipulated with haploids, $2n$ gametes, and through interspecific–interploidy crosses. Analytical breeding schemes rely mainly on ploidy manipulations to “capture” diversity from exotic (wild or nonadapted germplasm) and use $2n$ gametes to incorporate this genetic diversity through unilateral (USP; $n \times 2n$ or $2n \times n$) or bilateral (BSP; $2n \times 2n$) polyploidization.^[2] Haploids are propagules with the gametophytic chromosome number (n) and $2n$ gametes possess the sporophytic chromosome number of the parental source. The most interesting examples of analytical breeding are in vegetatively propagated species such as potato,^[3] sweet potato,^[4] and cassava^[5] among roots and tubers, and plantain/banana^[6] among fruit crops. This breeding approach appears promising in sugar cane,^[7] blackberry,^[8] blueberry,^[9] strawberry,^[10] and other fruit crops.^[11]

Potato may be regarded as the model crop either for breeding clones by conventional methods^[12] or for broadening the genetic base of crop production, particularly through analytical breeding.^[13] In potato ploidy manipulations, chromosome sets are easily managed with wild species, maternal haploids obtained through parthenogenesis, $2n$ gametes arising from meiotic mutants, and the endosperm balance number (EBN). This endosperm dosage system, also common to other angiosperm genera, requires a 2:1 ratio of maternal to paternal contributions to achieve normal seed development after hybridization.^[14] The wild species (mostly diploids) bring new genetic variation to the breeding pool, whereas haploids “capture” this genetic diversity by crossing them with diploid wild species. The resulting haploid–species hybrids—producing $2n$ gametes—and the EBN are the means for broadening the genetic base of the cultivated potato through USP or BSP (Fig. 2), which recent analysis with genetic markers has confirmed.^[15] Furthermore, such

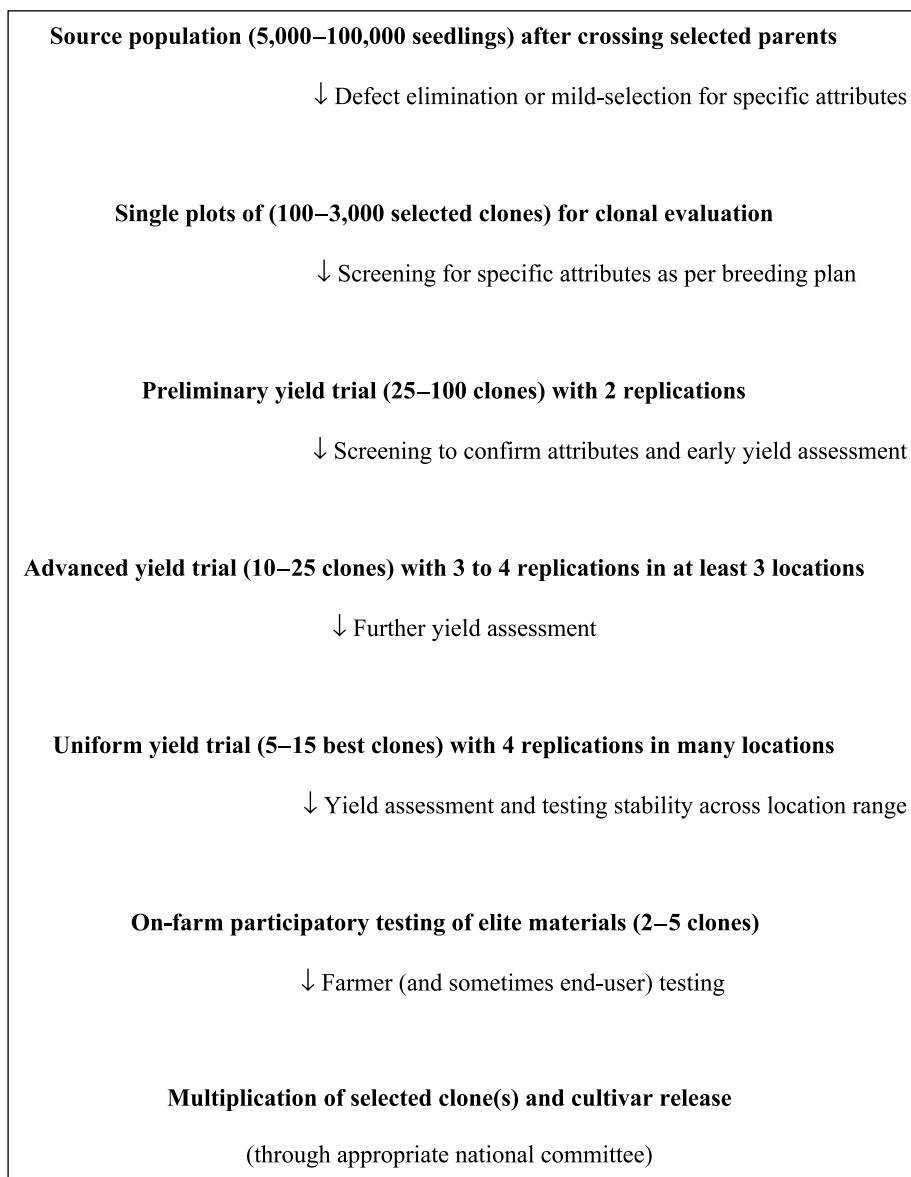

Fig. 1 Common breeding scheme for vegetatively propagated tropical crops at the International Institute of Tropical Agriculture. Propagule numbers are crop-dependent.

analysis suggests that the need for broadening the genetic base in potato may be met by specific chromosomes or regions within chromosomes.

EVOLUTIONARY APPROACH

Genetic bottlenecks could happen during the evolution of vegetatively propagated crops because breeders of these crops (farmers in the early days, but nowadays mostly

trained professionals) may select a few sports (or mutants) with the desired characteristic, which could replace old cultivars in a large scale area. Triploid plantains provide an interesting example, in which most of the variation observed in approximately 120 cultivars (or landraces) known world-wide resulted from mutations accumulated throughout the history of cultivation of this crop and from farmer selection of a few strains.^[16] In this triploid crop, gene flow through pollen was prevented due to the low male fertility of the crop.^[17] Diploid banana species and plantain producing $2n$ eggs were the

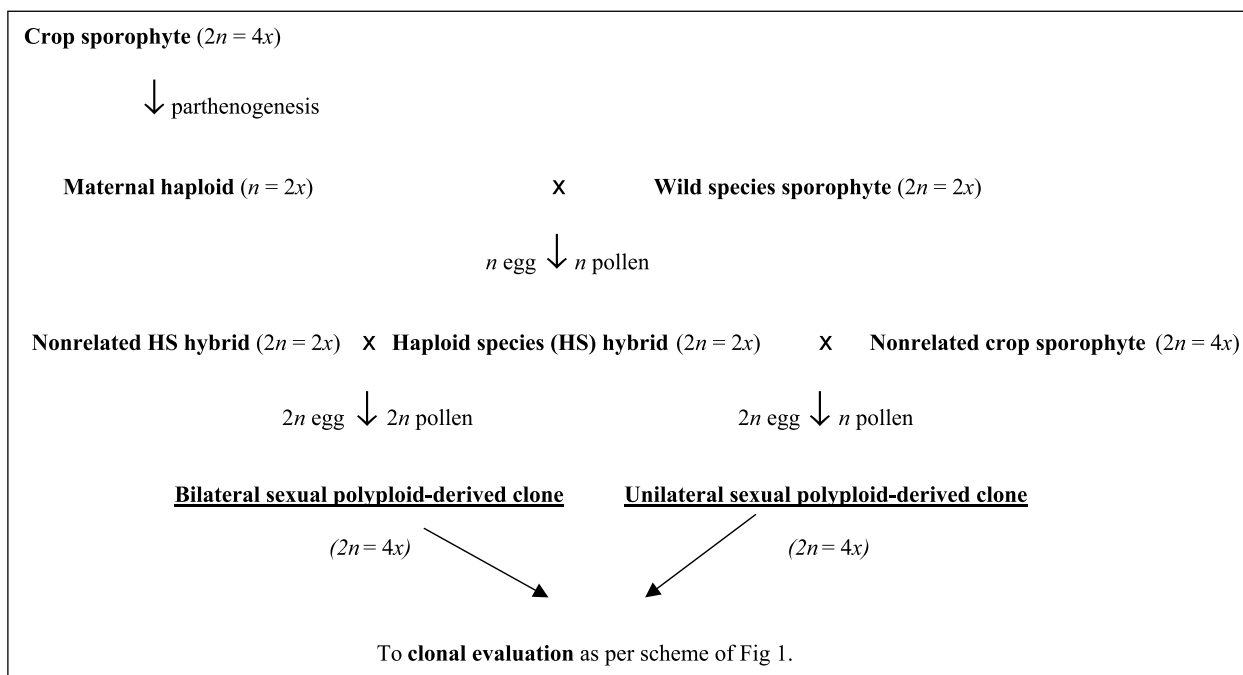

Fig. 2 Ploidy manipulations (or scaling up and down chromosome numbers) for breeding clones with haploids and $2n$ gametes in a crop within a polyploid series. The example refers to a tetraploid ($2n = 4x$) crop with diploid wild species.

tools for broadening the genetic base in this important tropical starchy crop. Tetraploid hybrids may be obtained by hybridizing $2n$ eggs from plantains with n pollen from diploid accessions. Plantain-derived diploids also result from such crosses.

In plantains, heterozygous triploid clones (which are farmers' selections that have been around for a long time) are the sources of allelic diversity. These alleles are released to the tetraploid hybrids through $2n$ eggs and are further broadened by the alleles provided by the diploid bananas. Advanced ploidy manipulations may lead to secondary triploids resulting from crosses between selected tetraploids and elite diploid stocks, both producing n gametes.^[18] Triploid *Musa* hybrids may also occur as a result of to USP among selected diploid stocks, because one of the parents produces $2n$ gametes. Such breeding methods for plantain should be regarded as part of an evolutionary improvement approach, because conventional breeding will be enhanced by innovative knowledge-led methods, as described above, for introducing additional genetic variation.^[19] Genetic markers may assist in the process of recurrent selection of plantain germplasm, and combining ability tests will assist the selection of elite parents at any ploidy level.^[20,21] Recent results from this approach show that prospects for plantain (and banana) breeding "are unlimited, and increased efforts will at once initiate a new phase of *Musa* evolution."^[22]

SOMACLONAL VARIATION

Irrespective of the advantages of tissue culture for vegetatively propagated crops, somaclonal variation may affect the true-to-type during micropropagation. Somaclonal variation refers to genetic variation arising from tissue culture regeneration among plants from the same original genotype. Careful plant breeders minimize somaclonal variation by: 1) selecting deliberately stable sources of materials for primary explants; 2) limited subculturing and multiplication (less cycles, short time for subculturing, and a few hundred plants per primary explant); and 3) nursery screening to detect and rogue off-types. Somaclonal variation may provide a potential source for genetic improvement of some vegetatively propagated crops. However, in most crops, the range of somaclonal variants recovered through shoot-tip culture seems to be narrow, mimics naturally occurring variation, or produces defective genotypes.

FUTURE PROSPECTS

Hybrid clones may result from artificial hand-pollination or through poly-crosses among parents that are selected for their specific combining ability. Poly-crossing refers to a pollination system based on natural random mating

among selected genotypes grown together in isolated plots. The seeds from the multiple hybrid mixtures may be also regarded as synthetic cultivars because they are derived from selected genotypes that combine well among them. A recent report on potato suggests that it will be feasible to obtain the same or better performance with a minimum number of parents in the source synthetic population and by allowing it to open-pollinate in an isolation plot.^[23]

Hybrid seed from poly-crosses are obtained from isolated plots to avoid contamination with pollen from other nonselected clones. Synthetic populations derived from these poly-crosses are tested in other locations to identify promising offspring for selection and cultivar development. Local selections follow a dynamic conservation approach to genetic resources because target farmers preserve distinct, locally adapted and improved genotypes across locations. Ploidy manipulations coupled with this breeding approach broaden the genetic base of vegetatively propagated crops, thereby enhancing crop adaptation and sustaining genetic gains in respective breeding pools. As pointed out, early locally adapted germplasm with enhanced adaptation to stress-prone environments or resistance to pest and diseases will allow the sustainable and environment-friendly production of vegetatively propagated crops, which often are affected by many biotic or abiotic stresses.

ACKNOWLEDGMENTS

Some of these ideas for crop breeding are the result of some stimulating discussions with my academic mentors: Prof. Francisco Delgado de la Flor, supervisor for the MSc degree at Univ. Nacional Agraria-La Molina, Perú; Em. Campbell-Bascom Prof. Stanley J. Peloquin, advisor for the Ph.D. degree at the Univ. of Wisconsin-Madison, USA); and Dr. Masaru Iwanaga (with whom I started my international professional career at the Centro Internacional de la Papa, Perú). These initial ideas were further developed in my early professional years at the International Institute of Tropical Agriculture (Nigeria) with the late Dirk R. Vuylsteke, a meticulous *Musa* scientist and humanitarian, who dedicated his short but outstanding professional life to improving African agriculture.

Breeding for Durable Resistance

Raoul A. Robinson (Retired)

Food and Agriculture Organization of the United Nations, Fergus, Ontario, Canada

INTRODUCTION

Since the recognition of Mendel's laws in 1900, plant breeders have shown a marked preference for single-gene resistances to crop pests and diseases. This preference has been greatly strengthened by the techniques of molecular modification, which, of necessity, also involve single-gene resistances. These single-gene, qualitative resistances have many advantages but, unfortunately, they are almost invariably *within* the capacity for genetic change of the crop parasite, and they endure only until the parasite produces a new strain that is unaffected by the resistance in question. A parallel phenomenon is seen with many synthetic insecticides and fungicides. Durable resistance, often called horizontal resistance, on the other hand, is normally controlled by polygenes. Such resistance endures in the same way, and for the same reason, that the effectiveness of copper and dithiocarbamate fungicides, or rotenone insecticides, endures. These protection mechanisms are *beyond* the capacity for genetic change of the crop parasite in question.

BRIEF LITERATURE REVIEW

The most comprehensive review of breeding for durable resistance is that of Simmonds.^[1] He gives examples of durable resistance in twenty-one species of crop, functioning variously against airborne and soil-borne fungal pathogens, bacteria, viruses, insects, and nematodes.

In 1992, Stoner^[2] reviewed 705 papers on plant host resistance to insects and mites in vegetables, and she also quotes reviews of this topic in grain crops, alfalfa, and cotton. She comments that, in most studies, the resistance is a quantitative trait, but she adds that there has been little plant breeding for resistance to insects.

Robinson^[3] has described the techniques of breeding for durable resistance, and the present article is a brief summary of those techniques. Robinson^[4] has also published free downloads of his books on the Internet.

BREEDING FOR QUANTITATIVE VARIABLES

Because durable resistance is almost invariably controlled by polygenes, it must be treated as a quantitative variable

with a maximum and a minimum. As a rule, the maximum level of quantitative resistance is represented by a negligible loss of crop in the absence of crop protection chemicals. The minimum level of quantitative resistance is represented by a total loss of crop in the absence of crop protection chemicals. Many modern cultivars have levels of quantitative resistance to some of their parasites that come close to this minimum.

Breeding for quantitative resistance is thus a progressive and cumulative process, in the sense that a good cultivar need never be replaced, except with a better cultivar. Even modest increases in the level of quantitative resistance will reduce the need for crop protection chemicals.

Breeding for quantitative variables requires recurrent mass selection, in which the best individuals in a large population become the parents of the next generation. The resistance accumulates mainly by transgressive segregation, and the entire program is likely to require some 10–15 breeding cycles. This approach is clearly a major departure from the classic breeding of autogamous crops such as wheat, beans, and rice. The recurrent mass selection must be conducted in accordance with the following rules.

Original Parents

Some 10–20 modern cultivars with high yield and high quality of crop product should be chosen as the original parents of the recurrent mass selection. While it does no harm to choose parents with a reasonably high quantitative resistance, this is not essential because transgressive segregation will accumulate adequate resistance from susceptible parents, provided the genetic base is reasonably wide. Robinson^[3] has described the remarkable effect of this process in maize in tropical Africa.

Cross-Pollination

The original parents must be cross-pollinated in a half-diallel cross (i.e., each parent is crossed with every other parent, without any self-pollinations, and without any distinction between male and female parents). Similar cross-pollination must occur with the selected individuals of each screening generation that become the parents of the next breeding cycle. The techniques of pollination depend on the nature of the crop in question. Beek^[5] used a

male gametocide to achieve several million crosses in a rather small population of wheat, and it appears that this technique can be used with other cereals. A marker gene can be used in crops such as beans, in which the levels of natural cross-pollination are low. Hand-pollination, following hand-emasculation, is useful when a single pollination produces many seeds, as with crops in the *Solanaceae* and *Cucurbitaceae*. In only a few crops (e.g., *Cicer arietinum*) is a labor-intensive hand-pollination inevitable.

On-Site Screening

On-site screening means that the screening population is screened 1) in the area of future cultivation; 2) in the time of year of future cultivation; and 3) according to the farming system of future cultivation (e.g., organic versus artificial fertilizers, irrigated versus rain-fed). On-site screening is necessary because the epidemiological competence of crop parasites varies markedly and differentially between agro-ecosystems. A cultivar that has all its quantitative resistances in balance with one agro-ecosystem, is likely to have too much resistance to some parasites, and too little to others, when taken to a different agro-ecosystem. However, most agro-ecosystems are large enough to justify a breeding program for each of their important species of crop.

Screen for Yield and Quality

The screening population should be screened primarily for high yield, on the grounds that susceptible individuals cannot yield well in the presence of parasites. As the original parents were high quality cultivars, it is necessary to ensure that the level of this quality does not decline and that individuals with a reduced quality should not become parents in the next breeding cycle.

Inoculate to Prevent Chance Escape

It is imperative that that every individual in the screening population is parasitized with every locally important parasite. This is because the level of quantitative resistance can be assessed only in terms of the level of parasitism. A chance escape from parasitism will provide an entirely false indication of resistance, and using such an individual as a parent would seriously reduce the genetic advance.

Ensure That No Single-Gene Resistances Are Functioning

The level of quantitative resistance can be assessed only by the level of parasitism. Consequently, it is essential that no single-gene resistances are functioning in the screening

population. If these resistances cannot be eliminated genetically, they can be inactivated, usually by the "one-pathotype technique" described elsewhere by Robinson.^[3]

Avoid the Vertifolia Effect

Vanderplank^[6] first recognized a phenomenon that he called the "vertifolia effect." This is the loss of quantitative resistance that occurs during breeding for single-gene resistance. The vertifolia effect also occurs if crop protection chemicals are used to protect the screening population. In breeding potatoes, the vertifolia effect has probably been occurring with quantitative resistance to blight (*Phytophthora infestans*) since the discovery of Bordeaux mixture in 1882, and subsequently during many years of breeding for single-gene resistances. In cotton, a vertifolia effect in insect resistance was probably initiated with the discovery of DDT.

Selection Pressures

During the early screening generations, the selection pressures for quantitative resistance are likely to be too high. There is then a danger that the screening population, which has a very low level of resistance, will be destroyed entirely by its parasites. Should this appear likely, crop protection chemicals should be used, as late as safety permits, in order to preserve the minority of the least susceptible individuals. Conversely, as quantitative resistance accumulates in the later screening generations, the selection pressures for resistance decline. Inoculation of the screening population will then be necessary to determine the levels of resistance.

TWO SOURCES OF MAJOR ERROR

Robinson^[3] has discussed two sources of major error that have apparently been responsible for the general neglect of quantitative resistance during the past century. These sources of error have so denigrated the appearance of quantitative resistance as to make it appear valueless or even nonexistent. And they indicate that a considerably lower level of resistance than we may believe will achieve an adequate control of crop parasites. They are biological anarchy and parasite interference.

Biological Anarchy

Robinson^[3] defined biological anarchy as the loss of biological control that occurs when the various organisms contributing to biological control are reduced or eliminated by crop protection chemicals. The crop parasites then behave with a savagery that would be impossible if

their numbers had been kept down by their natural enemies. The importance of biological anarchy is that it obscures levels of quantitative resistance that might provide a complete control if the natural biological controls are functioning. In other words, we probably need considerably lower levels of quantitative resistance than we may currently believe. The importance of biological anarchy can be assessed by the general usefulness of the entomological techniques of integrated pest management (IPM). The best way to restore biological control is to use horizontal resistance. And the best way to enhance the effects of horizontal resistance is to restore biological controls. The two effects are mutually reinforcing.

Parasite Interference

Parasite interference was first recognised by Vanderplank^[6] and it occurs because crop parasites can move from one field plot to another. James et al.^[7] assessed its importance in potatoes. Parasite interference can easily increase the levels of parasitism in test plots by several orders of magnitude. Perhaps the most dramatic example of parasite interference is seen in the small plots used by small cereal breeders working with single-gene resistances. These family-selection (i.e., ear-to-row) plots exhibit the hypersensitive flecks that result from non-matching infections, but these flecks may occur in millions. There can be so many of them that the resistant cereal appears to be severely diseased, and the breeders warn that this phenomenon must not be mistaken for true disease.

Parasite interference also occurs during recurrent mass selection because an individual resistant plant is likely to be surrounded by more susceptible individuals. That resistant individual will then have a level of parasitism far higher than it would in a farmer's field where there is no parasite interference. For this reason, all assessments of the level of parasitism during recurrent mass selection must be relative measurements. Only the least parasitized (or highest yielding) individuals are selected, however severely parasitized (or low yielding) they may be in more general terms.

PLANT BREEDING CLUBS

Robinson^[3] has argued that breeding for durable resistance is so easy that it can be undertaken by amateurs. The proof of this comes from the remarkably successful, but illegal, amateur breeding of marijuana. Amateur breeding would be at its most successful when amateurs organized themselves into a plant breeding club. He suggests that the most useful and productive clubs would be student clubs in colleges and universities.

Breeding for Nutritional Quality

Brian J. Just

University of Wisconsin, Madison, Wisconsin, U.S.A.

Philipp W. Simon

USDA—ARS, Madison, Wisconsin, U.S.A.

INTRODUCTION

Breeding plants for improved nutritional quality is an old idea. One can imagine early gatherers and farmers avoiding eating certain plants that made them ill. In more modern times, selection for sugar content of sugarbeet has been ongoing for over 250 years, whereas selection for oil and protein content in maize and soybean is approaching 100 years in practice. As research in the nutritional sciences continues to demonstrate the importance to our health and well-being of plant-derived nutrients in foods, more breeding is underway to increase the type and amount of nutrients in cereals, legumes, vegetables, and fruits. The human diet consists of a diverse array of crops. Because specific nutrient levels in many of these crops are often under genetic control, the prospects for improving the nutritional quality of food through plant breeding are promising.

TARGETS FOR IMPROVEMENT

Traditionally, nutrients in the human diet have been defined as components required for the proper growth and function of the body. These essential nutrients are usually categorized into two classes: the macronutrients and the micronutrients. Macronutrients are compounds that are required in large amounts and include carbohydrates, proteins, and lipids. Over 90% of the U.S. dietary carbohydrates come from plant sources (Table 1). Micronutrients are needed in smaller amounts but are nonetheless critical for general maintenance of the body. The micronutrients include minerals and vitamins. Over 90% of the vitamin C; 70% of the thiamin, folate, Fe, and Cu; and 50% of vitamin E, niacin, Mg, and K come from plant sources (Table 1). In less developed countries, plants contribute much higher proportions of these nutrients to the diet.

Beyond essential nutrients, phytonutrients are another class of compounds derived from plants that have also been recently studied. Phytonutrients (also called phytochemicals) are not specifically required for bodily

function, but have been documented or implicated as having a positive impact on human health. Many phytonutrients act as antioxidants and help prevent diseases such as cancer, heart disease, and strokes. There is a wide diversity of phytonutrients and they include pigments (e.g., carotenoids and anthocyanins), glucosinolates, terpenoids, saponins, and a host of other organic molecules. In the future, many more phytonutrients may be discovered.

In addition to nutrients, antinutrients and allergens are known to exist in some crops. Antinutrients are substances that have a toxic effect or inhibit the uptake of nutrients. Examples of antinutrients are glycoalkaloids in some potatoes and phytate in some legumes. Compounds from each of these nutrient and antinutrient classes have been the targets of, or have been suggested as future targets for, plant breeding efforts.

BREEDING METHODS AND EXAMPLES OF BREEDING FOR IMPROVED NUTRITIONAL QUALITY

Breeding for nutrient composition of a crop species is not fundamentally different from breeding for other quality or yield traits. Choice of method depends on limitations imposed by the biology of the species, number of genes controlling the trait, level of variation in source material utilized in the breeding program, ease of measuring the level of the nutrient, and extent to which environment affects nutrient levels.

Breeding for any trait begins with a survey of the variability within a crop species of the trait of interest. Once useful variability for a nutritional quality trait is identified, the breeder usually elucidates the mode of inheritance. Nutritional quality traits can be either monogenic (qualitative), oligogenic, or polygenic (quantitative). Within the germplasm to be utilized, a heritability estimate is obtained that gives the breeder an idea of how much of the observed variation is genetic in nature and how easily that genetic variation can be exploited by various breeding methods.

Table 1 Plant sources of macronutrients, vitamins, and minerals in the U.S. food supply: 1990

Nutrient	Plant sources—total %; Major sources	Breeding effort		
		Developing countries, for food	Developed countries, for food	Developed countries, for extraction/feed

K	55; Vegetables, fruits, and potatoes			

(From Ref. 1.)

If a nutritional trait is governed by a single gene, the usual approach is to introgress the allele causing the desired phenotype into an appropriate background. This can be achieved by backcross breeding. Numerous single gene mutations have been identified in many crop species that affect the level of a nutritionally important compound; examples are listed in Table 2. After introgressing the allele of choice into commercially acceptable backgrounds, quantitative variation for expression of the trait may be observed and exploited for further improvement. However, introgressed genes can also negatively affect other agronomically important traits. These undesirable

effects can be because of pleiotropy or because the gene of interest is tightly linked to genes with undesirable effects. Further breeding may be necessary to eliminate or reduce the negative attributes caused by the introgressed gene or genes linked to it. For example, the *opaque-2* mutation in corn, which confers the desirable high-lysine phenotype, is associated with a soft endosperm that is commercially unacceptable. Recurrent selection has recently been used to increase endosperm hardness in high-lysine maize synthetics.^[6]

If a trait exhibits quantitative variation, which is characteristic of traits under polygenic control, recurrent

Table 2 Examples of loci with large effect on production of nutrient or anti nutrient compounds

Locus	Crop	Nutrient class	Phenotype	Reference
<i>opaque-2</i>	Corn	Macronutrient	Alters protein profile to include more lysine, an essential amino acid	2
<i>hp</i>	Tomato	Micronutrient	Increases provitamin A and vitamin C content in fruits	3
<i>P₁</i>	Carrot	Phytochemical	Induces anthocyanin production in the root	4
<i>Bi</i>	Squash	Anti-nutrient	Controls production of cucurbitacin E, a toxin in squash fruits	5

(From Refs. 2–5.)

selection methods can be used to increase the mean level of the nutrient in a population over several cycles of selection. An example of this approach is illustrated by the breeding of the high-carotene mass (HCM) carrot population. Over eleven cycles of mass selection, the provitamin A carotenoid content was increased to over four times the level found in typical carrots.^[7] The longest continuous plant breeding effort has been the Illinois project in which selection for oil and protein levels in corn for 100 generations continues to be effective.^[8]

In some cases, the necessary variability of the nutritional trait may not be available in cultivated germplasm. It may then be necessary to use exotic germplasm such as wild relatives of the crop plant or unadapted landraces to improve nutritional quality. Species related to the cultivated tomato (*Lycopersicon pimpinellifolium*) were used to more than double vitamin C content of tomatoes. However, use of this vitamin C-enhanced germplasm has been limited because tomato breeders have not yet been able to overcome negative effects on yield associated with the nutrient enhancing genes.^[9]

Recent developments in genetic engineering offer new ways to improve nutrient content in plants. This approach allows geneticists to introduce genetic variation into a species that is unavailable in its germplasm pool. Genetic engineering of plants can either be used to introduce a completely novel trait or to manipulate a known biochemical pathway. This metabolic engineering approach was used to induce rice plants to accumulate β -carotene (provitamin A) in the endosperm of the grain, albeit at low levels.^[10] It may be possible to further increase the β -carotene levels in this transgenic rice (known as Golden Rice) by recurrent selection or by backcrossing into different backgrounds.

OTHER ASPECTS OF NUTRITIONAL QUALITY IMPROVEMENT

The success of a breeding program to improve nutritional quality is largely dependent on the ability of the breeder to

accurately assess and improve the phenotype. For some nutrients, such as those involving beneficial plant pigments, selection by visual examination may be successful. However, more sophisticated chemical analysis is required to assess levels of most plant nutrient compounds. A wide variety of analytical chemistry methods exist to assay the level of nutrients in plants. If a particular target nutrient is difficult, time-consuming, or expensive to assay, it may be worthwhile to develop molecular markers linked to the genes that affect nutrient level. These markers can then be used to assist the breeder in selection for the trait.

Another important factor in the breeding of plants with increased nutritional quality is environmental effects on expression. For example, crops bred for increased uptake and storage of a mineral nutrient must have that nutrient available in the soil. Similarly, environmental effects such as temperature and disease pressure can alter the chemistry of the plant, which may in turn affect the nutrient composition. This variation due to nongenetic factors accounts for genotype by environment interactions. A genotype with increased levels of a nutrient in one environment may have lower levels of the same nutrient in a different environment. Hence, multilocation testing is essential for the development of nutritionally enhanced cultivars.

Breeding plants for increased levels of a nutrient per se may not be effective in increasing the level of that nutrient in the human diet. The term “bioavailability” refers to the ease with which a nutrient can be assimilated and utilized by the consumer. For example, bioavailability of carotenoids is influenced by the matrix in which these pigments exist in the plant, the postharvest handling of the crop, the method of food preparation, and the nutritional status of the consumer.^[11] Very little is known about the factors that contribute to the bioavailability of many micronutrients. Future research will be needed to determine the factors in the plant that contribute to nutrient bioavailability and whether those factors can be manipulated through plant breeding.

CONCLUSION

The end use for plant varieties with increased nutrient levels may be direct consumption or for extraction of the nutrient for use in supplements. Breeding for extractable nutrients such as plant oils, carbohydrates, protein, pigments, and vitamins has long been successfully pursued to yield the ingredients for home and processed food industry use. With these ingredients, food products can be enriched or fortified through processing. However, breeding for increased nutrients in whole foods for consumption is important because it provides a more direct way to deliver nutrients to consumers, especially in developing countries where the enhancement of diet is most critical. Furthermore, nutritionally improved cultivars can provide a locally sustainable nutrient source and even an additional source of farm income in developing countries. As our knowledge of plant genetics and human nutrition grows, breeding for nutritional quality will no doubt become a more important target for plant improvement.

Breeding for Subsistence Agriculture: Developing Technologies for Resource-Poor Farmers

Shivaji Pandey

International Maize and Wheat Improvement Center (CIMMYT), Mexico City, Mexico

INTRODUCTION

Subsistence agriculture is a common livelihood strategy in rural areas of less developed countries where farmers use little or no purchased inputs, farmers eat and use much of what they produce, and their production has little impact on the market. The term *subsistence agriculture* is synonymously used with traditional, small-scale, peasant, low-income, resource-poor, and low-input farming.

CHARACTERISTICS OF SUBSISTENCE AGRICULTURE

On a global basis, subsistence agriculture covers 40% of all cultivated lands and sustains 50–60% of the world population.^[1] In developing countries, nearly 440 million farmers practice subsistence farming on 50% of agricultural lands.^[2] Subsistence farmers generally raise several crops and animals to meet their needs for food, feed, and fiber. Subsistence agriculture is labor-intensive, utilizing mainly family labor, provided in many countries by women. In many situations, subsistence agriculture is the only means of survival for the rural population. Subsistence farmers lack the resources to buy expensive chemicals, fertilizers, and seed, so they are of little interest to the private sector. Therefore they are mostly served by the public and nongovernmental organizations. Unfortunately, public sector investment in agricultural research and development has been declining, further reducing the technological options for subsistence farmers. Their capacity to bear risk is low. They have small plots with little possibility of mechanization and they largely practice rain-fed agriculture. Their crops are exposed to a variety of abiotic (heat, cold, quality and duration of light, drought, waterlogging, and soil mineral toxicities and deficiencies) and biotic (diseases, insects, and weeds) stresses. Because food security is their most important concern, they prefer stable and predictable production from year to year even if production is low, rather than variable and unpredictable production with potentially high yields in different years. Because they largely depend on food they produce, their meals are not nutritionally balanced. Therefore, subsistence farm-

ers need low-cost technologies that offer stable production and enhanced nutritional quality.

DEVELOPMENT OF TECHNOLOGIES FOR SUBSISTENCE AGRICULTURE

Plant breeding offers an effective means for developing low-cost technologies for resource-poor farmers. Strategies include types of varieties whose seeds can be saved by the farmer for the next planting—varieties that take less water and nutrients and produce more useful products (i.e., are input-use efficient), are resistant to diseases and insects, or produce more in the presence of stresses (stress-tolerant), allowing subsistence farmers to produce more with low inputs and avoid losses to pests. Technologies that provide them adequate food and fiber, and simultaneously enrich their soils for the current and/or following crops, are desirable. Technologies that enhance the quality of their products without sacrificing quantity are also needed for subsistence agriculture. In summary, agricultural technologies for subsistence farmers should allow them to harvest more food and fiber from their land without significantly increasing the cost of production and should help maintain or enhance their natural resource base.

Stress-tolerant varieties have been developed in most crops, often exploiting within-species genetic variability, but interspecific and intergeneric genetic variations have also been exploited. As an example, considerable progress has been made in developing drought-tolerant maize cultivars, exploiting within-species genetic variability.^[3] Several maize populations have improved tolerance to midseason drought (the stage at which drought causes maximum yield loss in maize) from which superior varieties have been developed. Some of these varieties yield more than the farmers' own varieties in the fields of subsistence farmers^[4] (Table 1).

Development of stress-tolerant varieties requires breeding techniques that maximize the heritability of desirable traits. For this, adequate genetic variation for the trait as well as efficient and reliable screening techniques for identification of superior genotypes are necessary. Targeted breeding for tolerance to stresses is more

Table 1 Maize grain yield of Masika (farmers' variety) and ZM621 (improved variety) under recommended and farmer fertilizer practices across 13 smallholder farms during 2000 in Malawi

efficient at developing stress-tolerant cultivars than breeding under nonstress conditions.^[5] Genotypes are screened under natural and/or managed levels of stress in the field or laboratories. Managed stress nurseries provide more reliable information but are more expensive to run than evaluation under natural conditions. At times, a combination of laboratory and field screening or natural and managed stress screening is used to develop a more robust variety.

Varieties with higher levels of nutrients (proteins, carbohydrates, vitamins, and minerals) have also been developed by plant breeders, which provide better nutrition and improve the health of the resource-poor. As an example, the homozygous recessive state of the *opaque-2* (*o2o2*) gene nearly doubles lysine and tryptophan (essential amino acids deficient in cereals) levels in the maize endosperm.^[6] However, this state of *opaque-2* also contributes to lower yield, soft and undesirable endosperm, increased ear rots, and greater susceptibility to storage pests, which are corrected by

Table 2 Performance of white Quality Protein Maize hybrids across 35 locations in Latin America, Asia, and Africa during 1997–1998

modifier genes. Fortunately, scientists have succeeded in developing quality protein maize (QPM) cultivars that retain the higher nutritional benefits conferred by the *opaque-2* gene, without the undesirable associated traits^[7] (Table 2). QPM is now grown on nearly a million hectares in developing countries and has been shown to bring significant health benefits to resource-poor farmers and consumers who depend on maize for food, as well as to nonruminant livestock fed unfortified maize-based diets.

For enhanced nutritional quality, the same breeding and genetic principles apply as for stress tolerance. Adequate genetic variation and efficient screening techniques are the keys. Much of the screening of genotypes for nutritional traits is done in laboratories. Production and interpretation of laboratory information require collaboration between biochemists and plant breeders. The environment in which the genotypes are grown can have significant influence on the nutritional levels of the genotypes. Therefore, crop management practices must be appropriate and uniform. In addition, because very small samples of the plant parts are usually analyzed in the laboratories, any contamination of the sample or fault in laboratory procedures can produce grossly erroneous results. Human nutritional studies are conducted with the final product to determine its value to the consumers. Such studies are expensive, complex, and require collaboration among nutritionists, medical professionals, and social scientists.

Cultural and agronomic practices that reduce the incidence of stresses and/or enhance the nutritional status of the soil allow for more efficient water harvests, and

Fig. 1 Yield (Mg ha⁻¹) of maize and groundnut in two cycles of a groundnut–maize–maize–groundnut rotation without fertilizers, averaged over five smallholder farms during 1995–2000 in Zimbabwe. (View this art in color at www.dekker.com.)

ameliorated soil toxicities have been developed. Integrated pest management in crop protection is widely accepted as an effective, less expensive, and long-term pest management strategy.^[8] Legume-based crop rotations and mixed cropping for soil enhancement, crops that suppress weeds and reduce weed population increases, crops that repel or attract and trap insects, and tied ridges to increase water harvest potential have been developed for subsistence farming systems and have been used with varying degrees of success. For example, groundnut–maize–maize–groundnut–maize–maize rotation has resulted in greater production of both groundnut and maize in subsistence farming systems and contributes to enhanced food security (Fig. 1).^[9] Although many of these technologies have potential, adoption is slow, especially when they involve growing crops that compete for land and labor with the food, feed, and fiber crops required by the subsistence farmers.

In recent years, the development of technologies directly in the fields of resource-poor farmers and involving farmers in the research process has been receiving attention.^[10] Several terms with “participatory” prefix are used. The hypothesis is that experiment stations do not represent the subsistence farmers’ fields and scientists do not fully understand the needs of farmers. No critical results are yet available to compare the efficiencies of the two methods in developing useful technologies for the subsistent farmers. On one hand, highly variable environmental conditions that characterize fields of resource-poor farmers can reduce the precision of research results and lower the efficiency of technology development. Variable environmental conditions also reduce heritability and gain from selection. On the other hand, research at research stations may take place in unrepresentative environments and result in technologies unsuitable for the resource-poor farmers. Perhaps a better and more cost-effective option would be to conduct basic research under more uniform environmental conditions, ensuring as much as possible that the research environments also represent the conditions prevalent in the farmers’ fields. Thus the superior technologies developed should be widely tested in farmers’ fields for validation and promotion, jointly by farmers and researchers.

CONCLUSION

Ideally, subsistence farming will disappear and subsistence farmers would become commercial farmers. However, that would require major policy changes and investments in the development of infrastructure (roads,

irrigation systems, and markets), enhancement of availability of credit, and training and education of farmers, which few developing countries have the will, or the resources, to do. Therefore subsistence farming is likely to continue in the foreseeable future in many developing countries, although its prevalence should decrease as progress is made.

Much progress has been made in developing technologies for subsistence agriculture but much remains to be done. Abiotic and biotic stresses continue to reduce production in farmers’ fields. The seed of improved cultivars is not available to subsistence farmers at affordable prices. Similarly, the role of nutritional enhancement of crops farmers grow and eat is large. Development of stress-tolerant and more nutritious varieties will continue in the foreseeable future, using traditional breeding methods. In recent years, molecular and genetic engineering techniques that promise to increase the rate of progress in their development and even open opportunities not previously thought possible have become available by moving genes across genera. Development of cultural and agronomic practices that are more farmer-friendly, complementary, inexpensive, contribute to more efficient use of available inputs, and maintain or enhance the natural resource base will also continue. The role of women in subsistence agriculture is now beginning to be recognized and addressed in technology development. Much greater efforts are needed to ensure that appropriate technologies reach and are adopted by resource-poor farmers. Modern tools, such as geographic information systems and crop simulation models, would help increase the efficiency in the development and transfer of technologies. One of the major indirect benefits of improvement in conditions of subsistence farmers may well be a decrease in rural-to-urban migration—a phenomenon that is only transferring misery from the farms to the cities.

Breeding Hybrids

Arnel R. Hallauer

Iowa State University, Ames, Iowa, U.S.A.

INTRODUCTION

Hybrids are crosses between two parents that either occur naturally in plant populations or occur when plant breeders and geneticists manually produce crosses between selected parents.^[1,2] The relative importance of hybrids varies among plant species, but in nearly all instances hybrids have a role in plant improvement. In allogamous (cross-fertilizing) plant species each plant is theoretically a hybrid because of the union of gametes between the male and female parents. Except for specific instances, the frequency of hybrids would be less in autogamous (self-fertilizing) plant species. In most plant breeding programs, hybrids are produced between elite parents to develop F₂ populations by either selfing or sibbing (plant-to-plant crosses) the hybrid (F₁) plants. Selfing and selection is initiated within the F₂ populations to develop pure lines (or inbreds) that may be used either as pure-line cultivars for autogamous plant species or as parents to produce hybrids for allogamous crop species. Hybrids for autogamous crop species are vehicles to develop segregating populations in which selection is practiced to develop pure-line cultivars for use by the producers. In allogamous plant species hybrids are often the starting point to develop pure lines that are ultimately used as parents to produce hybrids for use by the producers. Generally hybrids are associated with greater productivity and vigor, but this varies among and within autogamous and allogamous crop species and for different plant traits.

Hybrids have become the predominant form of cultivar in many crops. In industrialized countries, many allogamous crops including maize, sunflower, brassicas, cucurbits, carrots, beets, and onions are predominately produced as hybrid cultivars. Hybrid cultivars are also common in certain autogamous crops, including sorghum, tomato, and peppers. In nonindustrialized countries use of hybrid cultivars in allogamous species is increasing and hybrid rice has become important in China.

HISTORY OF HYBRIDS

The occurrence and interest in hybrids were studied during the 18th and 19th centuries.^[1,2] Mendel and

Darwin also produced hybrids and reported that the hybrids tended to have greater vigor and growth than the parents of the hybrids. Beal studied hybrids of open-pollinated varieties (variety crosses) of maize (*Zea mays* L.) in 1880 and reported that the yields of the hybrids exceeded yields of the parent varieties.^[3] Further crosses among maize varieties were produced, but the hybrid yields were not consistently greater than the parents of the hybrids. Data for 244 variety hybrids of maize produced during the first two decades of the 20th century were summarized and the chances were about equal that yield of the variety hybrids was or was not better than the greater yielding parent.^[4,5] Because the hybrids were often produced in a haphazard manner and yields of the hybrids were not consistently greater than the parental varieties, hybrids of open-pollinated maize varieties were not widely accepted. Choice of parents, production methods, and genetic variability of the parent varieties were contributing factors for the inconsistent performance of the maize variety hybrids.

Early studies of hybrids were of interest, but the researchers did not recognize the commercial possibilities of hybrids. They were examining potential of the uniqueness and benefits of hybrids for the gardeners and farmers. Success in development of maize hybrids stimulated interest in other crop species, and success was attained in most instances.^[6] Greater interests and efforts were emphasized in those plant species that had potential to be exploited commercially. Ownership of the parents of successful hybrids permitted control by the originator of the parents of the hybrids.

The modern concept of hybrids was developed from inbreeding and crossing studies of maize conducted 1908 to 1910.^[7-9] Methods were explicitly described for development of pure lines (inbreds), crossing of the inbreds to produce single-cross hybrids ($A \times B$ and $C \times D$), and testing of single-cross hybrids to determine the best hybrid to provide to the producers. The concepts were not readily accepted because of the difficulties of producing adequate quantities of hybrid seed on the weak, poor-yielding inbreds. The cost limitation was reduced when it was suggested that single-cross hybrids ($A \times B$ and $C \times D$) be used to produce double-cross hybrids ($A \times B$) ($C \times D$). The four inbreds (A, B, C, and D) were not closely unrelated, and the yield of the double-cross hybrids was similar to

the yield of the single-cross hybrids. The suggestion for use of double-cross hybrids stimulated greater interest in hybrids, and maize research programs were initiated during the 1920s to test the proposed concepts.^[7,8]

HYBRID MAIZE

The genetic studies conducted by G. H. Shull were the basis for developing maize hybrids.^[7] The concept of and research on the commercialization of maize hybrids have been the model used to develop hybrids in other plant species.^[6] Development of superior maize hybrids includes isolation of pure lines (or inbreds), usually by self-pollination, and the evaluation of inbreds in hybrids to determine which hybrids have superior performance. The original suggestion was for single-cross hybrids [crosses of two inbreds ($A \times B$)]. Extensive research on inbreds and double-cross hybrids was conducted during the 1920s for inbred development, relation between inbred traits and their hybrid traits, initial evaluation of inbreds for combining ability in testcrosses, prediction of performance of inbreds in double-cross hybrids, and evaluation of predicted double crosses. Initially, yields of the first double-cross hybrids were not significantly greater than the landrace cultivars from which the inbreds were derived. During the 1930s, double-cross hybrids that were superior to the landrace cultivars became available. Entrepreneurs recognized the potential commercial value of hybrids, and organizations were developed to produce and sell consistently high-quality seed to the producers. Inbreds used to produce the double-cross hybrids were developed by public sector breeding programs.^[3]

Acceptance of maize hybrids was rapid and nearly 100% of the U.S. Corn Belt area was planted with double-cross hybrids by 1950. Consequently, commercial organizations rapidly expanded and developed their own breeding programs. Commercial breeding programs developed improved inbreds and hybrids by pedigree selection within elite-line crosses. Vigor and seed yields of the recycled inbreds were better than the original (first-cycle) inbreds developed from the landrace varieties. Because breeding, selection, and testing methods were simpler for single-cross hybrids, the improved inbreds could be used to produce single-cross hybrids at costs acceptable to the producers. Starting in the 1960s, single-cross hybrids were produced and sold to the producers. Presently, nearly 100% of the U.S. maize area is planted with single-cross hybrids, which was the original type of hybrid described in 1910.^[7]

The development of the inbred-hybrid concept has had tremendous impact on U.S. maize production. Average U.S. maize yields seldom exceeded 1.88 tons per hectare

from 1866 to 1935. From 1935 to 1965, average U.S. maize yields doubled and from 1965 to 1995 average U.S. maize yields again doubled. By 2000, U.S. producers averaged more than 8.75 tons per hectare. Since 1932, average U.S. maize yields have increased more than five-fold and total production of more than 5 billion metric tons are produced on nearly 30% less area. The inbred-hybrid concept can rightfully claim to be one of greatest plant breeding achievements of the 20th century.

GENETIC BASIS OF HYBRID VIGOR

Hybrids are defined as being superior to either the mean of their parents or to the high parent. For practical purposes, hybrids greater than the better parents are desired. Although crosses between parents have generally been superior to their parents, the genetic basis of hybrid superiority (hybrid vigor or heterosis) has not been resolved.^[6,10] Different genetic hypotheses have been proposed, but definitive evidence in support of one specific hypothesis has not been adequate for explaining the phenomenon of hybrid vigor. Genetic explanations of hybrid vigor have included additivity of favorable alleles with partial to complete dominance effects and nonadditive effects due to overdominance and epistatic effects. Although research has focused on whether hybrid vigor is due to additive gene effects or nonadditive gene effects, in reality, however, all types of genetic effects are probably involved in the expression of hybrid vigor. The exact genetic basis of hybrid vigor may never be determined because the genetic effects will vary among crosses within a plant species and among plant species. Hybrid vigor is dependent on two factors: differences in gene frequencies between the two parents and some level of dominance. Hybrids among different inbreds identify some crosses that have greater hybrid vigor than other crosses. Origin of parents may suggest certain patterns where greater hybrid vigor may be expected. Hybrids have been tested extensively in maize breeding programs, and sources of parents for hybrids have been identified that have greater hybrid superiority than other sources. For example, inbreds that trace their origin to Reid Yellow Dent and Lancaster Sure Crop open-pollinated maize species are designated as heterotic groups because hybrids that include one parent from Reid Yellow Dent and one parent from Lancaster Sure Crop have greater hybrid vigor than hybrids whose parents are both from either Reid Yellow Dent or Lancaster Sure Crop. Inbreds of Reid Yellow Dent origin are usually the female parents to produce the single-cross seed. Similar heterotic groups have been identified in other areas of the world for maize. Similar patterns of heterotic groups have not been identified for

other plant species, probably because research has not been as extensive as in maize.

Breeding Hybrids and Marker-Assisted Selection

Alain Charcosset

*INRA-UPS-INAPG-CNRS, Station de Génétique Végétale,
Ferme du Moulon, Gif-sur-Yvette, France*

INTRODUCTION

Molecular markers bring new elements to the organization of genetic diversity in plant species. This information can be used by plant breeding programs in identifying original genetic resources to create new breeding populations and protecting new cultivars. Molecular markers offer additional applications of key interest in the case of hybrid breeding programs, including the organization of complementary genetic pools and the prediction of F1 hybrid performance based on parental information. These applications along with the use of molecular markers to assemble favorable alleles in new parental lines for hybrid development are described here.

ORGANIZATION OF GENETIC DIVERSITY— HETEROSIS PREDICTION

In the final part of the breeding program (Fig. 1), breeders have to determine hybrid combinations to be evaluated among numerous possible crosses of inbred lines. They also have to anticipate this choice to some extent when starting a new breeding population and choosing a tester for hybrid evaluation of the progenies.

Organizing breeding programs into complementary heterotic (or combining ability) groups is a common and practical approach to achieve these goals. These groups gather material that show similar hybrid response when crossed with a large range of material (or in other words show similar “specific combining abilities”) and sometimes share a common genetic origin (e.g., same ancestral population). As an illustration, maize inbred lines derived from European flint populations and American dent populations form two complementary groups for maize breeding in Northern Europe. In Northern America, inbred lines related to the Stiff Stalk Synthetic form a well-established heterotic group that has proven complementary to diverse other materials, considered presently as a “Nonstiff Stalk” heterotic group. When this approach is strictly applied, all hybrids tested will originate from between-group crosses, whereas all new breeding populations will originate from within-group crosses, leading to reciprocal selection of the two groups. For maize, it

is well established that molecular markers provide grouping of lines that are consistent with present heterotic groups (Fig. 2).^[2] Consequently, markers can be useful to establish the position of materials with uncertain origins with respect to these groups. Regarding plant species for which the possibility to develop hybrids is recent and no heterotic groups have been established yet, one can use markers for the better understanding of the organization of genetic diversity. This is particularly relevant to choose representative parental materials to be crossed for a preliminary evaluation of hybrid performance and combining ability. It should be mentioned here that European and Northern American breeding illustrate two contrasted situations, where successful heterotic groups were respectively pre-existing in traditional population varieties, or shaped by hybrid breeding from a mostly unstructured genetic pool.^[3,4] Both possibilities should therefore be compared in preliminary experiments.

One additional step toward choosing a priori hybrid combinations would be a direct prediction of performance. The relationship between molecular distance and hybrid performance or heterosis (advantage in performance of the hybrid over its parental inbred lines) has received extensive attention in this context. Heterosis of a hybrid is related positively to the divergence between its parents at quantitative trait loci (QTL) that display dominance effects. Divergence estimated with molecular markers will therefore be related positively to heterosis, provided that these markers display linkage disequilibrium with QTL involved in heterosis variation.^[5] The last condition explains to a large extent why prediction will be very efficient when considering hybrids between related inbred lines and/or a mixture of both between-group and within-group crosses (Fig. 3).^[2] On the other hand, divergence estimated using neutral markers will not be predictive of heterosis when only between-groups crosses are considered. Estimating divergence directly at genes involved in heterosis would improve prediction efficiency in this situation. Efforts are underway to better understand the genetic basis of heterosis in several crops, but this remains a long-term objective.

An interesting alternative to the former approach is to consider the property that two inbred lines that are

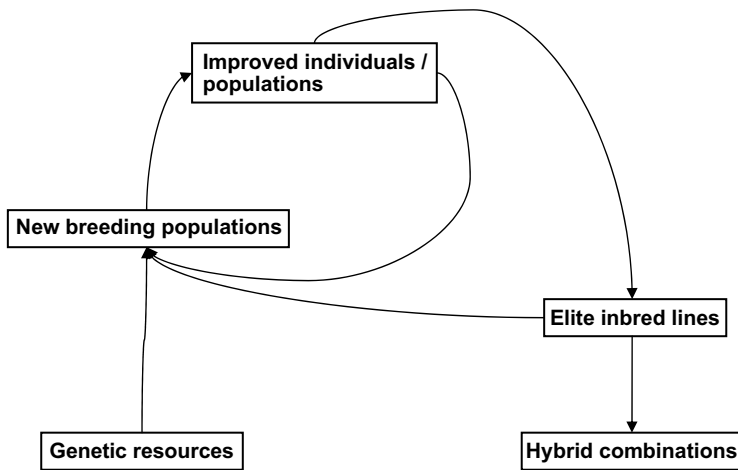

Fig. 1 Schematic representation of fluxes of genetic material within a hybrid breeding program. Boxes indicate the various types of materials. Arrows indicate selection followed by crossing (and/or selfing). All these steps can benefit from marker information.

similar for molecular markers should also display similar phenotypic values for most quantitative traits. As a consequence, two hybrids $A \times B$ and $A' \times B'$ that have similar parents at the level of genetic markers (e.g., A' close to A and B' close to B) should display similar heterosis or specific combining abilities. Bernardo^[6] developed a method based on best linear unbiased prediction (BLUP) to formalize this approach. The distances between lines are used here to estimate covariances between individuals whose performance is known, on the one hand, and individuals whose

performance needs to be predicted, on the other. Predictions can then be made by combining all information available in an optimal way. It is experimentally demonstrated that this approach can be efficient in situations where the distance approach is not efficient.^[7] It also has to be noted that the use of BLUP can increase the precision in the evaluation of general combining ability of inbred parental lines. It may also be used at any step of a breeding program to estimate the performance of the individual candidates prior to selection better.

MARKER-ASSISTED ASSEMBLING OF FAVORABLE ALLELES TO DEVELOP NEW HYBRID PARENTS

It is now well established that markers make it possible to determine the regions of the genome that contribute to the variation of trait's economical interest. Correlatively, it is also possible to identify favorable alleles for these regions (e.g., superiority of genotype AA vs. BB, A and B being the parental alleles). Several strategies can be used to take advantage of this information to assemble favorable alleles in new cultivars.^[8]

It is possible to develop an improved version of existing elite germplasm, the "recipient," by the targeted replacement of (a) given gene(s) or genome region(s) from the "donor" germplasm. This introgression is achieved by repeated backcrossing. Markers can be used sequentially in two complementary ways: facilitate, or make possible, the identification of individuals that carry the donor segment (foreground selection), and, among these, identify individuals that have the largest recipient genotype content outside the region which is considered (background selection). This approach can be of key interest in hybrid breeding to introgress genes involved in male sterility restoration.^[9] It can be applied to any Mendelian trait, considering possible dominance effects to determine whether a single or both parental lines of a hybrid should be introgressed to guarantee trait expression. Introgression can also be applied to quantitative traits. In this case, the uncertainty in QTL positions has to be taken into account and several markers appropriately spaced are generally needed to determine the individuals that carry the donor allele. This approach was used by Bouchez et al.^[10] to introgress three genomic regions involved in maize maturity and grain production.

Introgression reaches limits, however, when obtaining a sufficient genetic gain would necessitate the transfer of an "unrealistic" number of segments in the recipient cultivar, and/or when phenotypic selection is needed to obtain a genetic gain at undetected QTL. In this case, one should generally prefer a recurrent scheme that combines marker-assisted and phenotypic selection.^[11] Only few experimental results on the efficiency of this strategy for either pure line or hybrid breeding are, at present, publicly available. They confirm that cyclic selection conducted only with markers is very efficient for rapidly increasing the frequency of QTL alleles identified as favorable in the initial QTL mapping generation,^[12] and for increasing average performance, although results vary among experiments.^[13]

It has to be noted that the choice of QTL mapping designs for marker-assisted selection in hybrid crops raises specific questions when compared to pure line crops. Per se evaluation of selfed progenies should be recommended only for traits that display a high correlation between combining ability and per se performance for the trait(s) of interest. This is generally not the case for productivity traits for which the evaluation of test-cross progenies is recommended.^[10,14] Hybrid progenies between individuals from the segregating population derived from the cross A_1 and A_2 and tester line B make it possible to compare the effects of genotypes A_1B and A_2B at QTL. Marker-assisted selection then aims at assembling in a new line A_x alleles that lead to superior A_xB genotypes. As for traditional breeding, one may wonder about the genetic gain for hybrids between A_x and lines other than B, so that crossing with two or more testers may be considered.^[15,16] Finally, it should be noted that the combination of multiparental mapping populations and several testers^[17,18] offers interesting perspectives to better understand the genetics

of hybrid performance and better use of genetic diversity in marker-assisted breeding.

CONCLUSIONS

“Molecular markers provide new tools for breeding hybrids, including specific applications such as heterotic groups management and prediction of hybrid performance. Efforts are currently underway to better understand the genetic basis of heterosis through a combination of genomic approaches, fine mapping and expression studies in particular. The identification of genes and polymorphism involved should further extend the efficiency of hybrid breeding, thanks to a finer prediction of the performance of crosses between distant materials, as well as that of new genotypes created by marker assisted selection.”

Breeding Plants and Heterosis

Kendall R. Lamkey

Jode W. Edwards

University of Alabama, Birmingham, Alabama, U.S.A.

INTRODUCTION

Heterosis may be one of the most important biological concepts to emerge from the 20th century because of its fundamental role in the hybrid corn industry. Crabb considers the development of hybrid corn to be one of the seminal achievements of the 20th century.^[1] Corn yields were stagnant during the period when open-pollinated varieties were predominantly grown (pre-1930s), and since the discovery and implementation of the inbred-hybrid concept of breeding corn, yields have continued to increase and there are no signs of a plateau in yield.

DEFINITION

The term heterosis was coined by G. H. Shull in a lecture he gave in Berlin, Germany in 1912.^[2] Shull coined the word heterosis to avoid the implications that hybrid vigor was Mendelian in origin.^[3] Heterosis and hybrid vigor are now used as synonyms and refer to the increased vigor of a cross or hybrid over the average of its parents. Shull defined heterosis as "... the interpretation of increased vigor, size, fruitfulness, speed of development, resistance to disease and to insect pests, or to climatic rigors of any kind, manifested by crossbred organisms as compared with corresponding inbreds, as the specific results of unlikeness in the constitutions of the uniting parental gametes."^[2]

Shull's definition of the heterosis concept is a phenomenological definition and suggests no hypothesis about the underlying genetic basis of heterosis. The genetic basis of heterosis and the exploitation of heterosis in crop plants have been major foci of research since Shull's^[4,5] seminal papers on inbreeding and outcrossing. Two major volumes^[6,7] and several minor volumes and reviews have been devoted to the historic, scientific, and breeding aspects of heterosis.

SHULL'S COMPOSITION OF A FIELD OF MAIZE

The concept of heterosis can best be appreciated by reviewing Shull's description of the composition of an open-pollinated field of maize.^[8] After observing the effects of inbreeding and cross-breeding in maize, Shull observed "The obvious conclusion to be reached is that an ordinary corn field is a series of very complex hybrids produced by the combination of numerous elementary species. Self-fertilization soon eliminates the hybrid elements and reduces the strain to its elementary components." What Shull was saying was that every plant in an open-pollinated field of corn is a hybrid resulting from the cross of two random (i.e., different) gametes. Selfing the individual plants of the open-pollinated variety to homozygosity would result in the fixation of the individual gametes in the population in inbred lines. Crossing these inbred lines together would "re-create" the population and restore it to its original state of being a collection of hybrids.

Because an individual plant (which is a hybrid) of an open-pollinated field of corn cannot be reproduced identically by sexual or asexual methods, corn breeders must reduce segregating populations of corn to inbred lines to identify the superior gametes to cross for producing hybrids. Inbred lines are homozygous and homogeneous and can be maintained either by allowing them to open-pollinate in isolation or by self-pollinating. The reproducibility of inbreds means that hybrids can be reproduced indefinitely by making crosses between the inbred lines. Inbred lines, however, generally yield 40 to 70% less than the hybrid plant from which they were developed. This decrease in performance is known as inbreeding depression and is the converse of heterosis. Thus, to have heterosis of economic importance, the cross between two inbred lines must recover the performance lost from inbreeding depression and give an additional increase in performance above and beyond that lost by

inbreeding depression.^[9] Many believe that the key to understanding the genetic basis of heterosis lies with understanding inbreeding depression. Edwards and Lamkey have provided evidence that inbreeding depression is a heritable trait and that at least part of the observed inbreeding depression is due to a few genes with a large effect.^[10]

Thus, with the publication of Shull's paper,^[4] the hybrid corn industry was born. The quantitative genetics of agronomic traits and understanding the genetic mechanisms underlying heterosis became the focus of many research programs. Shull's concept that an open-pollinated population is a collection of hybrids was important conceptually to understanding the quantitative genetic basis of heterosis.

THE QUANTITATIVE GENETICS OF HETEROSIS

Studies in the genetics of heterosis have been mainly focused on issues of gene action, in particular, whether dominant or overdominant gene action is the basis of heterosis. There is little empirical evidence, from any species, to support overdominant gene action as the major cause of heterosis.^[11] The issue of overdominance versus dominance primarily affects choice of selection methodology in crop plants. Selection methods used in hybrid crops such as maize are optimal for both dominant and overdominant types of gene action. The debate over the type of gene action controlling heterosis was significant in that it served as the stimulus for much of the quantitative genetics research that has been conducted since the 1940s. This research has been reviewed extensively in the literature.^[11]

The terms "hybrids" and "heterosis" are not synonymous, as is often assumed. It is possible to produce hybrids that exhibit no heterosis, but it is not possible to have heterosis without producing a hybrid. The performance of a hybrid and the heterosis that a hybrid exhibits are two different functions of phenotype. Heterosis is most commonly defined as the difference between the performance of the hybrid and the average of its parents, which is usually called midparent heterosis, i.e., $H = \bar{F}_1 - \bar{MP}$, where H = heterosis, \bar{F}_1 = the hybrid performance, and \bar{MP} = the average of the two parents. Heterosis is often expressed as a percentage of the midparent, but this measure is difficult to interpret genetically and statistical tests are nearly impossible.^[9]

With this equation, heterosis can be calculated for any hybrid as long as phenotypic measurements exist for the hybrid and the two parents. The genetic expectation of this quantity is, however, a more difficult matter. For example, it would not be valid to calculate heterosis from the cross

of two inbred lines (F (inbreeding coefficient) = 1) and compare that value with the heterosis obtained from crossing two random mating and non-inbred populations ($F = 0$). The genetic expectation of the resulting estimate of heterosis is different for the two cases for two reasons.^[9] First, the inbreeding levels of the parents are different for the two cases and second, the reference populations are different. Hybrids made from more inbred parents will necessarily exhibit higher heterosis. Because heterosis is reference-population dependent, quantitative genetic interpretation of comparisons of heterosis among hybrids requires that the two estimates share a common reference population and have parents with equivalent inbreeding levels. For example, if the difference in heterosis between two single-cross hybrids is to be genetically interpreted, the parents of the two single-cross hybrids must be derived from the same reference population and have equivalent inbreeding coefficients.

THE PRACTICAL APPLICATION OF HETEROSIS

Despite the scientific interest in understanding the genetic basis of heterosis, hybrid crop breeders do not select hybrids with high heterosis and farmers do not plant hybrids because they have high heterosis. Both farmers and breeders want hybrids with the highest hybrid (F_1) yields. There appears to be no relationship between the increase in hybrid yields and an increase in heterosis. Yields in corn have gone up over time, but the experimental data suggest that heterosis has not increased over time.^[12] This would suggest that the benefits of heterosis have already been realized and that future gains in crop improvement in hybrid crops will not come from increasing heterosis (Fig. 1).

There are many advantages for farmers who grow F_1 hybrids. Chief among them is uniformity. Another advantage from a breeding perspective is that hybrids always outyield open-pollinated varieties because hybrid breeders are working in the tails of the distribution of phenotypes of an open-pollinated variety. For example, if we assume that an open-pollinated variety is a collection of hybrids that are normally distributed with some mean and variance (Fig. 2), farmers growing this open-pollinated variety will report yields near the mean of the distribution of hybrids. Hybrid breeders, however, will be working to identify, extract, and reproduce the best hybrid from the upper tail of the distribution. Even if open-pollinated breeders improve the population's performance, hybrid breeders can still take advantage of this shift in the mean of the distribution and extract F_1 hybrids even better than the ones from the unimproved population (Fig. 2). This shifting of the mean of the distribution while

Fig. 1 Maize yields in the United States from 1866 to 2001. The regression coefficients (b) for each of the periods of time represent the increase in grain yield (bu/ac) per year. (Data from the USDA-National Agricultural Statistics Service.)

Fig. 2 A comparison of the phenotypic distributions of two open-pollinated varieties before (with mean \bar{X}_{C0}) and after (with mean \bar{X}_{Cn}) selection showing that even if open-pollinated variety breeders are successful in improving their varieties, the best hybrids will still come from the tails of that distribution and be 2 to 4 standard deviations better than the mean of the variety. (Adapted from Ref. [13].)

maintaining the variance of the distribution is one of the fundamental objectives of recurrent selection programs and provides the long-term foundation for genetic variation that hybrid breeders need to continue making genetic gains.^[14]

Breeding Plants with Transgenes

Duška Stojšin

Monsanto Company, St. Louis, Missouri, U.S.A.

Carl F. Behr

Wyffels Hybrids Inc., Geneseo, Illinois, U.S.A.

INTRODUCTION

Transgenic crop breeding and evaluation strategies are based on the same general principles as those practiced by breeders working with nontransgenic crops. There are, however, specific considerations associated with evaluation of transgenic crops due to inheritance differences, evaluation criteria, and regulatory requirements.

Generally there are two distinct breeding stages associated with the commercial development of a transgene. The first stage involves evaluating and selecting a transgenic event, while the second phase involves integrating the selected event into commercial germplasm.

STAGE 1: CONSTRUCT AND EVENT SELECTION

A construct contains an engineered DNA sequence that is inserted into the plant genome via a transformation method. Numerous transformants are usually generated for a construct, each resulting in unique insertion site(s). These independent transformation events need to be evaluated in order to select those with superior performance. The construct and event evaluation process is based on five major criteria:^[1] 1) transgene expression/efficacy, 2) molecular characterization of the insert, 3) segregation of the trait of interest, 4) agronomics of the developed lines, and 5) stability of the transgene expression. Selection criteria usually stay the same throughout the evaluation process, but stringency of testing generally increases for each criterion in more advanced generations. As with traditional breeding, large population of independent transformation events and more thorough evaluation result in the greater chance of success.^[2]

1) Expression of a transgene is the level of protein or protein product controlled by the inserted DNA construct. Efficacy is the phenotypic expression of that gene of interest (GOI). Factors that can affect the level of expression and efficacy of a given event are insertion site, transgene copy number, intactness of the transgene, zygosity of the GOI, level of inbreeding associated

with a genotype, the genetic background, and environmental conditions.

2) Molecular characterization aids selection for transgenes with single, intact inserts. Molecular characterization requires a variety of assays to determine presence of GOI, copy number, insert number, insert complexity, presence of the vector backbone, and development of event-specific assays. Molecular characterization is a tool that assists in selection of events that exhibit simple inheritance and stable expression level of a transgene. It also provides tools for determining event purity and identity, and is a required component of various regulatory submissions.

3) Segregation of the trait of interest is tested in order to select transgenic events that follow a single-locus segregation pattern. A direct approach is to evaluate the segregation of the trait of interest; an indirect approach is to assess the selectable marker segregation (if one is associated with the transgene). Regardless of the approach, this criterion becomes more important once breeders can evaluate a large number of plants, family segregation, and the self-pollinated progeny of a given event.

4) Agronomic characteristics may vary among events due to somaclonal variation, insertional effects, homozygosity of a transgene, level of inbreeding of the plant genome, and genetic background. In advanced generations, agronomic performance should be evaluated in several genetic backgrounds in replicated trials. For hybrid crops, agronomic trials should be conducted in both inbred and hybrid background.

5) Stability of transgene expression needs to be tested in different generations, environments, and in different genetic backgrounds. Event instability over generations is often caused by transgene inactivation due to multiple transgene copies, zygosity level, highly methylated insertion site, or level of stress.^[3] Such events should be discarded even when gene silencing is reversible.

STAGE 2: COMMERCIAL PLANT BREEDING INVOLVING TRANSGENES

Transgenes used in commercial breeding programs generally have been selected for the criteria discussed above

before being transferred to commercial plant breeding programs. Generally, events with a single intact insert will be inherited as a single dominant gene and follow Mendelian segregation ratios. Commercial breeding strategies include 1) backcrossing and 2) forward breeding.

1) Backcrossing is an efficient breeding method when the goal is to recover the genotype of an elite inbred with the addition of a transgene. In each backcross generation, plants that contain the transgene are identified and crossed to the recurrent parent. Several backcross generations with selection for recurrent parent phenotype are generally used by commercial breeders to recover the genotype of the elite parent. During backcrossing the transgene is kept in a hemizygous state; therefore, at the end of backcrossing it is necessary to self- or sib-pollinate plants containing the transgene to fix the transgene in a homozygous state. The number of backcross generations can be reduced by molecular assisted backcrossing (MABC). The MABC method uses molecular markers to identify plants that are most similar to the recurrent parent in each backcross generation. With the use of MABC and appropriate population size, it is possible to identify plants that have recovered over 98% of the recurrent parent genome after only two or three backcross generations. By eliminating several generations of backcrossing, it is often possible to bring a commercial transgenic product to market one year earlier than a product produced by conventional backcrossing. Backcrossing and MABC are routinely used in the United States to develop transgenic crop products.

2) Forward breeding is any breeding method that has the goal of developing a transgenic variety, inbred line, or hybrid that is genotypically different, and superior, to the parents used to develop the improved genotype. When forward breeding a transgenic crop, selection pressure for the efficacy of the transgene is usually applied during each generation of the breeding program. Additionally, it is usually advantageous to fix the transgene in a homozygous state during the breeding process as soon as possible to uncover potential agronomic problems caused by unfavorable transgene \times genotype interactions. Forward breeding is used extensively in the United States to develop Roundup Ready[®] varieties of soybean [*Glycine max* (L.) Merr.] and cotton (*Gossypium hirsutum* L.), as well as Bollgard[™] cotton.

After integrating the transgene into commercial germplasm, the final product should be tested in multiple locations. Testing typically includes yield trials in trait neutral environments (e.g., insect free environments for insect-protected plants), as well as typical environments in the target market. If the new transgenic product has been derived from backcrossing, it is usually tested for equivalency by comparing it to the nontransgenic version in all environments.

QUALITY ASSURANCE AND QUALITY CONTROL

Because transgenic events are regulated by government agencies, it is important that commercial transgenic crops do not contain unintended transgenic events. Breeders working with transgenes must have appropriate quality assurance (QA) and quality control (QC) programs in place to avoid and/or detect errors that may result during the event evaluation and selection process.

1) Quality assurance is the set of best practices used to ensure the overall quality of the final product from the standpoint of transgene purity.^[4] The setup of a transgenic breeding nursery should be designed to minimize the possibility of contamination between nontransgenic and transgenic material or among different transgenic events. Nursery designs should use spatial and/or temporal isolation between nontransgenic and transgenic plants, as well as among different transgenic events. Other important QA methods include utilizing a consistent and concise pedigree nomenclature that clearly identifies the germplasm and transgene being integrated, checking phenotypic segregation ratios for the gene(s) of interest in each generation, and utilizing differences in germplasm to maximize the identification of off-types due to outcrossing. Additional QA measures are often practiced in cross-pollinated crops due to the increased risk of outcrossing. Some of these include restricting movement of a pollinating crew from one nursery to another, or increasing the spatial isolation between different transgenic events.

2) Quality control is the testing conducted to verify that the desired quality is actually achieved.^[4] Quality control is done with the objective to test the seed purity and integrity for the presence of an intended event. In addition, it is important to test for the absence of unintended transgenes, regardless of whether they control the same trait as the event of interest or different traits. Stringent QC standards ensure that the event purity and integrity is maintained in the evaluation, breeding, and seed-increase portion of transgene development.

CONCLUSION

The product of transgenic crop breeding is a new cultivar containing a specific transgene at a specific locus that controls or modifies expression of a specific trait. During the development and selection, events with single intact inserts and high and stable transgene expression should be selected. Efficacy and agronomic performance of the transgene needs to be demonstrated in different genetic backgrounds and in different environments. After integrating the transgene into commercial germplasm, the

final product should also be tested in multiple locations. Regulated handling of transgenic seed adds to the complexity of developing transgenic crops. However, social, economic, and environmental benefits associated with these products make these efforts worthwhile.

INTRODUCTION

Pure line cultivars are defined as cultivars that are “genetically pure or homozygous plants resulting from continued inbreeding or self-fertilization.” Plant breeding methods are usually determined by the pollination or reproductive biology of the plant that the breeder is trying to improve. Plants can be generally divided into three classes: self-pollinated [e.g., barley (*Hordeum vulgare* L.), rice (*Oryza sativa* L.), soybeans (*Glycine max* (L.) Merr.), wheat (*Triticum aestivum* L.)]; cross-pollinated [e.g., alfalfa (*Medicago sativa* L.), maize (*Zea mays* L.), sunflowers (*Helianthus annuus* L.)]; or apomictic [e.g., buffelgrass (*Cenchrus ciliaris* L.)]. Apomictic plants form seed from an asexual process that occurs in the ovary without the fusion of a male and a female gamete. Self-fertilization (selfing) occurs naturally in self-pollinated crops and can be done by hand pollinations in cross-pollinated crops. Hence, breeding pure lines is normally associated with self-pollinated crops, but is also an important part of breeding inbred lines that are used to make hybrids in self- or cross-pollinated crops. The inbred parents of hybrid crops are generally not available to farmers or producers, so they will not be discussed in detail here. However, their development is the same as a pure line that is intended to be released as a cultivar to farmers or producers; hence, the techniques described below are totally applicable.

THE PHASES OF PURE LINE PLANT BREEDING

There are three phases of pure line plant breeding, specifically: 1) the introduction of genetic variation; 2) inbreeding and selection; and 3) evaluation of the selected

lines.^[1,2] The first phase is to create variation for selection. The second phase uses inbreeding to separate the genetic variation into individual lines that can be selected. The third phase is to evaluate the selected variants in numerous environments to determine where the selected lines can be successfully grown and where they should not be grown.

Introduction of Genetic Variation

For self- or cross-pollinated plants, the introduction of variation is usually done by making a cross between two or more parents (a sexual hybrid). Variation can also be introduced by mutagens and genetic transformation (genetic engineering), but crossing is by far the most common method. When pure lines are used as parents, the crosses are often Parent 1 × Parent 2; (Parent 1 × Parent 2) × Parent 3; or (Parent 1 × Parent 2) × (Parent 3 × Parent 4). The crosses are known as single cross, three-way cross, or four-way (syn. double) cross. The progeny of these crosses are referred to as F₁ seed, where F is for filial (literally defined as “pertaining to a son or daughter”)^[3] and ₁ is the first generation of the cross. Succeeding generations are numbered in sequence, e.g., F₂, F₃, F₄, . . . , F_n. The F₁ seed form the initial population for the inbreeding and selection phase. Random mating populations (generally available only in cross-pollinated plants) can also be used as the initial populations for the inbreeding and selection phase. In most breeding programs, numerous populations are created each year.

Inbreeding and Selection

To understand inbreeding and selection in pure line breeding, the important concepts are: 1) the nature of inbreeding (usually selfing, but could be intermating

closely related individuals); 2) the approach to homozygosity; and 3) the type of selection involved (artificial or natural). Selfing has the quickest approach to homozygosity, and in self-pollinated crops it is the standard form of inbreeding. For a locus where the two parents have different alleles (e.g., AA vs. aa), the F₁ will be Aa (heterozygous). A heterozygous locus in the F₁ will segregate in later generations, so it is called a segregating locus. The F₂ will segregate 1/4 AA: 1/2 Aa: 1/4 aa (half of the progeny will be heterozygous and half of the progeny will be homozygous). In each successive generation without selection, heterozygosity will decrease by 1/2 and the level of homozygosity will be 1 minus the level of heterozygosity (Table 1). A locus can be either heterozygous or homozygous, so the sum of those progeny that are heterozygous and those progeny that are homozygous must equal 1. Plant genomes have tens of thousands of genes,^[4] so more than one important locus is heterozygous in the F₁. The formulae in Table 1 can be generalized, when *m* loci are heterozygous, to: 1) the proportion of progeny that are heterozygous at every segregating locus in F_{*n*} generation is (1/2)^{*n*}^{*m*}; and 2) the proportion of plants that are homozygous at every locus is (1 - (1/2)^{*n*})^{*m*}. The sum of the progeny that are heterozygous at every segregating locus and the progeny that are homozygous at every segregating locus does not sum to one because many individuals can be heterozygous at some loci and homozygous at other loci. The importance of knowing how many progeny are homozygous at every locus is that a pure line is genetically homozygous and should not segregate for important traits. The greater the number of segregating loci, the greater the number of selfing generations that are needed to create a pure line (Table 1).

With selection, the approach to homozygosity is improved and the number of lines with favorable alleles

is increased because unfavorable genotypes are eliminated. If aa is undesirable, for example, it can be removed at each generation, leaving only AA and Aa. Selection can be either artificial selection (selection done by the breeder) or natural selection (selection done by nature). Examples of artificial selection include the breeder selecting for earliness, plant type, or end-use quality. Some of these characteristics may be important in the marketplace, but do not affect plant performance. Examples of natural selection include: 1) disease or insect resistant plants producing more seed during infections/infestations than susceptible plants; and 2) fall-sown cereals surviving the winter to produce grain in the spring or summer. Plants that are diseased, eaten by insects, or winterkilled are removed from the segregating population by nature and not by the breeder (Fig. 1), hence the term "natural selection." Every time a plant is grown in the field, it is affected by natural selection.

The common inbreeding methods are pedigree, bulk, and single-seed descent.^[1,5,6] Briefly, in the pedigree system plants are selected in the early generations and their progeny are planted in a row (called a family). Early generation selection is for characters that are easily measured and highly heritable (e.g., the progeny will look like the parents). Often, early generation selection is based on culling, removing the plants with obviously poor or unwanted characters (e.g., disease susceptibility). Based on the phenotype of the family-row, individual plants are selected within each row that have the desirable characteristics for advancing to the next generation. No plants are selected in the families that do not have most or all of the desirable characteristics. As the family rows approach uniformity, whole families are selected, rather than individual plants within the rows (Fig. 2). Pedigree breeding uses both artificial selection and natural selection. In

Table 1 The consequences of inbreeding at a single locus and at multiple segregating loci on the proportion of lines homozygous at every locus^a

Generation	Single segregating locus		5 segregating loci	10 segregating loci
	Proportion heterozygous	Proportion homozygous	Proportion homozygous	Proportion homozygous
F1		1.0000	0.0000	0.0000
F2	1	0.5000	0.5000	0.0313
F3	2	0.2500	0.7500	0.2373
F4	3	0.1250	0.8750	0.5129
F5	4	0.0625	0.9375	0.7242
F6	5	0.0313	0.9688	0.8532
F7	6	0.0156	0.9844	0.9243
F8	7	0.0078	0.9922	0.9615
F _{<i>n</i>}		(1/2) ^{<i>n</i>} -1	1 - (1/2) ^{<i>n</i>} -1	

^aIdeally, a pure line should be completely homozygous. The more inbreeding, the greater the proportion or chance of selecting a homozygous line. Note that a homozygous line can have either the favorable or the unfavorable allele at the locus, in the absence of selection.

Fig. 1 Winter wheat F_2 populations growing at Mead, Nebraska in 2001. Surviving populations have lush, green plants; winterkilled populations are the bare spots in the field. The surviving and winterkilled populations are an example of natural selection, in that cold temperatures during the winter selected winterhardy plants and killed wintertender plants. No selection for winterhardiness by the breeder was needed.

the pedigree system, selection is done in every generation, and record keeping can become quite complex.

In the bulk breeding system, the progeny of a cross (or occasionally a number of crosses) are planted using commercial seeding rates and harvested in bulk in the early generations. The bulk breeding philosophy is that it is important to inbreed to a level of homozygosity before doing artificial selection. In later generations, lines are

selected from the bulk and planted as families, similar to the pedigree system. If the plants within a family are uniform, selection is based on the family. If the plants within a family are not uniform, then selection within the family is similar to that in the early generations of the pedigree system. In the bulk breeding system, natural selection occurs in every generation, but little artificial selection is done. Competition within a bulk population

Fig. 2 Experimental lines in the F_5 generation grown at Lincoln, Nebraska in 2002. Each line is grown in a four-row plot. The plots marked with red paint have been selected for harvest; the unmarked plots will be discarded. This is an example of family selection in which the families are sufficiently uniform that it is unnecessary to select plants within the family to further inbreed for uniformity.

consisting of different plant types is a concern, because competition may cause some desirable plant types that would be valuable as pure lines to be lost from the bulk population.^[7] Because the populations are kept as bulks, record keeping is minimal and very little time per bulk is needed. The simplicity of the bulk breeding method allows many populations to be in a breeding program concurrently.

In the single-seed descent breeding method, a large F_2 population is grown from the F_1 plants. A single seed from each F_2 plant is advanced to the next generation and the process of selfing and advancing a single seed is repeated for a number of generations, hence the name “single-seed descent.” After the appropriate number of generations, individual plants are harvested and their progeny are grown as families for selection. In single-seed descent breeding, the progeny of every plant is advanced, so there

is no artificial or natural selection. Because there is no selection, the plants can be grown in environments that do not represent normal growing conditions. For example, multiple generations are often grown in greenhouses or off-season nurseries under conditions that are completely unrepresentative of normal field conditions. The philosophy of single-seed descent breeding is that early-generation selection is not as valuable as inbreeding—often very rapid inbreeding.

Each of these three methods has its advantages and disadvantages, and often they are not used in their “pure” form, but rather are modified as needed. Pedigree breeding is often the most labor-intensive, because every plant in every generation is recorded and measured until it is discarded from the program. In crops such as maize, where selfing is done by hand and each plant is individually cared for, it is the only method that works.

Pedigree breeding, if resources were not limiting, would be the method of choice for most pure line breeders because it provides more information about each line than the other breeding procedures. The advantage of the bulk breeding method is that numerous populations can be easily manipulated concurrently. Bulk breeding is widely used in self-pollinated cereal crops. It is not unusual for a moderate-size wheat breeding program to create 500 to 700 new populations each year and to have over a million plants in each bulk generation. The disadvantage of bulk breeding is that less is known about a line and there is less artificial selection when compared to the pedigree breeding method. Single-seed descent breeding has the advantage that generations can be quickly advanced, often three generations or more per year. Hence, it is the quickest method to reach homozygosity, or uniformity, and it is commonly used in breeding soybeans. Its greatest disadvantage is that little selection is done during the selfing generations, so many undesirable lines are advanced. The lack of selection can be an advantage if artificial or natural selection may select the wrong lines. For example, single-seed descent can be used in Hawaii or Puerto Rico, due to their climate, for crops that will never be grown there. Because there is no selection, types that are adapted to other environments are maintained during selfing and their progeny can be selected in the appropriate environment.

An example of a breeding procedure using a mixture of these methods would be to use: 1) the bulk breeding method for the first two generations, to allow inbreeding and natural selection to reduce unwanted types; 2) the pedigree method in the middle generations, to select better plant types; and 3) single-seed descent for two or more rapid generations in the greenhouse or Hawaii, to increase inbreeding and line uniformity of the now highly selected lines.

Evaluation of Selected Lines

In this phase, the goal is to carefully evaluate the selected lines to determine which truly have potential for being produced as cultivars, to determine their area of adaptation, and to provide useful information for those growing the lines in the future. Regardless of the parents of the population or the breeding method used, the evaluation method will be the same, in that it involves replicated testing of advanced experimental lines in numerous environments. Replicated trials are expensive and labor intensive, so only the best lines are evaluated. Though there may be millions of plants in the early generations, less than 1% of the progeny reach the advanced experimental stage and are evaluated each year in replicated trials. Usually, fewer than five—and often none—are released as cultivars in a year.

CONCLUSION

With the advances in plant genomics and transformation, sources of genetic variation are greatly expanding. Inbreeding and selection will continue to be very important in breeding pure lines and will be augmented by marker-assisted selection using molecular markers. The near-finished products (the advanced experimental lines) will continue to be evaluated, using replicated field trials, to ensure they have the attributes that make them worthy of production.

Breeding Self-Pollinated Crops Through Marker-Assisted Selection

Brian W. Diers

University of Illinois, Urbana, Illinois, U.S.A.

INTRODUCTION

Plant breeders have made great strides in improving crop plants. These improvements have been made primarily through traditional breeding methods. These methods typically include the development of segregating germplasm and the selection of those genotypes with the best performance for traits of interest through direct trait evaluation. Marker-assisted selection (MAS) can be used by breeders to improve the efficiency of selection. With MAS, breeders select for traits of interest through genetic markers linked to genes controlling the trait or through backcrossing for the recurrent parent genome. For some traits, MAS could potentially increase the efficiency of selection compared to phenotypic selection.

The discussion in this article will be limited to MAS in self-pollinated crop plants that are grown commercially as inbred cultivars. Marker-assisted selection in hybrid crops will be covered in another article. Inbred cultivars are commonly grown for small grain and legume crops.

GENETIC MARKERS

The genetic markers typically applied in MAS are DNA polymorphisms. These polymorphisms are abundant in genomes and can be revealed through a number of methods. A widely used system to reveal polymorphisms is simple sequence repeat (SSR) markers. These markers are widely used because they are highly polymorphic, inexpensive, and relatively easy to use. These markers are being employed by breeders to map traits and conduct MAS. Additional genotyping methods such as allele-specific hybridizations, and TaqmanTM probes have also been developed for automated assays of specific genetic regions.

USES OF MARKER-ASSISTED SELECTION

Before MAS can be done, markers must be identified that are tightly linked to the genes being selected. These linkage associations are typically identified in genetic

populations that are phenotyped for the trait of interest and screened with a battery of genetic markers. These data are analyzed and the positions of the genes relative to markers are determined.

A primary use of marker-assisted selection is in the identification of plants or experimental lines within segregating populations that carry favorable alleles. In the development of inbred cultivars, breeders typically cross parents to develop segregating populations.^[1] Plants in the populations would be selfed until an acceptable level of homozygosity is reached and inbred lines would be derived from the plants. Selection may occur during inbreeding, or single-seed descent^[2] may be done without selection. Marker-assisted selection could be employed any time during this process to assist in the identification of desired individuals.

With MAS, breeders would use markers linked to genes of interest to select plants or lines that have a high probability of carrying the desired genes. Compared to traditional phenotypic selection, MAS could potentially reduce costs, increase the total number of plants or lines available for selection, increase the effectiveness of selection, and reduce the time required for a breeding cycle. The efficiency of MAS for quantitative traits has been evaluated using modeling and simulation methods.^[3,4] The overall conclusions from these studies are that MAS could be more efficient than phenotypic selection when populations are large and traits have a low heritability. An additional consideration is the cost of phenotypic selection. Even when traits are highly heritable, if the cost of phenotypic selection is high, MAS would be cost effective if markers linked closely to the genes of interest are available.

An example of a trait that is effectively selected with markers is resistance to soybean cyst nematode (SCN, *Heterodera glycines* Inchohe) in soybean [*Glycine max* (L.) Merr.]. Because of the importance of SCN resistance in soybean cultivars, this is a major breeding objective worldwide. Phenotypic selection for SCN resistance is done by counting the number of female nematodes produced on the roots of inoculated plants, which is tedious and expensive. Although SCN resistance in populations is quantitative, a few major quantitative trait loci (QTL) control a large proportion of the resistance and these

QTL have been targets of selection. Mudge et al.^[5] showed that by selecting two SSR markers that flank the major SCN resistance gene *rhg1*, they could identify 98% of the lines that had a 70% reduction in female nematodes on the roots compared to the susceptible check. Concibido et al.^[6] estimated that the cost of phenotypic screening for SCN resistance was \$1.70 per data point, whereas PCR-based MAS cost \$1.50 per data point. Since the writing of Concibido et al.^[6] in 1996, the cost of phenotypic screening has increased and the cost of MAS has been reduced. Both private and public breeders have incorporated MAS for SCN resistance into their breeding programs.

In contrast to disease resistance, MAS in segregating populations for other traits such as yield will likely be difficult in elite germplasm. This difficulty exists because it is often not obvious which parent of an elite population carries each positive allele for QTL until mapping is done within the population. This is inefficient because it requires the collection of phenotypic data prior to MAS. In addition, there is likely insufficient linkage disequilibrium present in crop species to make predictions of what QTL alleles are present in parents based on all but very closely linked markers.^[7]

Selection during backcrossing is another important use of genetic markers in the development of inbred varieties. Backcrossing is a breeding method in which one or more genes is transferred from a donor parent into a recurrent parent through a series of crosses back to the recurrent parent. The recurrent parent typically has high performance, but is deficient for one or more traits carried by the donor parent. For example, this method is often employed to add new disease resistance genes or transgenic traits into cultivars that are used as recurrent parents. Markers can increase the speed of backcrossing through selection both for genes being backcrossed and for the recurrent parent genome.

Markers are especially useful in selecting the gene being backcrossed when the phenotype of the gene can not be easily assayed. This includes cases in which the gene is recessive, a destructive test is required for phenotyping, the phenotype is only expressed after pollination, or the gene contributes to a quantitative trait that can be evaluated only in replicated tests. Selections can be made, based on markers linked to the gene being backcrossed, that alleviate the need for progeny testing between cycles of backcrossing. It is especially important to have markers tightly linked to the gene or there is a significant risk that recombination between markers and the gene may occur. Such an event would result in the loss of the gene during backcrossing.

The recovery speed of the recurrent parent can be increased using markers in the selection of backcross

individuals that carry the greatest proportion of the recurrent parent genome. For example, during each generation of backcrossing, F_1 individuals can be tested with a set of markers spaced throughout the genome. Those individuals fixed for the greatest proportion of recurrent parent alleles are selected. Using modeling experiments, Hospital et al.^[8] determined that if fewer than 10% of the backcross F_1 individuals were selected based on markers each generation, the amount of recurrent parent genome in individuals after three generations of backcrossing is about equal to or greater than expected without selection at the fifth backcross generation. A difficulty that many breeders working with self-pollinated crops face in selecting for the recurrent parent genome is in generating sufficient backcross F_1 seed to select among. This is especially true in legume species such as soybean, where the production of large numbers of hybrid seed is time consuming and expensive.

An example of MAS during backcrossing was provided by Zhou et al.^[9] They improved grain quality through MAS by incorporating the *Waxy* gene into the cultivar Zhenshan 97 through three backcrosses and one selfing. During backcrossing, MAS was done to select for the *Waxy* gene, to identify recombinants close to the gene, and to recover the recurrent parent genome. The incorporation of the gene improved grain quality of both the line by itself and the line in a hybrid combination. The agronomic performance of both the backcross line and the hybrid were essentially identical to the recurrent parent with the exception of reduced grain weight.

CONCLUSION

It is expected that the cost of marker technology will continue to decrease. In addition, more genes controlling quantitative and qualitative traits will be mapped and cloned. These factors are expected to result in more widespread use of MAS in the future.

Breeding Synthetic Cultivars

Steven E. Smith

University of Arizona, Tucson, Arizona, U.S.A.

INTRODUCTION

Synthetics and the specialized populations derived from them—known as synthetic cultivars (also commonly referred to as synthetic varieties,^[1] which are considered completely equivalent to synthetic cultivars here)—are common products of plant breeding activities in a wide array of cross-pollinated species. Various definitions have been applied to these populations and some plant breeders have considered them to be equivalent, although this can lead to confusion. Following Lonnquist,^[2] a synthetic is an open-pollinated population maintained in isolated plantings that is derived from the random mating of selfed plants or lines or other genotypes (parents) produced from mass selection. As such, a synthetic is simply the bulked seed resulting from one or more cycles of population improvement that involve artificial selection.

WHAT ARE SYNTHETIC CULTIVARS?

Synthetic cultivars have generally come to represent a specific type of synthetic that is intended for commercial (on-farm) use.^[3] As such, the parents of synthetic cultivars are also preserved for future synthesis of the cultivar and may be inbred or sibbed lines, clones, F_1 hybrids, or populations.^[4] When open-pollinated populations are intermated, the resulting population is sometimes referred to as a composite or composite variety, in contrast to synthetics or synthetic cultivars.^[5] The original concept behind the production of synthetic cultivars is attributed to Hayes and Garber^[6] and their work with maize. They described the “synthetic production of a variety” as involving hybridization among several inbred lines, with selection among F_1 progenies and advanced generations to produce an improved open-pollinated population. In early formal definitions of synthetic cultivars, the selection of parents was necessarily based on some test of their combining ability, which could be used to differentiate synthetic cultivars from synthetics or typical open-pollinated populations. However, some plant breeders have broadened the use of the term “synthetic cultivar” to include any open-pollinated population produced in plant breeding that is intended for direct commercial use.^[5,7]

Specialized abbreviations are used to describe the generations represented by individual synthetics or synthetic cultivars.^[2] Most commonly, genotypes initially intermated to produce a synthetic (or synthetic cultivar) represent the Syn-0 generation. Likewise, the Syn-1, Syn-2, etc. generations represent the seed produced by intermating progenies produced by Syn-0 and Syn-1 plants, respectively.

PARENTAL PERFORMANCE

Parental performance due to additive gene action is preserved within synthetic cultivars. The use of synthetic cultivars also allows for the controlled exploitation of heterosis. This is most important in cases where the production of hybrid varieties is not possible because it is not economical to control pollination adequately for the production of hybrid seed. With completely random mating, the Syn-1 generation will result from all $n(n-1)/2$ possible crosses between n parents, and is assumed to contain equal numbers of progenies from each of these crosses. The performance of advanced generations in synthetics depends on the number of parents (n), the mean performance of the parents themselves (\bar{P}), the mean performance of all possible hybrid combinations among the parents (\bar{F}_1), (which is equivalent to general combining ability), and the amount of self fertilization that occurs. If only a few parents are included, the average performance of Syn-1 offspring would be expected to be higher, but this would also be associated with a higher coefficient of inbreeding in later generations. A simple relationship, now commonly known as Wright’s formula, has been developed to estimate the performance of the Syn-2 generation (denoted by \hat{F}_2) where parents are in Hardy-Weinberg equilibrium:^[5]

$$\hat{F}_2 = \bar{F}_1 - \frac{(\bar{F}_1 - \bar{P})}{n}$$

The rationale behind this relationship is based on the value $\bar{F}_1 - \bar{P}$, representing performance attributable to heterosis and the theoretical expectation that $1/n$ of the heterosis in the F_1 (Syn-1) will be lost in the F_2 (Syn-2) or, alternatively, $(n-1)/n$ of this heterosis will be retained.^[8] Assuming random mating and no selection, no loss of heterosis is expected in later generations in diploid orga-

nisms. As the number of parents in a synthetic increases, the performance of the synthetic will approach that of the source population. While there remains much disagreement, the optimum number of parents for a synthetic cultivar may be as few as four, although in practice larger numbers of parents are common.^[9] Very large numbers of parents may be used in cases where stability of performance is considered more important than absolute performance. Extensive description of the theory related to the prediction of synthetic cultivar performance and gene action responsible for this has been presented.^[9,10]

CONCLUSION

Synthetics are a common component of population improvement programs in most cross-pollinated crop species, although the term may not be routinely applied by plant breeders. Cultivars in many perennial forage crops are regularly referred to as synthetic varieties.^[3,11] In these species the broadest definition of the synthetic cultivar is generally adopted and parents are usually highly heterozygous, are typically not selected for combining ability, and are most often preserved for resynthesis as vegetative propagules. Natural intermating and successive generations of seed increase are important elements of the synthetic cultivar concept in these species because commercial quantities of seed may not be available until Syn-3 or Syn-4 generations.^[3] Other than in these perennial forage species, synthetic cultivars are most common in maize, where parents are often inbred lines. Such synthetic cultivars are generally intended for use in environments where stability of performance may be paramount and the infrastructure necessary for the production of hybrid varieties does not exist.^[12] Limited efforts have also been directed toward the development of synthetic cultivars in some partially self-pollinated crop species.^[13]

Breeding Using Doubled Haploids

Richard E. Veilleux

Virginia Polytechnic Institute & State University, Blacksburg, Virginia, U.S.A.

INTRODUCTION

Haploids are organisms with the gametic chromosome number (i.e., half the number of somatic cells). In seed plants, haploids can be derived from the tissue culture of gametic cells (microspores, megaspores) occurring in the anthers or ovules of flowers or by wide crosses. Doubling the chromosome number of haploids results in completely homozygous plants useful in various plant breeding applications. In self-pollinating crops (e.g., barley, tomato, wheat), doubled haploids (DH) have been used to construct linkage maps of molecular markers and to estimate the number of genes controlling complex traits and even directly released as cultivars. In cross-pollinating crops (e.g., maize, potato, cucumber), DH have been used to examine the effects of inbreeding and to derive inbred lines. Such lines can be used for hybrid cultivar production or for studying the inheritance of useful traits. Molecular maps based on DH of cross-pollinated crops have many skewed loci due to selection against deleterious alleles during haploid derivation. A single cycle of haploidization and chromosome doubling can dramatically reduce the time required to develop homozygous lines, compared to the usual method of inbreeding for many generations.

OCCURRENCE OF HAPLOIDS

In nature, haploids occur sporadically as weak, sterile plants with half the usual chromosome number for a given species. Charles Rick, an eminent plant geneticist, scoured the tomato fields of central California, selecting unfruitful plants. By cytogenetic analysis, he reported that two of 66 unfruitful plants were haploid ($2n = 1x = 12$), occurring at a frequency of 0.0036%.^[1] Spontaneous haploids often occur in twin seedlings, where two plants emerge from the same seed: one from a normal zygotic embryo after fertilization of an egg cell by a sperm, and the other through adventive embryogenesis of a haploid cell within the embryo sac, likely a synergid. The frequency of spontaneous haploids varies with species and cultivar. The general sterility of haploids precludes their direct utilization in breeding programs, so for many years they were regarded as botanical curiosities; it seemed surprising that higher plants could even survive with so few chromosomes.

ANTHER/MICROSPORE CULTURE

Sipra Guha, a graduate student in botany studying plant developmental biology under Satish C. Maheshwari at the University of Delhi in the 1960s, cultured floral organs of the jimson weed (*Datura stramonium*) to observe their development in plant tissue culture. The appearance of embryos in cultured anthers after several weeks was unexpected; that these embryos had the haploid chromosome number was even more surprising.^[2] The process whereby the gametophytic development of immature pollen is redirected to sporophytic development of haploid embryos and plants is called androgenesis. The anther culture technique is now available for many species. Isolated microspore culture—wherein immature microspores are extracted from anthers, purified, and cultured on a synthetic growth medium—has also been used, albeit with less success. Anther culture is a reasonably simple technique: Immature buds are selected with microspores at the late uninucleate stage (just at the first pollen mitosis that ordinarily results in the formation of vegetative and generative nuclei); after surface sterilization, the buds are dissected in a laminar-flow hood and the detached anthers placed in either liquid or solid sterile culture medium that may be amended with plant growth regulators or other substances; after 4–6 weeks, embryos or plantlets may emerge from the cultured anthers. The anther culture response is variable, the frequency of embryos from cultured anthers is often low. Embryos must be transferred to a different medium—usually with a high cytokinin/auxin ratio—to encourage regeneration (Fig. 1). Plantlets can be transferred directly to basal medium. Haploids can be verified by chromosome counts, flow cytometry of nuclei stained with a DNA stain, or chloroplast counts in guard cell pairs. If anther culture is unsuccessful, haploids may be obtained by ovule culture, used successfully for beet and onion.

WIDE CROSSES

Haploid plants can also be obtained through interspecific hybridization, e.g., in barley [*Hordeum vulgare* × *H. bulbosum*^[3]], wheat [*Triticum aestivum* × *Zea mays*^[4]], potato [*Solanum tuberosum* × *S. phureja*^[5]], and tobacco [*Nicotiana tabacum* × *N. africanum*^[6]]. In such crosses the

endosperm may develop normally but the unfertilized egg grows into a haploid embryo. Otherwise, the embryo resulting from a fertilized egg may undergo elimination of paternal chromosomes. Elimination may be incomplete, resulting in the transmission of fragments of the paternal genome to predominantly maternal haploids. Embryo rescue—the excision and culture of immature embryos—may be required to prevent premature embryo abortion. In some cases (e.g., in apple and potato), a dominant homozygous marker has been linked to the locus that facilitates haploid induction in the pollinator. With this refinement, true hybrids carry the easily scored marker and can be discarded; individuals without the marker are putative haploids.

CHROMOSOME DOUBLING

Colchicine—an extract of the autumn crocus, *Colchicum autumnale*—has been used to double the chromosome number of plants,^[7] thus providing a means to convert haploids to homozygous lines. Colchicine may be incorporated into the medium used for anther or microspore culture to increase the frequency of DH directly. Colchicine can otherwise be applied in a separate treatment to previously identified haploid plants. Alternatively, DH can be spontaneously regenerated by tissue culture of nonmeristematic explants of haploids (Fig. 2). Thus, androgenic or gynogenic DH populations can be obtained for many crops.

DOUBLED HAPLOIDS

The genetic architecture of haploid and doubled haploid populations differs with the breeding structure of the

species. Self-pollinated crops tolerate inbreeding. They harbor no onerous genetic load (i.e., the recessive deleterious and lethal alleles found in cross-pollinated species). Therefore, a DH population derived from a hybrid of two inbred lines of a self-pollinated species is expected to represent a random gametic array of genotypes. However, with cross-pollinated species, exposure of deleterious and lethal alleles on haploidization, when there is no alternative viable allele to compensate, would result in the death of haploid embryos or plants bearing such lethals. Hence, the rigorous selection imposed by haploidization may result in a population of plants that differs dramatically from products of a random gametic array.

BREEDING WITH DOUBLED HAPLOIDS IN SELF-POLLINATING CROPS

In self-pollinating crops with true-breeding cultivars (i.e., wherein the progeny resemble the parents except for infrequent mutations), the general breeding strategy is to cross parents with contrasting desirable traits. The progeny are then selected over several generations of self-pollination until complementary traits are fixed in an inbred line that, after several years of evaluation, becomes a new cultivar. An obvious advantage of employing DH in such a breeding scheme is to fix complementary traits in inbred lines by extraction of haploids from the F_1 hybrid and doubling the chromosome number. Depending on the life cycle of the species, this can reduce by several years the time for developing a new cultivar. Anther-derived DH of wheat released as cultivars in France and Hungary required approximately half the usual time to develop.^[8]

Because this process requires fewer generations than does inbreeding, it involves fewer cycles of genetic recombination. For DH derived from an F_1 hybrid, only a single recombination occurs before homozygosity is fixed; for inbreeding by self-pollination in a diploid

Fig. 2 Monoploid potato at left with 12 chromosomes and its doubled monoploid counterpart at right with 24 chromosomes. (View this art in color at www.dekker.com.)

species, six cycles are required to reach 98% homozygosity, with each cycle affording another opportunity for genetic recombination. Actually, fewer cycles did not appreciably affect the quality of barley inbreds.^[9] Although there were slight agronomic advantages among plants that had undergone a second cycle of recombination (e.g., taller plants, higher yield, more kernels per spike), the marginal advantage did not warrant postponing DH production.

Considerable effort has been focused in recent years on constructing genetic linkage maps of crop plants. The complete sequence of the model plant *Arabidopsis thaliana* has been determined.^[10] Its comparatively small genome size has assisted this effort. DH populations derived from an F₁ between parents that differ for many traits have been used to construct linkage maps in barley,^[11,12] rice,^[13] and canola (*Brassica napus*),^[14] among others. Parallel linkage maps have been constructed from rice hybrids using both a DH and a recombinant inbred line (RIL) population of common genetic origin.^[15] RIL were derived by self-pollinating and selecting single seedlings over nine generations. The major difference between the two populations was expected to reflect the number of opportunities for genetic recombination. With only a single exception, the markers retained the same relative positions on the two maps, but were further apart in the DH population. The RIL map was 70% of the length of the DH map.

The method of derivation of DH can also affect the length of a genetic map. Because of a generally higher recombination rate during microsporogenesis (male gamete formation) compared with megasporogenesis (female gamete formation) in plants,^[16] maps based on anther-derived DH are predicted to be shorter than those derived from gynogenic DH, as observed with barley.^[11]

BREEDING WITH DOUBLED HAPLOIDS IN CROSS-POLLINATING CROPS

In cross-pollinating crops, hybrid cultivars that result from crossing selected inbred lines dominate the market. Such cultivars may have a significant yield advantage over other types of cultivars. In addition, seed companies retain proprietary rights to hybrid cultivars. Because hybrid cultivars do not breed true, growers must purchase fresh seed each year rather than save seed from the previous year's harvest. Therefore, development of superior inbred lines and their test-crossing to evaluate hybrid combinations are important for breeding cross-pollinating crops. DH are an important source of homozygous lines. Asparagus is a unique situation because it has both male and female plants (dioecy) with a sex determination system similar to that in humans (i.e., XX females and XY males). The male plants are considered more desirable

because of their more tender spears. Through the use of DH, both XX and YY plants can be produced, although the latter (supermales) would not naturally occur. By crossing XX and YY DH, uniform all-male hybrid cultivars are possible.

In many cross-pollinated crops, self-pollination reveals inbreeding depression, whereby lethal and deleterious recessive genes—usually masked by heterozygosity—are expressed. Eventually, the plants become too weak to be of any breeding value. The same process occurs on haploidization except that the weakest plants perish and the survivors represent unique genetic arrays with adequate vigor. These DH may not be fertile because sexual fertility is not prerequisite to survival, as for self-pollination. Haploids and their corresponding DH may be the only homozygous germplasm available in many cross-pollinating crops. However, their utilization as parents of hybrid cultivars is likely to require additional breeding. The first maize inbreds developed in the early 20th century were too weak to generate vigorous F₁ hybrids directly; therefore, hybrid seed produced by double crosses involving four different inbreds were used. Ultimately, more vigorous inbreds were developed such that true F₁ hybrids now dominate production fields. We could expect similar results with initial homozygotes of other highly heterozygous cross-pollinated species.

When DH are easily obtained, as for tobacco or canola, a DH population from an F₁ hybrid can be used to reduce genetic complexity of segregation patterns. As demonstrated in Fig. 3, for a dihybrid cross without linkage, only 25% of the F₂ are homozygous. However, with DH extraction from the same F₁ plant, the resulting population consists of only four classes of homozygous individuals, thus simplifying segregation ratios by eliminating heterozygous genotypes. The frequency of homozygous recessive

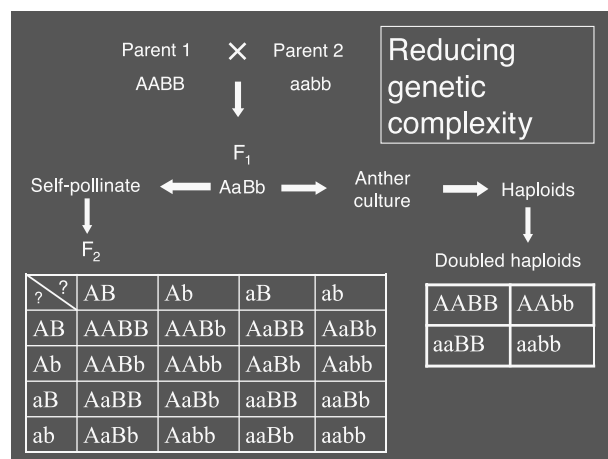

Fig. 3 Genotypic segregation in an F₂ vs. a doubled haploid population resulting from a dihybrid cross (AABB × aabb). (View this art in color at www.dekker.com.)

genotypes in an F_2 population is calculated as $(1/2)^{2n}$, whereas that of the DH population is $(1/2)^n$ where n = the number of independent genes that differ among parents. As the number of genes differentiating parents increases, the difference in genetic segregation between the two types of populations becomes more dramatic.

CONCLUSION

DH are only recently available for many crops. Yet they have already been exploited in plant breeding and genetic research. Cultivars have been released for several crops using DH parents, and many genetic maps have been constructed using DH populations. With self-pollinated crops, DH can easily be integrated into cultivar development schemes. However, with cross-pollinated crops, DH represent genetic equivalents to primitive inbred lines and will need considerable improvement before they have a significant impact on breeding.

Breeding Widely Adapted Cultivars: Examples from Maize

A. Forrest Troyer

University of Illinois, DeKalb, Illinois, U.S.A.

INTRODUCTION

Adaptation is the driving force of evolution. Local adaptation was important for open-pollinated varieties of maize (*Zea mays* L.). The number of varieties increased from about 250 to more than 1000 as the United States grew westward during the 1800s. Some varieties—Reid Yellow Dent, Minnesota 13, Lancaster Sure Crop, Northwestern Dent, and Leaming Corn—were more widely adapted and thus more widely grown. They persisted and then prevailed in the background of today's hybrids because they had more genes for adaptation to the U.S. Corn Belt. Hybrid maize provided wider adaptation. Aggressive, research-oriented maize seed companies grew at the expense of smaller, local companies. The number of maize seed companies decreased from thousands in 1930 to fewer than 300 today. Widely adapted hybrids do better in variable weather conditions. The farmer worries less about the weather.

CREATING VARIABILITY FOR ADAPTATION

Darwin's first topic in *Origin of Species* is causes of variability, which he attributes to changed conditions of life.^[1] Flint maize variability increased during domestication in tropical southern Mexico, during travel northwest to what is now the southwest United States, and then during travel northeast across the Great Plains to New England. Dent maize variability increased as Spanish Conquistadors moved it to Florida from Mexico via Cuba. American colonists and settlers selected in flint by dent crosses to obtain larger ears with straighter rows of kernels and greater numbers of rows. Corn Belt dent variability increased as maize moved with American westward expansion. Resulting open-pollinated varieties contain enormous variability caused by past adaptation to many changes in conditions of life over 6500 years of travel.

NATURAL ENVIRONMENTS AND ADAPTATION

Stevens^[2] states temperate climates have fewer but more widely adapted species than tropical climates. Temperate

climates are more variable and stressful. Temperate growing seasons have longer and more variable day length, cooler average and minimum temperatures, less frequent and less total rainfall, and shorter seasons. Flint maize has been in what is now the United States 2500 years longer than dent maize. Northern flints are typically earlier maturing and lower yielding than southern dents. Flint by dent crosses with subsequent natural and human (artificial) selection provided better adapted, higher yielding, open-pollinated varieties for all environmental niches in the United States.

Adapted maize flowers late enough in the growing season to provide adequate plant size, yet early enough to complete or nearly complete grain filling in an average length season.^[3] Maize maturity zones are based on accumulated heat units during the frost-free period. They match season warmth and length with plant flowering time and grain harvest moisture. Full-season maize usually yields more where season length is limiting. Short-day photoperiod reaction limits north-south adaptation.

The U.S. corn belt is a large area with several adaptive zones. Maize grown west of the Mississippi River requires more heat and drought tolerance, and less ear and stalk rot disease tolerance due to hotter, drier summers and drier autumns. Stronger ear retention is required because of greater European corn borer (*Ostrinia nubilalis*) pressure and windier autumns. East of the Mississippi River, the climate is more humid and maize requires more tolerance to fungal diseases and better root strength. Virus tolerance (MDMV and MCDV) may be needed for the Ohio River Valley, Tennessee, and wherever Johnson grass (*Sorghum halepense* L.) is present.

ADAPTATION AND OPEN-POLLINATED VARIETY DEVELOPMENT

Human (artificial) selection emphasized good ears because more good ears were desired. Successful seed maize companies spanned human generations to modify varieties and establish reputations. More drought tolerance and earlier maturity were needed for westward expansion. A few varieties were more widely adapted and more popular than others: Reid Yellow Dent, Leaming Corn, and Lancaster Sure Crop varieties were selected under more

favorable natural conditions; Minnesota 13 and Northwestern Dent were selected under lower-rainfall, cooler-temperature, stressful natural conditions.^[4]

Darwin, in *Origin of Species*, notes the association of wider adaptation with greater taxonomic subdivision because larger areas contain more environmental niches where natural selection causes subdivisions.^[1] Adding human selection for cultural practices and different uses resulted in further subdivision and more open-pollinated varieties. Montgomery estimated 250 varieties existed before America's westward expansion and 1000 varieties afterward.^[5] Newer varieties were better adapted farther north and west as the southern corn belt of the 1830s moved to the Midwest by the 1880s. Adaptation for narrower environmental niches occurred just as Darwin predicted.^[1]

ADAPTATION AND HYBRID DEVELOPMENT

Hybrid maize began to replace open-pollinated varieties in the 1930s. Hybrid maize no longer relied on local

selection and production to become better adapted. Aggressive, research-oriented, hybrid maize seed companies grew at the expense of smaller companies. The number of maize seed companies decreased from thousands in 1930 to fewer than 300 today. Hybrids tested at several locations for a few years replaced varieties developed with many years of natural and human selection at one location. The five major, widely adapted varieties were outnumbered (91 to 5) by more locally adapted varieties in the initial development of inbreds for hybrid maize.^[6] But, the widely adapted germplasm persisted in hybrid breeding programs, and now these five varieties make up 87% of the known background of today's hybrids because they contained more genes for adaptation to the U.S. corn belt environment.^[4,7]

In 1921 G.S. Carter produced the first commercial maize hybrid (Burr-Leaming double cross) near Clinton, Connecticut. In 1924 H.A. Wallace's Copper Cross hybrid was sold in Iowa. In 1933 hybrid corn grew on 54,675 hectares (ha) (135,000 acres or about 0.1% of U.S. acres). In 1945 Iowa farmers grew 99% hybrid maize; 39,000 mechanical pickers harvested 75% of the Iowa crop.

Fig. 1 Average U.S. corn yields and kinds of corn, Civil War to 2000; periods dominated by open-pollinated, by four-parent crosses, and by two-parent crosses are shown; “b” values (regressions) indicate average gain per year. (Data compiled by the USDA.)

In 1950 the Corn Belt grew 99% hybrid maize. From 1960 to 1980, single-cross hybrids replaced double-cross hybrids (Fig. 1).

ARTIFICIAL ENVIRONMENTS (CULTURAL PRACTICES) AND ADAPTATION

Dobzhansky states in *Mankind Evolving* that ethnic culture modifies environments to help people adapt.^[8] Agronomic cultural practices modify environments to help maize adapt. Successful maize breeders selected for better adaptation to high intensity cultural practices^[9–11] (Figs. 1 and 2). Inorganic fertilizers proved useful in the early 1900s. Plant population densities in the Corn Belt tripled in 100 years and doubled in the last 40 (Fig. 2).^[10] From 1946 to 1950, Dr. Scarseth of Purdue conducted higher fertility, continuous corn trials.^[12] In 1954 2,4-D herbicide was first commercially used. In the early 1960s, agricultural nitrogen became much cheaper. Farmers averaged 50 kg/ha (45#/A.) in 1960 and 146 kg/ha (130#/A.) by 1980 (Fig. 2).^[11] In 1965 Atrazine[®] herbicide was first commercially used. In the late 1960s maize row width narrowed from 102 to 76 cm (40 to 30 in.). In the 1970s combines (field shelling) provided harvest-time yield results (faster feedback). Tax credits encouraged the purchase of larger machinery for more timely operations. In the 1980s nitrogen rates leveled off but plant densities continued to increase.

GENOTYPE-BY-ENVIRONMENT INTERACTION AND ADAPTATION

Genetic diversity (multiple genotypes) is an adaptive response to different environments. A more homogenous environment allows fewer genotypes to prevail. A completely homogenous environment allows a single genotype to always be superior. More plants per acre, earlier planting, more nitrogen, narrower rows, and better pest control provide a more homogenous environment that requires fewer genotypes. Such an environment particularly favors those genotypes surviving natural and artificial selection for adaptation to these resources and practices.^[9,13]

Ceccarelli emphasizes that plant characteristics for maximum yield are different under optimum conditions than under stressful conditions.^[14] He generates significant variety crossover interactions with widely different stability regression coefficients (0.80 vs. 1.17) extended to very low 1820 kg/ha (29 bu/acre) yield levels. He advocates breeding for these lower yield levels. Stability coefficients less than 1.0 are conservative (for stressed, lower-yield environments) and regressions greater than 1.0 are aggressive (for higher-yield environments). Farmers choose aggressive and conservative hybrids based on risk tolerance. Stability regression coefficients for popular hybrids in the U.S. corn belt usually range from 0.95 to 1.10. United States maize farmers average 9400 kg/ha (140 bu/ac) and expect more than 1820 kg/ha (29 bu/acre)

Fig. 2 Corn plant density (determined every five to seven years) and nitrogen fertilizer increase over time (1950–1990) in the U.S. corn belt. (From Refs. 9 and 10.)

at planting (hybrid choice) time—no market exists for special low-yielding maize hybrids.

Lower-yielding environments are important when breeding for wide adaptation. Calculating performance as the percent of location mean equalizes high- and low-yielding environments. Thus each environment will have equal weight when selecting top performers. Farmers produce maize and exchange it for money to pay bills. Yield results in local market dollars per unit area on date of harvest compensate lower-yielding seasons and earlier-maturity hybrids via higher prices. This identifies, over time, the higher-value hybrids for an area. Hybrid by year (growing season) is the most important interaction. Years (growing seasons) may be warm, cold, long, short, wet, or dry. Hybrid by location interaction in the U.S. midwest is usually caused by differing moisture availability at flowering time.

WIDELY ADAPTED HYBRIDS

Widely adapted hybrids perform well under variable weather conditions and are more likely to produce higher yields. The farmer worries less and profits more.^[13] Fewer hybrids are necessary for all concerned. Regional hybrids have deficiencies that limit wider adaptation. Multiple-year results measure the consistency of hybrid performance and the value of the company's hybrid graduation system. Weather and cultural practices greatly affect maize performance. Many testing sites are necessary to adequately sample the total environment. More testing sites identify more genes for adaptation. Modern testing programs eliminate artifacts, use modern information management, and provide pertinent hybrid comparisons. Strip tests (large plots) mimic farmers' fields with less border effect, no alleys, and farmer management. Adaptation is critical; quality of germplasm is more important than quantity (number of chances) or diversity of germplasm. Successful U.S. corn belt maize breeding programs improve the adaptation of a tropical crop to a temperate environment.^[4,7]

High plant-density stress is the ultimate stress for maize. Selection against silk delay and for good ear development at higher plant densities is survival of the fittest in its purest form.^[9] It develops tougher inbreds and hybrids that are more widely adapted.^[13] Pioneer brand hybrids 3780 and 3732 were the world's two most popular maize hybrids. Three of their four parent inbreds were developed and the two hybrids were evaluated under high

plant-density stress. We applied 368 kg/ha (300#/acre) of nitrogen to nurseries and to yield test fields.^[13] Darwin states that excess of nutriment is perhaps the single most efficient exciting cause of variability.^[11]

Breeding: Choice of Parents

John W. Dudley

University of Illinois, Urbana, Illinois, U.S.A.

INTRODUCTION

The choice of parents for use in a plant breeding program is one of the most important decisions a breeder makes. It will determine the ultimate success, or lack thereof, in a breeding program. This critical choice should be based on the objectives of the breeding program; the germplasm, technology, and resources available to the breeder; the ease of manipulation of reproduction in the species; and some basic scientific principles. The purpose of this article is to outline the basic principles involved in choice of parents and to provide some basic guidelines useful to a breeder.

BREEDING STRATEGIES

A clear statement of the objectives of a particular breeding program is a necessary first step in determining choice of parents. For example, if the objective is to add a single gene for disease resistance to a cultivar with otherwise acceptable agronomic and quality characteristics, one of the parents must have the disease resistance gene, regardless of its other characteristics. On the other hand, if the objective is to develop a higher yielding cultivar of wheat (*Triticum aestivum*, L.) by crossing two good lines, then the parents should both be high-yielding to maximize the opportunity for producing a new line with higher yields than either of the parents' yields.

The types of breeding strategies for which parents are chosen can be grouped into three major categories, regardless of mode of reproduction: 1) Backcross programs in which the objective is to add a single gene or small number of genes to an existing elite cultivar. The usual objective is to add a gene for disease resistance or a quality factor without disturbing the unique combination of genes that make the cultivar elite; 2) crossing of elite lines to produce a segregating generation from which new lines with characteristics superior to either of the parents' characteristics will be selected. This second category is usually used for quantitative traits such as grain yield; and 3) development of segregating populations such as synthetic varieties, either for direct use in production or as a pool for recurrent selection.

BACKCROSSING

In the past, the choice of parents for backcrossing programs was limited by the availability of the single genes of interest in species that could be crossed with the cultivar to be improved. However, with the introduction of transformation technology, the source of a gene for improvement of a specific species can be any species. A prime example is the development of corn resistant to the European corn borer (*Ostrinia nubilalis*) using a gene from the bacterium *Bacillus thuringiensis*. The gene from the bacterium is introduced into a particular corn inbred by transformation. Once the gene is stabilized in the new inbred, the breeding procedure is the same as if a single gene had been found in a corn (*Zea mays*, L.) inbred. This topic is developed further in the articles on Backcross Breeding (Tracy, this volume) and Breeding with transgenes.

SELECTION WITHIN AN F₂

The basic principles for selection within a segregating population (such as within an F₂) are the same whether the species is self-pollinated (as, e.g., wheat) or is cross-pollinated and the inbred-hybrid system is used as in corn. The objective is to obtain a segregating population with a high mean and adequate genetic variance. Such a population would satisfy the usefulness criterion of Schnell.^[1] This criterion is expressed mathematically as $U_{(x)} = Y \pm \Delta G_{(x)}$, where $U_{(x)}$ is the usefulness of a population, Y is the mean of the unselected population, and $\Delta G_{(x)}$ is the expected gain from selection. $\Delta G_{(x)}$ is a function of the genetic variance in the population, the selection intensity, and a mating factor based on whether selection can be done prior to or after pollination. Thus, all other things being equal, a population with both a high mean and a high genetic variance would be more useful. This principle holds whether the population being developed is an F₂ from a cross between two pure lines or a synthetic from intercrossing several lines.

The identification of parents with potential to produce segregating populations with a high mean and a high genetic variance has been the subject of several studies.

Prediction of the mean of a cross is often based on the midparent value of the lines to be crossed. This prediction can be enhanced by use of the Best Linear Unbiased Prediction (BLUP) technique,^[2] which takes advantage of relationships among lines being considered. Prediction of genetic variance in a particular cross has been attempted by using genetic distance between parents based on either known pedigree relationships or distance calculated from molecular marker data.^[3] A general recommendation is to select as parents the pairs of lines with the highest predicted midparent values and within that set, select the pair or pairs that are most genetically diverse.

The usual axiom for plant breeders is to cross good by good in order to obtain something better. This basic principle for choosing parents of a cross between two inbreds is supported by theory based on the concept of classes of loci.^[4] For any pair of homozygous lines, there are four classes of loci that can be designated as *i*, *j*, *k*, and *l*. Class *i* loci are ++ for both parents, class *j* are ++ for P₁ and -- for P₂, class *k* are -- for P₁ and ++ for P₂, whereas class *l* loci are -- for both P₁ and P₂. Thus the only classes of loci useful for improvement of the population are classes *j* and *k*. The maximum probability of isolating a new line, homozygous for more favorable alleles than either P₁ or P₂, is obtained when the number of class *i* loci is equal to the number of class *j* loci.^[5] When one parent has several more loci with favorable alleles in classes *i* and *j* than the other, backcrossing to the parent with the largest number of loci with favorable alleles enhances the probability of obtaining a new line with more favorable alleles than either of the parents' alleles.^[4,6]

The concept of classes of loci can be extended to the choice of parents for improving a single-cross hybrid. In this case, three lines are involved: P₁, P₂, and a donor line (P_w). As shown by Dudley,^[7] eight classes of loci exist for three lines. The objective is to incorporate alleles from P_w into either P₁ or P₂ to improve the performance of the hybrid between them. Four basic questions need to be answered in choosing a particular P_w:^[7] 1) Which hybrid should be improved? The usual answer is the best hybrid for the target set of environments; 2) which parent line should be improved? In hybrid breeding programs based on heterotic patterns, the parent to be improved is the one to which the donor line is most closely related. This choice maintains the heterotic pattern, thus maximizing heterosis in the new hybrid; 3) which donor line should be selected? The short answer is: the line with the maximum number of loci with favorable alleles at loci where neither parent has favorable alleles and a minimum at loci where the donor has unfavorable alleles, the parent to be improved has favorable alleles, and the other parent has unfavorable alleles; 4) should selfing begin in the F₂ or should backcrossing be used? The answer to this

question is based on the principle that if the donor and the line to be improved have similar numbers of loci homozygous for favorable alleles at loci where they differ, then the maximum probability for identifying a line with more loci with favorable alleles than either parent is obtained. If the parent to be improved has many more loci homozygous favorable than the donor has, then backcrossing is indicated. These questions and their answers can be applied to use of a donor population as well as to a donor inbred.^[7]

SELECTION OF PARENTS FOR A SYNTHETIC

Again, the principle of usefulness applies. However, the prediction of mean performance of a potential synthetic is a function of the mean of all possible crosses among the parents and inbreeding depression.^[8] The equation $Y_2 = Y_1 - (Y_1 - Y_0)/n$ (where Y_2 is the mean of a synthetic obtained by intercrossing all possible single crosses among a set of n lines, Y_1 is the average performance of all possible single crosses, and Y_0 is the mean performance of the n parental inbreds) predicts the synthetic mean. This prediction says nothing about the variation in the population.

CONCLUSION

The basic principle of crossing good by good is not likely to change in plant breeding programs in the future. Current techniques for identifying parents are useful and provide an advantage over breeder's intuition. However, the availability of genomic technology may lead to refined methods of identifying parents having complementary sets of genes that will provide useful genetic variability for selection. This is particularly likely to be true if an adequate understanding of the genetic control of metabolic pathways involved in stress resistance and yield is obtained.

Breeding: Evolutionary Aspects

Irwin L. Goldman

Department of Horticulture, University of Wisconsin-Madison, Madison, Wisconsin, U.S.A.

INTRODUCTION

Breeding plants is a process that results in changes in the genetic makeup of plant populations. The process encompasses many of the key elements of evolution via a mechanism known as natural selection, with one major exception: The directional changes are dictated by humans rather than by the vagaries of natural environments. While the mechanism of change in breeding populations of crop plants is identical to that observed in natural populations, the scope and scale of the two processes are often viewed differently. Evolution via natural selection is often studied with respect to speciation and higher order branching, whereas most artificial selection work takes place below the species level. Artificial selection includes both human-directed selection and natural selection, albeit in disturbed environments common to agriculture; natural selection, in its pure form, is strictly a natural phenomenon. In addition, genetic drift and neutral variation have received far greater attention in evolution than in breeding, although their importance in breeding is significantly underestimated. Despite these differences, artificial and natural selections are analogous in many important respects. It is the goal of this entry to describe their key similarities and it also reveals as to how a view of these processes in concert may heighten our understanding of the ways in which genes can change frequency in plant populations.

ARTIFICIAL AND NATURAL SELECTIONS ARE ANALOGOUS

Distilled down to the essence, artificial and natural selections have three key elements: 1) fecundity, 2) heritable variation, and 3) differential reproduction and survival.^[1] These are the key principles outlined by Darwin^[2] for his mechanism of evolution known as natural selection. However, natural selection occurs mainly in nature and is nondirectional (in the sense that different phenotypes are selected in response to different environments and that such changes oscillate with a fluctuating environment), while artificial selection is practiced by humans and is often directional. It is important to note that both natural and artificial

selections may be operative in breeding populations. Allard^[3] suggested that farming itself can play an important role in adapting wild plants to cultivation. Darwin's deep respect for the process of artificial selection paved the way for acceptance of the idea of natural selection. Moreover, Darwin^[2] was inspired by breeders to reflect on the power of selection while thinking about evolution in nature.^[4] After his trip to the Galapagos, Darwin^[2] wrote (*italics mine*):

I often asked myself how these many peculiar animals and plants had been produced: the simplest answer seemed to be that the inhabitants of the several islands had descended from each other, undergoing modification in the course of their descent; and that all the inhabitants of the archipelago had descended from those of the nearest land, namely America. But it long remained to me an inexplicable problem how the necessary degree of modification could have been effected, and it would have thus remained forever, *had I not studied domestic production, and thus acquired a just idea of the power of Selection.*

Today, the relationship between artificial and natural selections is not often considered by breeders, but it may be helpful to reflect on the similarities of these two processes for a better understanding of how genes change frequency in domestic and wild populations. It should be said at the outset that natural selection in its strictest sense is not part of the changes that occur in breeding populations. This is because any human intervention renders the population subject to some type of artificial selection, even if it is minimal. For these reasons, use of the phrase "natural selection" in the context of a breeding program in this entry is an attempt to describe a mechanism functioning with minimal human directedness.

Attempts have been made to simulate the balance between artificial and natural selections in both breeding and natural environments. Perhaps the two best examples in crop breeding are the Composite Cross II experiment with barley in California and the Illinois long-term selection experiment (ILTSE) with maize in Illinois. Both are discussed in this entry. But before addressing these specific examples, it is important to point out that humans have been breeding plants for at least 10,000 years since the beginning of agriculture.^[5,6]

During this period, both artificial and natural selections have been operative in crop populations, which have resulted in the tremendous adaptation that we find in modern agriculture.

Adaptation is the process by which an organism acquires traits that will enhance its fitness and survival, and the process of adaptation follows directly from both artificial and natural breeding methods. It is important to keep in mind that the bulk of this work in adapting crops to particular environments took place prior to the codification of plant breeding as a science in the 20th century.^[5,7] Thus, our debt is to our farmer ancestors, who brought our crops out of the wild and initiated the process of artificial selection that we recognize today as scientific breeding.

RECONCILING DARWINIAN EVOLUTION AND SELECTION

Breeding and the process of artificial selection actually helped answer a number of important questions about evolutionary biology that were initiated with Darwin's work.^[2] Goldman^[8] described that for decades, a controversy existed among geneticists as to the nature of genetic changes following selection. One school maintained that selection was actually influencing the gene itself, rather than the frequency of the gene. Another school disagreed. Based on experiments suggested by Sewall Wright,^[9] in 1919, a selectionist point of view emerged from the research fields and laboratories in the U.S.A. The selectionist point of view, which caused scientists to think about their work in a population framework rather than about specific ideotypes of individuals in a population, had a profound effect on the progression of genetics in the U.S.A. Provine^[9] described the importance of early breeding research by Castle and East and their students at Harvard's Bussey Institution as "turning geneticists toward a selectionist view of evolution in nature and in domestic populations." This view enabled others in the scientific community to equate selection in nature with the process of selection under domestication because it brought about an understanding of variation within a population to the forefront. Even though there is an obvious difference in these two processes with respect to directionality and human control, the similarity is a fundamental truth that became recognized because of the work of these pioneering geneticists. This was true as early as in 1920s, according to Provine^[9]:

In 1925, the best evidence for natural selection in nature came from its similarity to the efficacy of artificial selection, the evidence for which (as in the experiments of Hopkins, Castle, Sturtevant, Payne, and others) was overwhelming.

The Case of Composite Cross II Barley

Beginning in 1928, experiments at the University of California-Davis shed light on many evolutionary aspects of plant breeding. Starting with a diverse collection of barley populations from cultivated areas around the world, the Composite Cross II population was subjected to natural selection in agricultural environments for many successive generations, and seed was harvested in bulk in each generation and replanted. Bulk harvesting of seed allowed for natural selection to take place in the exact setting in which the crop was being grown, in the absence of specific artificial selection objectives. In such a case, both natural selection and drift would be operative and the changes in the genetic composition of this population would be owing to their action alone.^[10]

During the first decades of this experiment, yields were quite low, but increased significantly as the experiment continued. The greatest gains were shown in yield stability and in disease resistance. In addition, many of the key components of yield increased such as grain per spike and weight of grain, which are components of fecundity.^[3] One of the most important conclusions of the Composite Cross research was the finding that environmental conditions are a primary driver of the response to natural selection in experiments like this, hence it is most crucial to study genetic changes over many generations in a well-characterized environment. Second was the finding that natural selection alone was powerful enough to make very large changes in phenotype in a relatively short period of time. When outcrossing occurred at a greater rate, such as in *Phaseolus* or sorghum undergoing similar selection experiments, improvement in adaptedness developed at a slow rate, perhaps because multilocus interactions were broken up more frequently owing to increased recombination.^[3] Barley has a selfing rate of approximately 99%, which greatly facilitated the increase in uniformity noted in this experiment. In the case of the highly self-pollinated barley, favorable multilocus interactions were developed in highly homozygous lines quite quickly, suggesting that outcrossing and selfing species respond differently to natural selection in such environments. Interestingly, the inbred-hybrid method of breeding that constitutes much of modern plant breeding today often makes use of highly inbred lines as parents. These inbred lines likely possess favorable multilocus complexes that are then combined into a superior hybrid combination.

Suneson^[11] proposed an evolutionary plant breeding method that would capture the best features of the Composite Cross experiment.^[11] His idea was to develop broad-base populations and expose them to the same selection pressures they would face in agricultural environments, in the absence of direct selection

by plant breeders. In some respects, this is essentially what farmers around the world had been doing with their crops since the beginning of agriculture some 10,000 years ago.^[12] However, for many farmers, unintentional selection for specific traits and severe forms of genetic drift were operative in their crop populations, simply from the selection of small or unbalanced samples to constitute the next generation of seeds for planting. Such selection may have been dictated by visually pleasing morphology, seed size, or maturity to name a few possibilities. In any case, evolutionary methods of breeding would certainly have been part of domestication and much of agriculture.

The Illinois Long-Term Selection Experiment

The Illinois long-term selection experiment represents a key transition in our understanding of how the selection principles that underlie evolution via natural selection could be applied to crop breeding. The experiment was influenced primarily by work conducted in France by early breeders of the fodder beet.^[7,13,14] The goal of the experiment was to increase and decrease specific chemical constituents in the corn kernel through breeding. The goal was based on “Darwin’s principle of selection,” according to Hopkins, who saw an opportunity to use selection tools to modify the feed value of corn. Today, the ILTSE is the longest continuous plant breeding experiment in the U.S.A. and perhaps in the world. More than 100 generations of selection for protein and oil in the maize kernel have been completed, with striking changes in composition brought about by intense artificial selection and perhaps by other related forces such as genetic drift. Most importantly, this experiment reflects the tremendous power that breeding can have in plant populations, when intense selection is practiced for many generations.

The success of the ILTSE is unmatched among plant breeding experiments of the 20th century. Perhaps most striking about the experiment is the continuing gain from selection despite what would appear to be large reductions in genetic variance and large increases in inbreeding. The paradox of the ILTSE is the cause for celebration among plant breeders, who often see it in terms of a limitless source of variation for selection and a reason by which they can continue to make gain from selection in breeding populations.^[8]

Additionally, Goldman^[8] suggested that in courses and textbooks on evolutionary biology throughout the U.S.A., the ILTSE is often used as an example for the power of selection, encouraging readers to imagine how natural selection and the process of speciation might operate. That such tremendous changes were brought about by selection in this experiment seems to be highly compelling. That such changes still

continue makes this experiment remarkable. Goldman^[8] argued that the legacy of the ILTSE is represented by several of the most important developments in modern crop breeding, including the relationship of “Darwinian selection” to improve plants and animals, the inbred-hybrid method for producing F1 hybrid cultivars, an understanding of the genetic basis of quantitative variation, selection during inbreeding, and the beginnings of an educational system designed to train scientific plant breeders. This experiment serves to link observations about evolution in nature with modern breeding practices, emphasizing the close connection between these two processes.

CONCLUSIONS

Plant breeding is an evolutionary process. It focuses on creating and managing genetic changes in a population over time, which is also the way we would define organic evolution. The major exception, of course, is that breeding and artificial selection involve human desires, while natural selection is subject only to the vagaries of the natural environment. Breeders have demonstrated that both artificial and natural selections are operative in breeding populations. Breeders have even shown that in the absence of artificial selection, natural selection can do a great deal to improve plant populations for traits of interest to farmers. Breeders work day in and day out with fecundity, heritable variation, and differential reproduction and survival of their lines, strains, genotypes, and populations, just as natural selection does with natural materials. Both artificial and natural selections lead to adaptation, one of the greatest triumphs of agriculturists and modern day plant breeders. Gaining an understanding of the evolutionary nature of the breeding process emphasizes the power of differential reproduction and survival in changing gene frequency in populations.

Breeding: Genotype-by-Environment Interaction

Manjit S. Kang

Louisiana State University, Baton Rouge, Louisiana, U.S.A.

INTRODUCTION

Genotype-by-environment interaction (GEI)—a universal issue—relates to all living organisms, from bacteria to plants to humans. The subject is important in agricultural, genetic, evolutionary, and statistical research. Genotype-by-environment interaction refers to differential responses of different genotypes across a range of environments. Gene expression is dependent upon environmental factors and may be modified, enhanced, silenced, and/or timed by the regulatory mechanisms of the cell in response to internal and external forces. A range of phenotypes can result from a genotype in response to different environments; the phenomenon is called norms of reaction, or phenotypic plasticity. Norms of reaction represent the expression of phenotypic variability in individuals of a single genotype. The lack of phenotypic plasticity is called canalization.

In this article, discussion of GEI is limited to plant breeding—the art and science of improving plants. Plant breeding helps increase crop productivity by overcoming challenges posed by changes in soil and climatic factors, altered spectrum of pests, consumer demand, and economic policies.

GENE EXPRESSION AND ENVIRONMENT

Gene expression is the process whereby a gene produces a chemical product (protein) that carries out its designated function. The genotype (genetic make up—deoxyribose nucleic acid, DNA, or gene) of an individual and environmental conditions determine the physical appearance, or phenotype, of an individual. Genes carry the blueprint of an organism, which is translated into a phenotype under proper environmental conditions. Transcription of a gene into messenger ribose nucleic acid (mRNA) and its translation into a polypeptide (protein) represent the central dogma of genetics, i.e., DNA \Rightarrow mRNA \Rightarrow protein. The current, modified version of the central dogma is DNA \Leftrightarrow mRNA \Rightarrow protein, because reverse transcription does occur in certain organisms (retroviruses).

To understand GEI, it is important to know how genes express in different environments and how qualitative and

quantitative characters are influenced by environmental factors.^[1] Qualitative traits (controlled by one or two genes) are, in general, highly heritable, i.e., they are not affected by environmental factors. They exhibit a discontinuous variation in segregating generations, e.g., the second filial generation (F_2). For example, crossing of round (RR) and wrinkled (rr) seeded garden pea plants always yields the first filial generation (F_1) with round seeds, and F_2 plants segregate in a discrete, 3 round ($1 RR + 2 Rr$) to 1 wrinkled (rr) ratio, no matter where the cross is grown in the permissive range of environments. Certain qualitative traits, however, are influenced rather drastically by environmental factors. For example, the sun-red gene in maize (*Zea mays* L.) produces red kernels if kernels are exposed to direct sunlight, but in the absence of sunlight, the kernels remain white.^[2]

Quantitative traits, on the contrary, are controlled by several genes and invariably exhibit low heritability. They are, in general, highly influenced by environmental factors and display continuous variation.^[3,4] Most economically important plant traits, e.g., harvestable grain or forage yield, can be classified as quantitative or multigenic.^[5] Plant adaptation relative to quantitative traits is intimately connected to environment.^[6]

WHAT IS GENOTYPE-BY-ENVIRONMENT INTERACTION?

Crop performance—the observed phenotype—is a function of genotype (variety or cultivar), environment, and GEI. For interaction to be detected, there must be at least two distinct genotypes evaluated in at least two different environments. From a statistical standpoint

$$y_{ij} = \mu + g_i + e_j + (ge)_{ij}$$

where y_{ij} represents phenotype (e.g., yield) for i th genotype in j th environment; μ , overall mean performance; g_i , genotype effect; e_j , environment effect; and $(ge)_{ij}$, interaction between g_i and e_j . Thus, for a given genotype there can be many phenotypes, depending upon environmental conditions and the extent of GEI.

Fig. 1a represents absence of interaction, where responses of the two genotypes A and B to environments are similar, i.e., parallel responses. The norms of reaction for

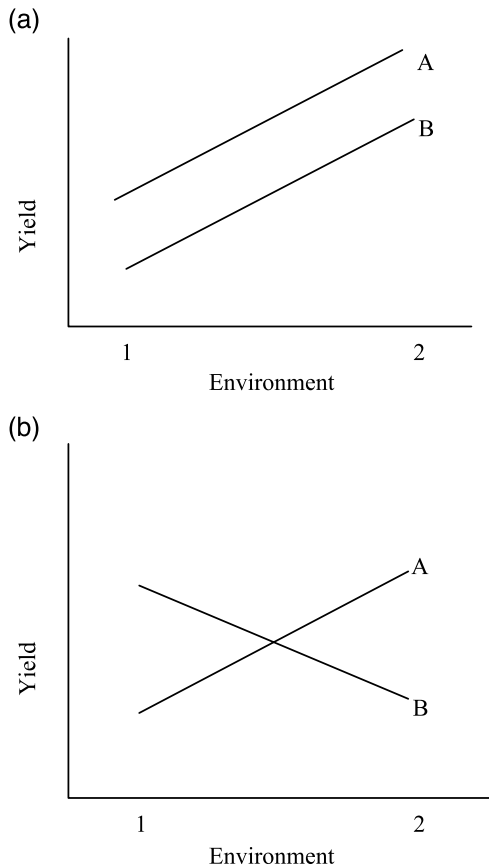

Fig. 1 (a) This graph shows no genotype-by-environment interaction. Genotypes A and B respond to the two environments in a similar manner. (b) This graph depicts a crossover type of interaction. Genotypes A and B switch ranks between the two environments.

the two genotypes are additive: A and B increase with change in environment.^[4]

Genotype-by-environment interaction represents non-parallel or nonadditive norms of reaction. Fig. 1b illustrates a crossover GEI (genotypes switch ranks between environments). The environmental modification of the two genotypes is opposite in direction: A increases but B decreases.

IMPORTANCE OF GENOTYPE-BY-ENVIRONMENT INTERACTION

With the expected doubling of world population from the current 6 billion to 10–12 billion by the mid-21st century, GEI and stability of crop performance across environments should become more relevant issues for breeders. Land and water resources being limited, a greater

emphasis will need to be placed on sustainable agricultural systems and on proper exploitation and use of GEI.

Information on GEI can help determine whether or not cultivars should be developed for an entire region in a single breeding program. The presence of a crossover GEI necessitates partitioning of a breeding program to develop cultivars for specific environments. In the complete absence of GEI, a single variety of any crop would produce its maximum yield the world over, and also variety trials would need to be conducted at only one location to provide universal results—but this is an unrealistic scenario.^[7] Genotype-by-environment interaction is routinely detected in multi-environment crop yield trials.

IMPLICATIONS OF GENOTYPE-BY-ENVIRONMENT INTERACTION IN PLANT BREEDING

Genotype-by-environment interaction offers both challenges and opportunities for breeders. Abiotic and biotic stresses are generally causes of GEI. Suboptimal levels of water (drought stress) can help identify water-use efficient genotypes. At superoptimal levels (flooding), flood-tolerant genotypes can be identified.

The larger the GEI component, the lower the heritability. The lower the heritability of a trait, the greater the difficulty in improving that trait. Other implications of GEI are:

1. Problem in identifying superior cultivars: As the magnitude of interaction between G and E increases, the usefulness and reliability of their main effects decrease. Crossover GEI increases the difficulty in identifying truly superior genotypes across environments.
2. Increased evaluation cost: A large GEI necessitates use of additional environments to obtain reliable results, which increases the cost of evaluating breeding lines. If weather patterns and/or management practices differ in target areas, testing must be done at several sites representative of the target areas.

Multi-environment testing allows identification of cultivars that perform consistently from year to year (low temporal variability) and those that perform consistently from location to location (low spatial variability). Temporal stability benefits growers, whereas spatial stability benefits seed companies and breeders. Analyses of multi-environment trial data allow identification of genotypes of broad adaptation as well as those specifically adapted to a particular environment. Broad adaptation, or stability of performance (reliability) across environments, helps conserve limited breeding resources. The desirability of stability of performance across environments depends on

Table 1 Mean yield of five barley cultivars (genotypes) from six environments

Genotypes↓	Environments→					
	E1	E2	E3	E4	E5	E6
G1	26.95	41.17	30.90	36.45	27.55	25.77
G2	31.28	42.92	30.40	30.55	23.15	23.97
G3	33.35	43.82	32.48	36.70	27.63	24.38
G4	32.82	56.53	45.20	44.38	25.20	32.27
G5	30.42	42.30	36.53	33.42	30.73	31.68

(Adapted from Yates, F. and Cochran, W.G. The analysis of groups of experiments. *Journal of Agricultural Science* **1938**, 28, 556–580.)

whether or not environmental differences are predictable. Breeders seek performance stability (a lack of GEI) against uncontrollable factors. If GEI is attributable to unpredictable environmental factors, e.g., weather variables, varieties with stable performance across a range of conditions should be selected or developed.^[8] If GEI is caused by variations in predictable factors, e.g., soil type and cultural practices, varieties specifically adapted to an environment should be developed.^[8] For certain genotypes to do well, additional agronomic inputs may be necessary, which tends to create a genotype-by-environment correlation.^[1]

CAUSES OF GENOTYPE-BY-ENVIRONMENT INTERACTION

Biotic stresses (insects, diseases, and weeds) are major constraints to crop productivity. Differences in insect and disease resistance among genotypes can be associated with stable or unstable performance across environments.^[1] Knowledge of the cause(s) of a significant interaction helps make accurate predictions of genotype performance in diverse environments. Understanding genotypic responses to individual factors aids in interpreting and exploiting GEI.

EXPLOITATION OF GENOTYPE-BY-ENVIRONMENT INTERACTION

There are numerous methods of analyzing GEI.^[8–10] Methods that integrate performance and stability of performance across environments are useful breeding tools.^[1,8] Only a brief reference will be made to some of them here. The Additive Main effects and Multiplicative Interaction (AMMI) method is useful for understanding complex GEI.^[7] The Shifted Multiplicative Model (SHMM) is helpful in identifying subsets of genotypes or environments with negligible rank changes.^[10]

Fig. 2 This polygon shows performances of five genotypes in six environments. Genotype G4 had the highest performance in all environments except E5. Genotype G5 had the best performance in E5. This graph was generated via the GGEbiplot software. (View this art in color at www.dekker.com.)

A recent method called GGE Biplot is a powerful tool for visualizing and interpreting two-way GEI data.^[8] Yield data shown in Table 1 were analyzed via GGEbiplot. In all environments except E5, G4 is the highest yielding cultivar (Fig. 2). Cultivar G5 yielded the most in E5. The other cultivars were not the highest yielding in any environment. The sites Regression Model (SREG) is similar to the GGE biplot technique, which helps in assessing both general and specific adaptation of genotypes.^[10]

CONCLUSION

Methods such as GGEbiplot, AMMI, and SHMM will play an increasingly greater role in interpreting and exploiting GEI in plant breeding in the 21st century. DNA-based markers (tags) should enhance our understanding and use of GEI. Proper understanding, use, and exploitation of GEI can help ease the food problem in the world.

Breeding: Incorporation of Exotic Germplasm

James B. Holland

USDA—ARS and North Carolina State University, Raleigh, North Carolina, U.S.A.

INTRODUCTION

Exotic germplasm refers to crop varieties unadapted to a breeder's target environment, and is an important resource for crop improvement. Because genetic diversity within elite cultivars of a crop is limited compared to the variability within the species and its relatives worldwide, genes from exotic germplasm can protect the crop against new biotic and abiotic stresses, and may represent unique alleles for productivity that are absent from elite crop gene pools. Introducing substantial amounts of genetic material from exotic sources into elite crop gene pools while maintaining their productivity is difficult, however. Exotic germplasm incorporation programs require long-term commitments and appropriate breeding strategies, and may be assisted by DNA marker technologies.

CROP DOMESTICATION AND GENETIC BOTTLENECKS

Cultivars of major crops in industrialized nations represent only a small sample of the genetic variability available in those species worldwide.^[1,2] Plant breeding per se often reduces genetic variation in crop species^[1–3] because only superior genotypes are selected, but Darwin^[4] suggested that selection by plant and animal breeders was a major cause of *increased* variation within domesticated species. Depending on circumstances, plant breeding may contribute to either increases or decreases in crop genetic variation.

Domestication of many crops involved genetic bottlenecks, initially reducing genetic diversity.^[3,5] However, selection for crop adaptation to widely varying agroecological habitats and for diverse uses by farmers resulted in subsequent increases in variability. For example, bread wheat is significantly less variable than its close wild relatives because it underwent a severe genetic bottleneck during domestication.^[5] Nevertheless, genetic variability exists among wheat varieties because human selection acted to preserve rare favorable variants in varieties adapted to different habitats and uses.^[5] However, modern plant breeding for industrial agriculture generally results in reduced genetic variation, because uniformity of type is demanded by most farmers, commodity handlers and

processors, and consumers.^[2] Therefore, plant breeding per se does not necessarily reduce genetic variation. This observation provides hope that the genetic bases of modern crops can be enhanced through plant breeding.

The limited genetic variation within modern crops is a concern because it may result in widespread crop-yield and quality losses if new pathogen populations or unusual abiotic stresses occur.^[2] Incorporation of new alleles from exotic germplasm that confer pathogen resistance can alleviate this genetic vulnerability.^[5,6] Furthermore, improvements in crop productivity may be achieved by incorporating exotic germplasm into elite gene pools since it is highly unlikely that all favorable alleles were sampled in the ancestors of modern cultivars.

CROP ENHANCEMENTS

What is the best way to enhance crops with new alleles from exotic parents and wild species? Simmonds^[1] distinguished between two general strategies: introgression and incorporation. Introgression involves backcrossing a few chromosome segments with easily identifiable effects (often disease resistances) into elite cultivars. In contrast, incorporation aims to create populations that are adapted to a breeder's target set of environments but that are also genetically distinct from elite cultivars. Incorporation requires isolating exotic populations from locally adapted populations and conducting many cycles of mild selection for adaptation while maximizing recombination. Only when exotic populations have been improved to a level of reasonably good productivity should they be crossed to elite germplasm. The aim of introgression is to disrupt elite genetic backgrounds as little as possible during the introduction of a relatively small number of exotic alleles. The objective of incorporation is to produce new breeding populations that have very high proportions of unique, exotic-derived alleles in order to broaden substantially the crop's genetic base.

EXAMPLES

Successful germplasm incorporation programs have been conducted in potato and sugarcane. In both cases,

broad-based exotic populations were introduced to target production environments and subjected to mild selection for adaptation, disease resistance, and productivity over many generations of sexual recombination.^[1] After about 20 to 30 years of selection in both crops, improved exotic populations had yields similar to local cultivars. Furthermore, crosses between local and exotic populations exhibited substantial high-parent heterosis and formed the basis for new commercial cultivars.^[1]

Similarly, Goodman et al.^[7] reported successful incorporation of exotic tropical maize into the narrow gene pool of agriculturally elite temperate maize. This program emphasized identifying superior exotic germplasm sources, creating selection populations by intercrossing tropical hybrids, and enhancing recombination during inbred line development by sib-mating rather than self-fertilizing. Although the tropical-derived inbreds themselves had inferior performance compared to adapted inbred lines, hybrids created from crosses between tropical-derived inbreds and temperate germplasm were agronomically competitive with commercial hybrids.

The most successful incorporation programs to date were conducted in clonally-propagated or hybrid crops because the heterosis achieved in the first generation of exotic-by-adapted crosses could be fully captured. However, many open-pollinated crops (including most forages) are not easily inbred; rather, they are managed as populations. In these crops, even though substantial heterosis often occurs in the F_1 generation of exotic-by-adapted crosses, pure F_1 hybrids cannot be created on a commercial scale.^[8] However, production of semihybrids formed through population crosses could capitalize commercially on a large portion of the heterosis, and should present new opportunities for germplasm incorporation in open-pollinated crops.^[8]

EXOTIC GERmplasm IN ATYPICAL SITUATIONS

Incorporation is more difficult to implement in naturally self-fertilizing crops^[9] because of two factors that hinder maintaining exotic germplasm independently from adapted populations. First, the best sources of genetic variation for many self-fertilizing crops are wild species that are entirely unadaptable to agriculture. Second, less recombination occurs during selfing than outcrossing generations. Therefore, selection within semiexotic populations created by crossing exotic and adapted germplasm is an appropriate strategy to introduce unique alleles at many loci into the narrow gene pools of self-pollinated crops, although it is not incorporation in the strict sense.

Frey and colleagues (reviewed in Refs. 9,10) extensively evaluated methods for introducing exotic germ-

plasm into self-pollinated crop gene pools using wild and cultivated oats as a model. Their results indicated that superior transgressive segregants were obtained following a few backcrosses of wild species germplasm into cultivated oats. Another successful approach was to hybridize diverse wild and cultivated oat germplasm to form genetically broad-based populations, and to enforce outcrossing among selected early-generation lines over many cycles of recurrent selection.

Even in cross-pollinated crops, development of semiexotic populations may be required to adapt exotic germplasm sufficiently so that it can contribute to the local gene pool. For example, "conversion" programs to adapt exotic tropical maize and sorghum germplasm rapidly to temperate environments have been implemented to overcome photoperiod-related maturity problems.^[6,7] Mild selection only for the most important adaptation characters is critical to avoid massive loss of exotic alleles from semiexotic populations before they have a chance to recombine with alleles carried on chromosomes from adapted parents.

Some attempts to incorporate exotic germplasm into elite gene pools have failed. A major difficulty is the inability to identify superior sources among the overwhelming numbers of samples stored in germplasm banks for many crops. Use of randomly chosen exotic germplasm has been unsuccessful.^[7,9] Information on the breeding value of exotic germplasm sources would be most helpful^[6] but phenotypic evaluations in local target environments (to which exotic germplasm is unadapted) are often worthless because beneficial alleles may not be expressed or may be masked by other genes that confer maladaptation.^[1,3,7]

One approach to selecting superior exotic germplasm is to evaluate first in environments to which exotic materials are adapted. If genotype-by-environment interactions are sufficiently strong, however, there may be no relationship (or worse, a negative relationship) between the performances of exotic germplasm in their regions of origin and as breeding parents with elite germplasm in local environments. This hypothesis is testable, however, and results in maize suggest that performance within environments to which exotics are adapted sufficiently predicts breeding value in temperate environments to be useful as an initial screen for source materials.^[7]

CONCLUSION

Incorporation of exotic germplasm is the best means to enhance the genetic base of modern crops substantially, but it is neither easy nor rapid. New directions for incorporation and introgression involve using DNA markers to characterize the value of specific genomic regions in

exotic germplasm sources.^[3] DNA marker analysis combined with phenotypic evaluations of exotic-by-adapted progenies permits identification of favorable alleles in exotic germplasm regardless of the effects of unfavorable alleles. Substantial gains in agronomic performance from marker-assisted backcrossing of chromosomal segments from wild tomato and rice strains into their cultivated counterparts have been reported.^[3] DNA marker-assisted selection could also be used to aid exotic “conversion” programs by ensuring introgression of only adaptation alleles from elite into exotic germplasms. However, DNA markers alone cannot solve the primary problem of how to identify superior sources of exotic germplasm. DNA marker-based strategies may complement, but cannot replace, long-term incorporation programs based on phenotypic selection.

Breeding: Mating Designs

Charles W. Stuber

North Carolina State University, Raleigh, North Carolina, U.S.A.

INTRODUCTION

Mating designs used by breeders and geneticists range from simple to complex, including some types of multipurpose designs. Selecting the kinds of mating techniques and arrangements depends upon: 1) predominate type of pollination (self or cross); 2) type of crossing used (artificial or natural); 3) type of pollen dissemination (wind or insect); 4) unique features, such as cytoplasmic or genetic sterility; 5) purpose of project (breeding or genetic); and 6) size of population required. A simple mating design, the top cross, is frequently used to evaluate a series of breeding lines, selections, or clones. Several designs of intermediate complexity are available for either generating synthetic populations or recombining selected entries in recurrent selection programs. Complex, multipurpose designs are available that may be used both to estimate genetic variances, or effects, and to generate families for use in either full-sib or half-sib selection schemes. All designs involve some type of hybrid crosses. Some may also include self-pollinations.

BASIC TYPES OF HYBRID CROSSES

Although the term ‘hybrid’ is defined as the cross between two genetically dissimilar parents, it is most commonly used to denote the F_1 from a cross of two inbred lines. Crosses among clones, open-pollinated cultivars, or other genetically dissimilar populations are included in the F_1 hybrid population category. The four types of hybrid crosses most frequently used are the single (two-way) cross, three-way cross, backcross, and double cross. The single cross involves two parents:

$$A \times B \rightarrow F_1 = \text{single cross}$$

As the name implies, the three-way cross involves three different parents:

$$(A \times B \rightarrow F_1) \times C \rightarrow \text{threeway cross}$$

The backcross involves the mating of a single cross to one of its parents:

$$(A \times B \rightarrow F_1) \times A \rightarrow \text{backcross}$$

The double cross involves the mating of two different single crosses as follows:

$$(A \times B \rightarrow F_1) \times (C \times D \rightarrow F_1) \rightarrow \text{double cross}$$

TOPCROSS MATING SCHEME

The topcross mating scheme involves the crossing of a number of selections, lines, or clones to a common parent (tester), which may be a cultivar, an inbred line, a single cross, etc., where the tester is the same for each mating. In cross-pollinated crops, such as corn, this type of mating is commonly an inbred-cultivar cross.^[1] It is frequently used for evaluation of general combining abilities for a group of lines, clones, or selections. The topcross method also has been used for initial evaluation of breeding potentials in exotic corn races.

If an isolated crossing block is available, natural hybridization can be used for topcrossing in many species. The tester is used as the male parent, and the females (lines or clones) to be tested are either male-sterile or self-incompatible or are emasculated before pollen shed. The ratio of number of male rows to female rows varies with species. Alternating rows may be required in crops such as sugar beet, whereas two male rows may be adequate to pollinate 10 to 12 female rows in castor. It may be necessary to delay planting dates if the male and female parents differ in days to flowering. If wind is a factor in pollen dissemination, tester rows should be planted perpendicular to prevailing winds. If isolation is not possible, the tester may be planted in paired rows with the materials to be evaluated. Hand pollinations are made between rows, and the tester may be used as either the male or the female parent.

BACKCROSS BREEDING METHOD

The backcross breeding method is a form of recurrent hybridization that is widely and effectively used to improve lines or cultivars that excel in most attributes but lack one or a few desirable characteristics.^[2] Characteristics transferred by backcrossing in traditional breeding projects are usually highly heritable traits, such

as resistance to disease or insect pests. The technique is used in both cross- and self-pollinated species but has been used infrequently in most perennial forage crops. Backcrossing is normally initiated by making an F_1 hybrid between the nonrecurrent (donor) parent and the recurrent parent. This F_1 is then backcrossed to the recurrent parent to produce the BC_1 . A number of BC_1 individuals are grown, and those with the desired trait from the donor parent are selected and crossed to the recurrent parent to produce the BC_2 . BC_2 individuals selected for the desired trait are crossed to the recurrent parent. This procedure, shown below, is continued until the desired number of backcrosses is completed:

$$(A \times B \rightarrow F_1) \times A \rightarrow BC_1 \times A \rightarrow BC_2 \times A \dots \rightarrow BC_n$$

For simply inherited traits, usually five to eight backcrosses are considered sufficient to effectively recover the genotype of the recurrent parent with the incorporated gene from the donor parent. However, with the advent of DNA-based marker technology, the number of required backcrosses can be reduced greatly because both the marker region of the donor gene and the marker complement of the recurrent parent can be monitored and selected during the backcrossing procedure.^[3] This technique is being used widely in the transfer of transgenes to elite lines.

POLY-CROSS MATING SCHEME

The polycross is a mating arrangement for interpollinating a group of cultivars or clones using natural hybridization in an isolated crossing block.^[4] If an isolation block is not available, hand-crossing is required, and the entries must be planted to facilitate the required interpollinations. The polycross is used frequently for forage grasses and legumes, sweet potato, and sugarcane. It is often used for generating synthetic cultivars and may be used for recombining selected entries or families in recurrent selection programs. Progeny from each entry have a common parent in the polycross design. Thus, half-sib families are generated, and these are frequently used for evaluating general combining abilities.

Because the purpose of the polycross is to provide an equal opportunity for each entry to be crossed with every other entry, the field layout is the critical feature of the design. If the number of entries is 10 or less, the Latin square is often used, as this places every entry in every row and column of the layout. If more than 10 cultivars or clones are to be interpollinated, a completely randomized block design, with adequate replications, is normally preferred for the polycross. When the seed is harvested, equal quantities from each replication of each entry are bulked. Although the polycross requires a minimum of

effort for intermating a group of entries, deviations from random mating may occur unless entries flower simultaneously. Planting of early entries can be delayed appropriately to avoid this problem in annual crops if days to flowering are known in advance.

DIALLEL AND PARTIAL-DIALLEL DESIGNS

The diallel is a mating design to cross three or more parents in all possible combinations. This design has been used extensively for developing breeding populations for recurrent selection.^[5] It probably has been used more frequently than any other design in crop plants to estimate general and specific combining ability effects and variances. Genetic interpretations and analyses are provided in numerous papers.^[6,7] The complete diallel includes all possible matings, including selfs and reciprocals, among a set of entries. These entries are usually homozygous inbred lines, pure lines, or clones, although an alternative design has been proposed and the analysis described for cultivar cross diallels.^[8] For the complete diallel, there are p^2 crosses among p parents. With no selfs or reciprocals, $p(p-1)/2$ crosses are included in the design. In crops such as corn, the parental lines are planted in paired rows for each mating. This requires $p-1$ rows for each parent and a total of $p(p-1)$ rows. Reciprocals may or may not be made, as desired, with this arrangement. Unless the two rows in a pair flower simultaneously, reciprocal crossings may not be possible. Selfs can be made on individual plants in the crossing block or in a separate selfing block.

A major disadvantage of the diallel is the large number of crosses generated in the mating scheme. However, several types of partial diallels have been evaluated and reviewed.^[9] It is suggested that an evaluation of five to seven crosses per parent in a partial diallel should give reliable estimates of general combining ability. Therefore, a large number of parents can be screened for their general combining abilities in a partial-diallel scheme, and the selected parents then might be evaluated in a full-diallel fashion.

MULTIPURPOSE MATING DESIGNS

Three widely used multipurpose mating designs—Design I, Design II, and Design III—have been proposed and described.^[10,11] Design I is a nested type of mating design in which each member of a group of parents used as males is mated to a different group of parents used as females. A frequently used arrangement involves the crossing of each male to four female parents, thus generating four full-sib families nested within a half-sib family. No female parent is involved in more than one mating. Males can be interchanged with females in the

design if the matings are more convenient. The design is used to estimate additive and dominance variances and can also be used to generate families for evaluation in full-sib or half-sib recurrent selection. Frequently, both functions are performed simultaneously.

Design II, a factorial design, is essentially a modification of Design I.^[10,11] It is used to estimate genetic variances and to evaluate inbred lines for combining ability. Each member of a group of parents used as males is mated to each member of another group of parents designated as females. Frequently four males and four females are designated to form each mating group, which will generate a total of 16 full-sib families. This design is well-suited to multiflowered plants because each plant can be used repeatedly as both male and female. For single-eared corn, the design is suitable only if the parents are inbred lines from some specific population. Thus, the female is repeated by using several plants from each female line.

Design III involves backcrossing of F_2 plants to the two parent inbred lines from which the F_2 was derived.^[10,11] The F_2 plants are used as male parents; the number of inbred plants crossed to each F_2 should be large enough to ensure sufficient seed for field evaluations. Design III is used infrequently and primarily to estimate the average dominance of genes. Estimates of genetic parameters tend to be more biased from epistasis in this design than in Designs I and II.

RECIPROCAL SELECTION DESIGNS

Design I is often used to generate families for recurrent selection programs and is particularly well-adapted to the reciprocal recurrent selection scheme.^[12] When Design I is used for reciprocal recurrent selection, males are selfed as well as crossed to females from the opposite population. After evaluation of half-sib progenies from each male, selfed seed from each selected male is used to produce plants for the recombination cycle, which generates the population for the next selection cycle.

A variation of the above scheme^[13] is called reciprocal full-sib selection and allows concurrent population improvement and development of single-cross hybrids. The design requires the ability to produce selfs and crosses on the same plant; thus, multiflowered (multieared for corn) plants are necessary. With the selfing feature, inbred lines are developed concurrently with the selection process, thus providing rapid development of new single crosses.

OTHER INTERMATING DESIGNS

Objectives for intermating include synthesis of populations, recombination of selected plants or families, and

maintenance or increase of populations. Matings generally are designed to ensure thorough recombination and an equal genetic contribution of each unit in a random fashion. Although designs such as the polycross and diallel (or partial diallel) are frequently used for this purpose, other arrangements may be more suitable. One procedure involves chain (cyclic) crossing whereby each plant is used once as a male parent and once as a female parent, as follows:

$$A \rightarrow B \rightarrow C \rightarrow D \rightarrow E \rightarrow F \rightarrow G \rightarrow H$$

where the arrows indicate the direction of pollen transport. This procedure ensures that each entry is equally represented, if equal amounts of seed are bulked from each mating. However, the procedure provides only a limited amount of recombination. It is useful, however, as a sibbing technique for population or synthetic cultivar increases or for population maintenance if a large number of plants are sampled (>200).

Another intermating method, called the bulk entry method for population development, provides for thorough recombination when a large number of parents are composited.^[14] In this method (designed specifically for corn), replicated plantings of individual entries are made in isolation, and plants are detasseled before pollen shed. Rows of bulked seed of all entries are planted between rows or ranges of the individual entries to provide pollen as in a topcross nursery. Ears of each entry are saved and bulked over replications at harvest to represent that entry in the following season. If desired, selection can be imposed and only ears from the best plants would be bulked. Other procedures for intermating a number of entries for population development may include combinations of diallel, partial-diallel, and chain-crossing designs.

CONCLUSION

Recombination and intermating in many self-pollinated species is difficult because of problems associated with artificial pollination and poor seed set. Genetic male sterility has been used successfully in crops such as barley and soybean to obtain natural crosses for synthesizing and intermating composite populations. Innovative researchers may use various combinations of the designs outlined above to accomplish the matings required in their breeding programs.

Breeding: Participatory Approaches

J. R. Witcombe

University of Wales, Bangor, Gwynedd, U.K.

INTRODUCTION

An efficient plant breeding system—the breeding of new varieties and their testing, release, and popularization—should result in farmers growing diverse, recently released varieties. Unfortunately, this is the case in few, if any, developing countries. One important reason may be the inadequate participation of farmers in the process, so participatory plant breeding (PPB) methods and participatory varietal selection (PVS) have been advocated in both marginal and favorable environments. PPB actively involves farmers at an early stage, from the setting of goals to selecting among early generation materials, whereas PVS is restricted to selecting among finished varieties that could simply be the products of conventional breeding.

Participatory methods can be used to increase the efficiency of formal breeding programs in producing and popularizing varieties appropriate for resource-poor farmers or to empower farmers, and promote development in farmers' communities.

PARTICIPATORY VARIETAL SELECTION

PVS has met with outstanding success among low-resource farmers for many crops in marginal areas and countries.^[1–3] Farmers identify varieties of greater utility than the ones they are growing because they have higher grain yield, earlier maturity, higher fodder yield, improved grain quality, or other favored characteristics. Usually suitable varieties already exist for marginal areas that are better than those currently grown, but farmers have simply never had the opportunity to try them.^[3]

PVS in marginal areas overcomes the difficulties of multilocational trials that often fail to represent well the environments in farmers' fields. Genetic improvement should be focused on traits of economic importance, but formal trial systems place an undue emphasis on grain yield, do not measure all economically important traits, and rarely employ a system of trade-offs between the traits that are measured.^[4] In PVS, farmers grow a wide choice of varieties and evaluate many traits that they trade off, for example, by accepting lower grain yields for higher quality or earlier maturity. PVS is a simpler, more direct approach than the alternative of using a selection index in

multilocational trials. It also accounts for differences in preferences among socio-economic groups and localities and accounts for temporal changes in farmers' preferences with, for example, trends in market price and fodder availability.

PVS is a powerful method of assessing quality traits that are difficult or expensive to evaluate in conventional trials, e.g., milling percentage based on large seed quantities, cooking, and maintaining quality, taste, and market price.

PVS is now broadly accepted and well documented (reviewed in Ref. 5), and several international agricultural research centers have substantial networks for PVS, e.g., CIMMYT for maize^[6] and WARDA for rice.^[7]

PARTICIPATORY PLANT BREEDING

PVS can be efficiently followed by PPB since farmer-preferred cultivars are the ideal parents for PPB programs. PPB is less well-documented and well-accepted than PVS and, with a few exceptions, results from PPB programs are only now emerging, e.g., in rice,^[8] maize,^[9] and cassava.^[10]

PPB can be consultative and collaborative: Farmers are consulted to set goals and choose parents, for example, and they collaborate by growing and selecting breeding materials in their own fields. The choice of consultative or collaborative methods will depend on the crop and the available resources.

Participation inevitably decentralizes the breeding program to farmers' fields, so the benefits of participation and decentralization are confounded. Selection in the target environment should result in faster genetic progress.^[11] There is also a gain in exploiting specific adaptation to a target environment, although this advantage may be outweighed by reduced economies of scale if more specifically adapted varieties have smaller areas of adoption.

FARMERS AND GOAL SETTING

Much conventional breeding produces widely adapted varieties for many farmers over a wide area, and farmers

participate little in setting breeding goals. Participatory goal setting helps in breeding varieties specifically adapted to well-defined physical or socioeconomic environments. It can be combined with PVS to help identify farmers' preferences for traits in diverse genetic material. In many cases, early maturity—perhaps even earlier than that of existing landraces or cultivars—is found to be as important as yield. Farmers sometimes set goals for quality traits not previously envisioned by breeders, such as pericarp color in rice.^[8]

Participatory breeding also identifies traits that breeders had not considered important or of which they were previously unaware. Examples are appetite delay in rice (farmers want varieties that satisfy appetite for longer) and strict requirements for ease of threshing in areas where threshing is done manually.

INVOLVING FARMERS SHOULD CHANGE BREEDING METHODS

Participation requires different breeding methods if resources are to be used efficiently. Farmers can easily and cheaply grow large populations, but growing complex nurseries of many entries is more difficult and can be done only with training or assistance from scientists. Hence, in outbreeding crops, selection can be restricted to a single composite, while in inbreeding crops, fewer crosses can reduce the number of entries. With fewer crosses, the population size of each cross can be much larger than is common in conventional plant breeding. Although contrary to common practice, using few crosses with large populations is supported strongly by theory, and choice of crosses is perhaps the most critical factor for success.^[12,13] PVS can identify superior parents, making it easier to carefully choose a few crosses, or varieties or landraces already popular with farmers can be used as parents.

Using only a few crosses in one inbreeding crop, rice, has been effective. From one cross, two rice varieties have been released from a PPB program in eastern India^[14] and from the same cross, farmers in Nepal are accepting varieties for different ecosystems in both early-season and main-season rice. A few-crosses strategy is effective because PPB is noncompetitive and simply aims to breed a better variety than the one farmers are growing. However, this is not sufficient in commercial breeding, because breeders have to produce a variety that is also superior to those of their competitors. Under these circumstances, more crosses may be appropriate.^[13]

Bulk-population methods have been recommended as more suited to participatory approaches in inbreeding crops.^[15] This is supported by theory, despite the

reliance of many breeding programs on pedigree breeding.^a Collaborative plant breeding using bulk breeding^b has been very effective. From heterogeneous bulks of populations of nearly homozygous lines, farmers have selected varieties that perform well. Another method tests pure lines^c derived from bulk populations. Here consultative participation—joint evaluation by farmers and breeders in the field—has been effective for selecting the best pure lines. Farmers subsequently evaluate the selected pure lines for grain quality traits.

In outbreeding crops, simple approaches such as mass selection have been effective in PPB for maize in both eastern and western India.^[9] It has proved easier to carry out selection on researcher-managed populations, because avoiding unwanted cross-pollination in crops grown in farmers' fields is more difficult.

PVS FOLLOWS PPB

PVS follows seamlessly from PPB. As soon as potential varieties have been produced by PPB, farmers test them using PVS. This is an important advantage, because the results of PPB reach farmers more quickly than the results of conventional breeding, where varieties typically are tested with farmers after a long delay for on-station testing and multiplication.^[1] This is an important advantage of PPB, since delay in obtaining benefits reduces the rate of return on the investment in plant breeding.^[16]

PPB AND CONVENTIONAL BREEDING ARE COMPLEMENTARY STRATEGIES

Conventional breeding and PPB are complementary. Many PVS and PPB programs use the widely adapted products of conventional breeding either as varieties per se or as parents.^[17] PPB uses more specialized parents than conventional breeding and produces different germplasm, so conventional breeding can benefit from this genetic resource. Screening large germplasm collections or strategic breeding that uses wide crosses between cultivated and wild species is beyond the scope of PPB. Partnerships between conventional and participatory

^aWhere individual plants or lines are selected on the basis of their desirability, judged individually and by their pedigree record (ancestry).

^cA pure line results from inbreeding until there is effectively no genetic variation within the line.

approaches are needed, and institutional structures will determine exactly how this is done.

Breeding: Recurrent Selection and Gain from Selection

James G. Coors

University of Wisconsin, Madison, Wisconsin, U.S.A.

INTRODUCTION

There are many ways to conduct selection in plants, and plant breeders usually develop specific breeding procedures that best capture the genetic potential of the germplasm at hand. Breeding systems must accommodate factors such as mating system and progeny size that are unique to particular species. Nonetheless, there are overall patterns that characterize a broad array of breeding techniques. Recurrent selection is one of the most common overlying patterns.

RECURRENT SELECTION

Recurrent selection is a cyclic process of population improvement (Fig. 1). Cycles consist of distinct steps involving evaluation, selection, and recombination to improve breeding populations continuously. Recurrent selection is designed to increase the frequency of favorable alleles for a specific trait in a breeding population over cycles of selection. Breeding populations are sources of potential cultivars such as synthetics, inbreds, or hybrids that may be developed using pedigree or some other selection technique. As long as the frequency of desirable alleles increases in the breeding population, the chance of extracting or developing desirable cultivars from the breeding population will also increase.

Recurrent selection is a long-term endeavor. Gene frequencies change slowly over cycles of selection, and commercial breeders with near-term objectives do not expend much effort on upgrading breeding populations from which adapted cultivars are developed. With the exception of maize (*Zea mays* L.), classical recurrent selection is rarely used for crop species where inbred or hybrid cultivars are common. Recurrent selection techniques are most often used for open-pollinated species where improved breeding populations may be used directly as cultivars. In maize, recurrent selection techniques are highly refined and many have been used extensively for research purposes, as well as to develop widely-used breeding populations, such as the Stiff Stalk Synthetic developed by Iowa State University.^[4]

Methods of Recurrent Selection

Methods of recurrent selection vary according to whether breeding populations are being improved for per se performance (intrapopulation improvement) or for improved combining ability with complementary breeding populations or tester lines (interpopulation improvement). Methods are further classified by type of progeny evaluated ("evaluation" units) and the type of progeny selected and recombined ("recombination" units).

Intrapopulation recurrent selection

Several intrapopulation recurrent selection methods are used to improve performance of breeding populations (Table 1). They differ based on the nature of the evaluation and recombination units. A simple mass selection program for an open-pollinated species might involve the evaluation of a number of plants for a specific trait, e.g., seed yield, where the seed obtained from the most desirable plants is harvested, composited, and replanted the next season to start the next cycle. In this case, the plants are the evaluation units, and the harvested seeds from the selected plants are the recombination units. Since seed yield is measured after seeds are formed via random pollination from nearby plants, only the maternal contribution (seed-yielding ability of a plant) is subject to selection. This is often referred to as uniparental mass selection. For some traits, e.g., seedling vigor, evaluation and selection can occur prior to fertilization, and both maternal and paternal contributions can be controlled by intermating only selected plants during the recombination phase. In such cases, the recombination units are the individual selected plants, and the selection system is termed biparental mass selection. As might be expected, expected gains from biparental selection are twice those from uniparental selection.

When traits are difficult to measure on individual plants, half-sib, full-sib, or inbred (S_1 , S_2 , etc.) families can be used as evaluation units. Families can be planted in multiple environments, and traits can be measured on several plants in each family. There are several options for recombination. For example, if half-sib

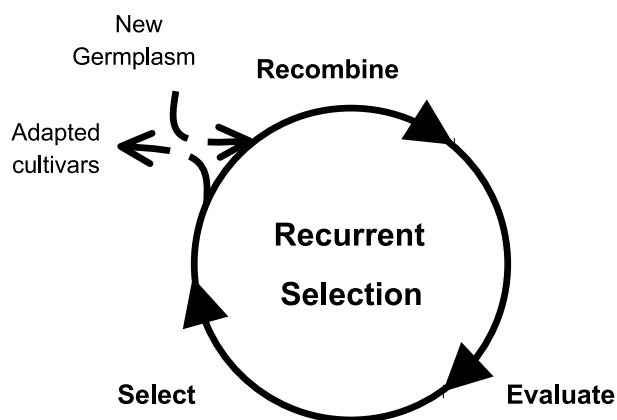

Fig. 1 Recurrent selection is a cyclic process involving evaluation, selection, and recombination to improve continuously breeding populations that are used as sources for cultivar development.

families are evaluated, recombination can be via: 1) compositing of open-pollinated seed harvested from the selected half-sib families, 2) compositing of remnant seed from the selected half-sib families, or 3) intermating the parents that gave rise to the selected half-sib families. On a cycle basis, method 3) is four times as effective as method 1) and twice as effective as method 2), but method 3) requires an additional season to plant and intermate the selected parental plants. The other family-based methods of intrapopulation recurrent selection have similar recombination options. Intrapopulation selection methods can easily be combined when appropriate.

Interpopulation recurrent selection

When breeders want to exploit hybrid vigor, they may choose to improve two breeding populations (Pop. A and Pop. B) simultaneously for combining ability, and the selection procedures are collectively referred to as reciprocal recurrent selection (Table 1). The evaluation units can be half-sib and full-sib families, but these families have a different structure than in intrapopulation recurrent selection. The mating of a single plant in Pop. A with a single plant from Pop. B would produce a full-sib family for reciprocal recurrent selection. A half-sib family might be created by pollinating a single plant from one population by pollen from a number of random plants from the other. In this example, there are two types of half-sib families for evaluation, those derived from individual maternal plants in Pop. A, and those derived from individual maternal plants in Pop. B.

For both full-sib and half-sib reciprocal recurrent selection, recombination occurs within each population in order to keep the breeding populations distinct from one another. Depending on the flowering habit and life cycle, there may be a number of different recombination options. One would be to recombine S_1 families derived by self-pollinating plants that were used to make the selected crosses. Or, if the parental plants can be vegetatively propagated and maintained for several seasons, the parent plants used to make the selected crosses can be directly intermated within each population to create seed for the improved breeding populations for the next cycle of selection.

Plant breeders often want to improve the combining ability of a single breeding population with a tester line, typically an elite inbred line used for hybrid seed

B

Table 1 Examples of typical intrapopulation and interpopulation recurrent selection programs

Method	Evaluation unit	Recombination unit
Intrapopulation improvement		
Mass, uniparental control	Individual plants	Open-pollinated seeds from selected plants
Mass, biparental control	Individual plants	Individual selected plants
Half-sib family, method 1	Half-sib families	Open-pollinated seed from selected half-sib families
Half-sib family, method 2	Half-sib families	Remnant seed from selected half-sib families
Half-sib family, method 3	Half-sib families	Common parents of selected families
Full-sib family	Full-sib families	Full-sib families
Selfed family	S_1 or S_2 families	S_1 or S_2 families
Interpopulation improvement		
Half-sib reciprocal recurrent	Half-sib families	S_1 or S_2 families
Full-sib reciprocal recurrent	Full-sib families	S_1 or S_2 families
Testcross	Testcross families	S_1 or S_2 families

(Adapted from Refs. 1 and 4.)

production. In this case, a breeder could develop inbred (S_1, S_2 , etc.) families that would all be crossed to the tester line. The testcrosses would be evaluated, and remnant seed from the selected inbreds from the breeding population would be used to recombine selected families for the next cycle.

GAINS FROM SELECTION

Expected Gains from Recurrent Selection

Expected gains can be calculated based on the form of the evaluation units, the form of recombination units, selection intensity, genetic and phenotypic variance of the trait, and number of seasons required for each cycle.^[6,7] The general form of the expected gains equation is

$$\Delta G = \frac{S}{\sigma_{ph}^2} \sum_{i=1} COV(p_i, g_i) \frac{\partial \bar{g}_i}{\partial p_i}$$

where S is the selection differential, σ_{ph}^2 is the phenotypic variance, $COV(p_i, g_i)$ is the covariance of allele frequency with genotypic value at locus i , and

$$\frac{\partial \bar{g}_i}{\partial p_i}$$

is the rate of change in mean genotypic value in the population as the allele frequency changes for locus i .

The general expected gains equation is used to develop specific formulae, such as those provide in Table 2, that

compare the relative potential of various selection schemes. While the expected gains presented in Table 2 are based on gain per cycle of selection, there are several other ways to express gain, including gain per unit time (e.g., gain per year) and gain per unit input (e.g., gain per dollar invested). From a plant breeder's perspective, gain per unit time and gain per unit input are often the most useful indicators of selection efficiency. These expected gains can be easily derived from gain per cycle once a particular breeding method is devised.

Realized Gains from Recurrent Selection

Measurement of realized gains from recurrent selection requires extensive evaluation over several cycles of selection. Response is highly variable from cycle to cycle due to environmental variation, sampling errors, and genetic drift. One of the most common ways to calculate realized gain is to regress the mean performance of the breeding population at each cycle on the cycle number. The linear regression coefficient then provides an estimate of gain per cycle. However, there are complicating issues that warrant other estimation techniques in particular situations.^[8]

Gains from selection are often less than expected when the effective population size is small. Small population size leads to unanticipated variation in response due to genetic drift, and genetic variation in the breeding population may be unnecessarily reduced over cycles if the number of selected plants or families recombined each cycle is small.

Table 2 Expected gains per cycle for several intrapopulation and interpopulation recurrent selection programs

Method	Expected gain	Generations per cycle
Intrapopulation improvement		
Mass selection, uniparental control	$(1/2)i\sigma_A^2/\sigma_P$	1
Mass selection, biparental control	$i\sigma_A^2/\sigma_P$	1
Half-sib selection, method 1	$(1/8)i_1\sigma_A^2/\sigma_{HS}$	1
Half-sib selection, method 2	$(1/4)i\sigma_A^2/\sigma_{HS}$	2
Half-sib selection, method 3	$(1/2)i\sigma_A^2/\sigma_{HS}$	3
Full-sib selection	$(1/2)i\sigma_A^2/\sigma_{FS}$	3
S_1 selection	$i(\sigma_A^2 + C_1)/\sigma_{S_1}$	3
S_2 selection	$(3/2)i(\sigma_A^2 + C_2)/\sigma_{S_2}$	4
Interpopulation improvement		
Half-sib reciprocal recurrent	$(1/4)i\sigma_{A12}^2/\sigma_{HS12} + (1/4)i\sigma_{A21}^2/\sigma_{HS21}$	3
Full-sib reciprocal recurrent	$(1/2)i\sigma_{A(12)}^2/\sigma_{FS(12)}$	3

i = selection intensity in standardized units; σ_A^2 = additive genetic variance; σ_{A12}^2 and σ_{A21}^2 are homologs of σ_A^2 and refer to the additive variance expressed among half sibs developed from each population used in reciprocal recurrent selection; σ_P = phenotypic standard deviation of single-plant measurements; σ_{HS} , σ_{FS} , σ_{S_1} , and σ_{S_2} are the standard deviations of family means; factors C_1 and C_2 for S_1 and S_2 selection depend on the degree of dominance in the population.

(Adapted from Ref. 4.)

The longest-running structured recurrent selection program known in plants is that for oil and protein in maize started at the University of Illinois in 1896 by C.G. Hopkins.^[9] More than 100 selection cycles have been completed for high oil and protein concentration. Mass selection was used in the initial cycles, but most of the selection has been by various half-sib family procedures. Even with 100 cycles completed, selection for high oil and protein continues without conspicuous loss of response. Unfortunately, there are few other such long-term recurrent selection studies in plants. Two mass selection programs in maize equal or exceed 30 cycles, one for ear length^[10,11] and the other for prolificacy.^[12] The longest-running reciprocal recurrent selection study is that at Iowa State University involving 15 cycles with the Iowa Stiff Stalk Synthetic and Iowa Corn Borer Synthetic #1.^[13] Most other selection studies in plants have been discontinued after fewer than 10 cycles. Some of the most informative studies regarding the nature of genetic variation and selection response are those from non-plant species with short generation times. For example, one of the longest known selection studies involves a 20,000-generation experiment with *Escherichia coli*.^[14]

Much of the research on recurrent selection in plants involves selection for grain yield in maize. In a survey of 133 selection studies in maize, the mean of all types of intrapopulation improvement averaged approximately 2 to 3% gain per cycle or 50 to 90 kg per ha year.^[15] The average gain for interpopulation improvement was higher: approximately 3 to 4% per cycle or 80 to 110 kg per ha year.

Intrapopulation recurrent selection methods based solely on additive genetic variance have been successful, and comparisons among selection methods for relative rate of improvement agree with theoretical expectations in most instances. Interpopulation improvement has been especially productive. Breeders have been able to use dominance efficiently to increase annual response rates in those species with heterotic potential. The fundamental message from recurrent selection, which also applies to nearly all breeding systems, is that rapid progression from evaluation to selection and finally recombination is essential for long-term germplasm improvement.

WHY IS RECURRENT SELECTION IMPORTANT?

There are two essential goals for plant breeders: 1) creating commercially viable varieties for the near-term and 2) increasing the genetic potential of germplasm so that breeders will continue to make gains in the future. At times, these goals are in conflict. While most individual

breeders' careers stand or fall on the production of commercial varieties, the long-term success of the seed industry depends on continued improvement of productive breeding populations from which commercial varieties will be developed by future breeders. The contrast between cultivar development and recurrent selection reflects, in part, the tradeoff plant breeders must make between short- and long-term goals.

Breeding: The Backcross Method

William F. Tracy

University of Wisconsin, Madison, Wisconsin, U.S.A.

INTRODUCTION

Backcross breeding has been an important tool for plant breeders for more than 80 years, and with the relatively recent incorporation of transformation as a plant breeding tool the importance of the backcross method has increased. The goal of most backcrossing programs is to improve a particular strain (recurrent parent) for a specific characteristic, usually a single gene, obtained from a donor parent. In most backcross programs the objective is to recover the recurrent parent essentially unchanged except for the introgression of the new characteristic. Backcrossing allows the plant breeder more precise control of allele frequencies than other traditional plant breeding methods. The addition of molecular markers to backcrossing programs allows even greater precision and more rapid incorporation of alleles into cultivars.

GENETIC BASIS OF BACKCROSSING

In a typical backcross program, with the objective of introgressing allele A^2 into the recurrent parent, an F_1 (A^1A^2) is made by crossing the recurrent parent (A^1A^1) and the donor parent (A^2A^2). The following growing season, the F_1 (A^1A^2) is backcrossed to the recurrent parent (A^1A^1). The progeny resulting from this cross is the backcross 1 (BC_1) generation. The backcrossing is repeated for a number of cycles. The number of cycles depends upon the objectives of the breeding program and other factors.^[1] In the progeny of the last backcross the donated allele will be heterozygous. For recessive traits one generation of self-pollination followed by progeny testing is needed to isolate and identify plants homozygous for the donated allele. For dominant traits two cycles of self-pollination followed by progeny testing are required to identify homozygous plants. If a codominant molecular marker is tightly linked to the dominant gene of interest it is possible to eliminate the second self-pollination and progeny test.

50% of the alleles in the F_1 individuals are from the recurrent parent and 50% are from the donor parent. In each successive backcross, average percentage of alleles from the recurrent parent increases by 50% (Table 1). Thus the average percent of recurrent alleles in the BC_1 is

75% and in the BC_2 87.5%. The equation to calculate average recovery of recurrent alleles is $1 - (1/2)^{n+1}$, where n = the number of backcross cycles.^[1] If the recurrent parent is an inbred cultivar, then this equation also gives the average homozygosity for each backcross. Recovery is given as an average because in each backcross there is a range among plants for the number of recurrent alleles. The individual plants in each backcross are a sample of the range of possible allele frequencies.

Selection and genetic linkage alter the average percent recovery of recurrent alleles.^[1] If plants backcrossed to the recurrent parent are chosen because they are phenotypically similar to the recurrent parent, then the recovery of recurrent alleles will increase. This is especially true in the early cycles of backcrossing when there is more phenotypic variation within backcross families. The use of genetic markers to determine the most similar plants in each backcross cycle can greatly increase the rate of recovery.^[2,3]

Genetic linkage reduces the recovery of those recurrent alleles linked to the locus that is being substituted. As the genetic distance between the desired donated allele, A^2 , and an undesirable allele, B^2 , decreases the recovery of the desired haplotype, A^2B^1 , becomes more difficult. The probability of eliminating allele B^2 is $1 - (1 - c)^n$, where c is the crossover rate and n is the number of backcrosses.^[4] If A^2 and B^2 are unlinked ($c = 0.5$), the probability that B^2 will be eliminated after five backcrosses is 0.969. On the other hand, if A^2 and B^2 are tightly linked, i.e., $c = 0.01$, the probability that B^2 will be eliminated after five backcrosses is 0.049. Backcrossing, however, does increase the likelihood of identifying favorable recombinants relative to selfing.^[4] Molecular markers can be used to identify desirable rare recombinants. Markers flanking the location of the donated allele can be used to set precisely the size of the donated section of DNA.^[3,5]

Another factor that slows the recovery of recurrent alleles is the effect of modifying genes. Backcrossing is most commonly used with simply inherited traits, but modifying genes or background effects affect the phenotype of many simply inherited traits. For example, the *shrunk2* allele, when backcrossed into corn (*Zea mays* L.) inbreds results in high sucrose concentration in the endosperm, which is useful for commercial sweet corn.^[6] However, in many genetic backgrounds the high sugar

Table 1 Average recovery of alleles of the recurrent parent during backcrossing

Generation	% Alleles from recurrent parent
F ₁	50
BC ₁	75
BC ₂	87.500
BC ₃	93.750
BC ₄	96.875
BC ₅	98.4375
BC ₆	99.21875

phenotype can result in very poor seed germination.^[7] Genes that improve germination are often present in the donor parent and in some cases must be introgressed into the recurrent parent along with the *shrunk2* gene.^[8] Each modifying gene will be linked to undesirable alleles from the donor parent and therefore reduce the average recovery of recurrent alleles. Usually the genetic locations of modifying genes are unknown and their effects are small. Thus they are less amenable to marker-assisted backcrossing than major genes. In cases when it is important for modifying genes to be introgressed, the breeder might opt for fewer cycles of backcrossing, followed by self-pollination and selection for types that have the best combination of modifiers and therefore best express the donated trait.

PROGENY TESTING

During backcrossing the presence of the donated allele in the backcross generations must be determined. When derived from two inbred parents the F₁ generation will be heterozygous (A¹A²). In the BC₁ generation 50% of the plants will be heterozygous at the gene of interest (A¹A²), and 50% of the plants will be homozygous for the allele from the recurrent parent (A¹A¹). If the donated allele is dominant and expressed prior to pollination, then the heterozygous plants can be identified and used for pollination and no progeny testing is needed. If the donor allele is recessive, then a progeny test must be done to determine which plants are heterozygous for the donated allele. Depending on the reproductive system, plants in the BC₁ generation can be self-pollinated or crossed to a tester to determine if the donated allele is present. For many species the testcross and backcross can be performed in the same generation by using the paired cross or paired progeny selection method.^[9] In this method BC₁ plants are numbered, self-pollinated, and backcrossed to the recurrent parent. Progeny derived from the backcross is given the same number as progeny from the self-

pollination. Following seed maturation the backcross and the selfed progenies are grown. The selfed progeny is evaluated for the trait of interest. The backcross progeny corresponding to those selfed progeny that have a copy of the donated allele (A¹A²) are backcrossed again. Those backcross progeny that correspond to selfed progeny that do not have the gene of interest (A¹A¹) are discarded, as are all of the selfed progeny. The paired cross method allows a backcross to be performed each growing season, saving time but using more labor for pollination and space.

Progeny testing need not be done every cycle of backcrossing as long as the number of individuals in each backcross generation is large enough to ensure that heterozygous individuals exist in the population.^[1]

PARENTS AND DIRECTION OF CROSS

Backcrossing is usually used to introgress a desirable trait into an otherwise high-performing cultivar. Since backcrossing requires a number of cycles it is important that the recurrent parent still be useful following the backcross program. If the recurrent parent is a marginal cultivar and it is likely that it will be quickly surpassed by newer cultivars even after the donated allele has been introgressed, then the time and dollars devoted to backcrossing will be wasted. Backcrossing a new allele into a well established, widely used cultivar has a high probability of resulting in a cultivar that will be successful. The donor parent should be the best adapted germplasm available that has the allele of interest. Wild or exotic germplasm will have more deleterious traits, and more cycles of backcrossing may be required to remove the deleterious traits.^[1]

The recurrent parent should be used as the female in the initial cross with the donor parent. This will preserve the relationship between the nuclear and cytoplasmic genomes of the recurrent parent. In the following backcrosses the direction of the cross is unimportant because both the parents will have the same cytoplasm. The exception is when the goal is to transfer an entire nuclear genome into a different cytoplasm. The nuclear genome would be from the recurrent parent, and the donor parent contributes the cytoplasm. This is commonly done when developing cytoplasmic male sterile lines.^[9]

BACKCROSSING OPEN-POLLINATED CULTIVARS

Backcrossing is simplest when the recurrent parent is homozygous and homogeneous, such as an inbred or pure line cultivar; however, it is possible to backcross traits into heterozygous, heterogeneous populations. In this case

adequate sampling of the alleles in the population must be done during each cycle of backcrossing. Numerous different individuals from the recurrent parent must be crossed to different individuals from each backcross generation. The number of individuals needed varies depending on the level of variability in the recurrent parent. A minimum of 100 individuals from the recurrent parent should contribute to the next generation. However, on average, only 50% of the backcrosses will be with heterozygous plants, so to obtain 100 successful pollinations more than 200 would need to be done. Fewer plants may be used in early cycles but the number should increase in later cycles. Progeny testing will have to be done for each backcross pollination, and this can require significant space and time.

NUMBER OF CYCLES

The number of cycles of backcrossing depends on the importance of fully recovering the phenotype of the recurrent parent, the amount of selection imposed during backcrossing, the adaptation of the donor parent, linkage between desirable and undesirable genes,^[1] and the availability of marker assisted selection systems. If the goal is to recover the recurrent parent essentially unchanged except for the donated allele, then a minimum of five backcrosses is needed. In many cases significant differences may persist beyond five or six backcrosses, and more backcrosses will be required. If the donor parent is unadapted or the donated allele is tightly linked to deleterious alleles, more than five backcrosses will be required. Selection, especially when based on molecular markers, decreases the number of backcrosses required.^[2,5] Marker-assisted backcrossing can reduce the number of backcrosses needed by 50% or more. Time is saved but cost per backcross cycle increases due to the cost of collecting marker data.

Many breeders will develop new lines from populations derived from one, two, or three cycles of backcrossing. The advantage of limited backcrossing is the possibility of identifying individuals superior to the recurrent parent. The likelihood of identifying transgressive segregants decreases with each cycle of backcrossing.^[1] Limited backcrossing may also be used when, in addition to the donated allele, modifying genes from the donor are important. Increased cycles of backcrossing decreases the probability of fixing multiple loci with small effects.

POLYGENIC TRAITS

Backcrossing can also be used to transfer traits controlled by multiple genes. To accomplish the transfer of poly-

genic traits, selection for the trait of interest must be done after each cycle of backcrossing. For example, in the growing season following the first backcross, a number of BC₁ plants are self-pollinated. In the following growing season these BC₁F₂ progeny are grown and evaluated for the trait of interest and similarity to the recurrent parent. Selected individuals will then be backcrossed to the recurrent parent. Polygenic traits are usually metric traits and affected by the environment. Therefore, evaluation and selection among the BC₁F₂ families may need to be based on replicated trials and multiple environments. This greatly increases the amount of resources required. Due to dealing with multiple loci spread throughout the genome the recovery of the parental type will generally be less complete than when backcrossing a simply inherited trait.

The advanced backcross system uses molecular markers to increase the precision and speed of incorporating polygenic traits.^[10] The advanced backcross method has been applied in numerous crops in crosses with wild germplasm to identify quantitative trait loci that may benefit the domesticated species.^[11,12] The linked markers are then used to introgress the alleles into elite germplasm using marker assisted backcrossing.

EVALUATION OF NEW CULTIVAR

The purpose of backcross breeding is to recover the recurrent parent essentially unchanged except for the donated trait. Backcross breeding programs have been very successful in the development of improved cultivars. As in most complex systems, however, unexpected and

Fig. 1 Rust- (*Puccinia sorghi*) susceptible (left) and rust-resistant (right) sweet corn hybrids. Rust resistance is controlled by a single gene, Rp1, which was incorporated by backcrossing. (Photo by Jerald Pataky.) (View this art in color at www.dekker.com.)

undesirable outcomes occur. It is imperative that any new cultivar, developed by any method, be extensively evaluated in the intended area of production prior to release. Because the backcross method is very effective at recovering the phenotype of the recurrent parent, breeders have been tempted to reduce the amount of evaluation prior to cultivar release. Rushing a new cultivar to market without adequate testing can lead to crop failure and puts the farmer at economic risk. Such failures are seldom published in scientific literature, but most breeders have numerous anecdotes regarding spectacular failures of new cultivars derived by backcross breeding. In my own breeding program I used the backcross method to introgress an allele (*Rp1d*) for resistance to common rust (*Puccinia sorghi*) into an elite commercial sweet corn inbred. After six backcrosses I had developed a new line that appeared identical to the recurrent parent except for improved rust resistance. Prior to release, to increase seed amounts, the original and new lines were grown in the same environment. The original inbred (recurrent parent) yielded 1000 kg/ha, while the backcross-derived line yielded 225 kg/ha. Clearly this would have been disastrous if released directly to farmers based solely on its phenotypic appearance (Fig. 1).

CONCLUSION

Backcross breeding is a powerful tool for rapidly and precisely introgressing traits of interest into established cultivars. It is easiest and fastest when used with pure lines and traits controlled by a single gene. Backcrossing can be used with open-pollinated cultivars and polygenic traits, but such programs require more dollars, space, and time. Marker technology can increase the precision and speed of backcrossing. Despite the apparent ease in recovering the phenotype of the recurrent parent it is critical to test the performance of the newly derived cultivar carefully prior to release to ensure that the new cultivar performs as expected.

C₃ Photosynthesis to Crassulacean Acid Metabolism Shift in *Mesembryanthemum crystallinum*: A Stress Tolerance Mechanism

John C. Cushman

University of Nevada, Reno, Nevada, U.S.A.

INTRODUCTION

Water is an essential requirement for all plant life. However, more than 35% of the earth's landmass is considered semiarid or arid. Crassulacean acid metabolism (CAM), one of three major modes of photosynthetic carbon fixation, is present in approximately 7% of terrestrial plants distributed across 33 families and 328 genera. CAM is a highly plastic adaptation to water limitation, which results in a five- to tenfold increase in water use efficiency under comparable conditions relative to C₄ and C₃ plants. Studies of the ecological distribution of CAM plants in predominantly arid habitats reinforce the notion that CAM confers a competitive advantage in hot, dry climates. Environmental conditions such as temperature, light intensity, and water availability have a profound effect on the degree to which this alternative photosynthetic carbon fixation pathway is manifested within the context of an evolutionary diverse continuum of intermediate, inducible, and obligate modes of CAM. A number of physiological, biochemical, and molecular genetic factors—such as carbohydrate and metabolite concentrations and a circadian clock—control the genotypic and phenotypic plasticity of CAM.

DEFINING CAM

The basic biochemical reactions of the CAM cycle are confined within single chloroplast-containing cells and constitute a pattern of CO₂ uptake, C₄ acid, and glucan formation that has been described as the diel repetition of four phases.^[1] Specifically, CAM involves the nocturnal fixation of atmospheric and respiratory CO₂ by phosphoenolpyruvate carboxylase (PEPC) resulting in the the formulation of oxaloacetate that is reduced to malate and stored in the vacuole (phase I). Subsequent daytime decarboxylation of these organic acids to release CO₂, which is refixed by ribulose-1,5-bisphosphate carboxylase/oxygenase (Rubisco) in the chloroplast, leads to carbohydrate production (phase III). In fully watered obligate CAM plants this phase is flanked by two transient periods of

atmospheric CO₂ uptake, which mark the transition from C₄ to C₃ metabolism in the morning (phase II) and from Rubisco to PEPC activity in the afternoon (phase IV). CO₂ release during the day when stomata remain closed concentrates CO₂ around Rubisco, suppressing its oxygenase activity. The temporal separation of the C₃ and C₄ carboxylase activities and the associated diurnal fluctuation of carbon are supported by a complex and tightly controlled system of enzymatic and metabolite transport activities. These activities are, in turn, initiated by developmental and environmental factors, and maintained by a circadian clock. This complexity is orchestrated, in large part, by an intricate network of control mechanisms that originates with changes in gene expression.

CAM PLASTICITY

The traditional definition of CAM within the earlier discussed four-phase framework was derived primarily from measuring changes in patterns of leaf-gas exchange, acidity, and malate concentrations in fully watered obligate CAM plants. However, developmental, morphological, and environmental conditions—such as temperature, light, and water availability—play important roles in modulating the performance of CAM against the backdrop of a continuum of CAM modes governed by a combination of ontogenetic and evolutionary factors.^[2,3] C₃-CAM intermediate species such as *Sedum telephium*, which do not progress beyond CAM-cycling, exhibit negligible nocturnal CO₂ uptake under well-water conditions along with some refixation of respiratory CO₂. However, following drought stress the relative contribution of nocturnal CO₂ uptake can increase in the absence of daytime stomatal closure. In inducible, highly plastic CAM species such as the well studied dicotyledonous tree *Clusia minor*, CAM induction can be extremely rapid (within one day) and is fully reversible.^[2] In the halophyte *M. crystallinum*, salinity or water limitation accelerates and magnifies a developmentally programmed C₃-CAM transition over several days and is not fully reversible.^[4] However, even well studied obligate CAM species such as *Kalanchoë*

daigremontiana will adjust to water deficit by reducing uptake during phases II and IV.^[5] Surveys of CAM plasticity within the Crassulaceae have revealed that the magnitude of nocturnal CO₂ fixation tends to correlate well with a greater degree of succulence in species that predominate in more arid climates.^[6] Furthermore, thinner-leaved *Kalanchoë* species are more plastic in photosynthetic expression than thicker-leaved, succulent relatives, which are bound to nocturnal CO₂ fixation, presumably due to the extreme CO₂-diffusion limits within their tissues.^[3]

CONTROL OF CAM INDUCTION

Although no unique enzymes are required to perform CAM, large changes in the abundance and regulation of an assortment of enzymes involved in organic acid and carbohydrate formation, turnover, and intracellular transport functions occur during CAM induction to meet the increased flow of carbon through the pathway and to avoid futile cycling of carbon skeletons contained within a single photosynthetic cell. To satisfy the metabolic demands for diel (day-night) carbon flux, CAM-specific members of multigene families appear to have become recruited during evolution.^[7] Recruited genes typically display elevated expression patterns, whereas other isoforms that presumably fulfill anapleurotic or tissue-specific functional roles undergo little change in expression and generally are expressed at low levels in CAM-performing tissues. Alternatively, a single gene may fulfill both C₃ photosynthesis- and CAM-specific functions. Nuclear run-on transcription assays and transient assays using promoter-reporter gene fusion studies have confirmed that transcriptional activation is the primary control point responsible for modulating the expression of many CAM-specific genes. PEPC is the most abundant CAM enzyme and plays a major regulatory role in controlling circadian patterns of CO₂ fixation leading to malate synthesis.^[8] Flux through PEPC is mediated by reversible protein phosphorylation, catalyzed by a circadianly controlled PEPC kinase that renders the enzyme considerably less sensitive to inhibition by negative effectors (e.g., L-malate) at night, but both more active and more sensitive to activation by positive effectors during the day (e.g., glucose-6-phosphate, triose phosphate). The kinase activity is, in turn, controlled by a circadian clock at the level of gene expression, with PEPC kinase transcripts up to twentyfold more abundant at night. Recent findings provide evidence for the coordinated regulation of Rubisco and PEPC over the diurnal phases of CAM in *K. daigremontiana*. Rubisco activation is exceptionally protracted over the diurnal course. During phase II, PEPC activity dominates, and Rubisco activation

increases with elevated CO₂, but does not attain maximal activity until phase IV. Delayed activation is thought to be a result of delayed action of inhibitors during phase II^[9] as well as delayed synthesis of Rubisco activase protein,^[5] which is in turn regulated at the level of transcript abundance under the control of the circadian clock. Thus, both PEPC and Rubisco appear to be highly regulated in order to prevent competing carboxylations, to minimize futile carbon cycling between the C₃ and C₄ pathways and to optimize CO₂ fixation during both short-term and long-term changes in environmental conditions.^[5]

A major metabolic constraint for CAM induction is the ability to distinguish between the large day-night reciprocating pool of carbohydrates required for CAM and those carbon skeletons destined for nitrogen metabolism, respiration, or growth. Acclimation to salinity and induction of CAM in *M. crystallinum* necessitates a reallocation of photosynthetically fixed carbon in order to fuel polyol accumulation and the dark reactions of CAM.^[10] This is accomplished by coordinated increases in the activities of a number of glycolytic, gluconeogenic, starch biosynthetic, and degradative enzymes and plastidic transport activities, which acquire pronounced diel changes in activity that are governed by corresponding circadian changes in gene expression. In addition, posttranscriptional and posttranslational processes are likely to be key control points for these activity changes. Elucidating the relative functional contribution of various enzymes and transporters involved in carbohydrate partitioning and turnover will require a comprehensive characterization of the corresponding genes or gene families in a variety of different CAM species exhibiting different carbohydrate storage strategies.

SIGNALING EVENTS IN CAM INDUCTION AND CIRCADIAN CONTROL

Investigation of the signaling mechanisms that regulate CAM induction and the diurnal or circadian regulation of the CAM cycle have focused almost exclusively on *M. crystallinum*.^[11] Signal transduction events initiated by water deficit, salinity stress, or abscisic acid (ABA) treatments that trigger expression of CAM genes are mediated by intracellular Ca²⁺, Ca²⁺/calmodulin-dependent protein kinases, protein phosphatases 2A and 1, phosphoinositides, and protein synthesis. Phytochrome and UV-A/Blue light have also been demonstrated to mediate CAM induction. Recent inhibitor studies in detached *M. crystallinum* leaves suggest that both ABA-dependent and -independent pathways may mediate CAM induction.^[11] In addition to ABA, various plant growth regulators, such as cytokinins and gibberellic acid, have also been implicated as signaling molecules that participate in CAM

induction in different ways depending on their mode of application.

Pharmacological treatments of detached leaves of *M. crystallinum* have produced evidence for the participation of phosphoinositide-dependent phospholipase C, inositol 1,4,5 triphosphate (IP₃)-gated tonoplast calcium channels, and a putative Ca²⁺-calmodulin-dependent protein kinase in the regulation of nocturnal PEPC kinase activity and the phosphorylation state of PEPC.^[12] Protein dephosphorylation events have also been implicated in the circadian signaling pathway that regulates PEPC kinase expression. Daytime/early dark phase alkalization of the cytosol was suggested to be the trigger for initiating PEPC phosphorylation by PEPC kinase. However, in contrast to C₄ plants, elevations in cytosolic pH appear to have little or no influence on PEPC kinase activity in *M. crystallinum* or *K. fedtschenkoi*, respectively. Both RNA and protein synthesis also appear to be essential to the signaling cascade that regulates PEPC kinase activity, an output of the circadian oscillator. PEPC kinase transcript abundance is inversely correlated with cytosolic malate concentrations in plants in which malate concentrations were manipulated by withholding CO₂.^[5] This observation suggests that cytosolic malate concentrations exert a negative effect on PEPC kinase gene expression or mRNA stability and override its circadian control. Temperature-gating experiments have provided further evidence that malate modulation of PEPC kinase expression is a secondary effect of the circadian clock, rather than a primary effect.^[12] Alternatively, other metabolites such as phosphoenolpyruvate (PEP), may act as a feed-forward activator of PEPC kinase expression.^[3] Cytosolic malate is likely to be controlled by transport of malate across the tonoplast membrane, a view that is well supported by temperature effects on tonoplast function and modeling studies.^[12] Thus, response to environmental factors that alter organic acid content or malate partitioning between the vacuole and cytosol may be able to override circadian rhythms of PEPC kinase activity, providing a possible fine-tuning mechanism for the rapid alterations in PEPC activity observed in some CAM species. However, it remains unclear whether the tonoplast functions as a master switch in generating circadian oscillations in CAM, or whether clock-controlled components exert their effect on malate transporters situated within the tonoplast membrane.

CONCLUSION

Although often viewed as an insignificant photosynthetic adaptation expressed in a small number of highly specialized, slow growing, arid land plants, it should be remembered that many horticulturally and agronomically important plants—including orchids (e.g., vanilla), bro-

meliads (e.g., pineapple), and cacti and agaves (used for tequila production)—perform CAM.^[3] Moreover, it is noteworthy that the photosynthetic plasticity and water-conserving features of CAM do not necessarily compromise the potential for high productivity. Steady advances in our understanding of the ecophysiology, physiology, and biochemical aspects of the induction and circadian regulation of CAM have been made through detailed investigations of a variety of well studied models. In the future, the development of a genetic model could facilitate the rapid exploration and understanding of the molecular mechanisms that underlie CAM induction and the circadian control of this specialized photosynthetic adaptation. Since the serendipitous discovery of the stress-inducible switch from C₃ photosynthesis to CAM in *M. crystallinum*, this species has been extensively studied. The inducible nature of CAM in this species allows a clear distinction to be made between molecular, biochemical, and physiological processes associated with C₃ photosynthesis versus those governing CAM.^[2] *M. crystallinum* grows rapidly, produces large numbers of seeds (10,000–15,000) per plant, and is self-fertile; large mutant collections exist for this species.^[13] Furthermore, *M. crystallinum* has a relatively small genome (390 Mb) relative to other CAM models and a large expressed sequence tag (EST) database with associated gene index.^[14] The availability of such molecular genetic resources will permit large-scale gene expression profiling to elucidate the regulatory control circuits involved in CAM induction and circadian rhythmicity and to provide insights into the functional significance of genes and enzymes that optimize physiological performance in arid environments. Finally, a reliable transformation technology will be required to perform reverse-genetic screens and to enable future studies of gene function by suppression or overexpression of specific genes of interest. In the near future, transcriptome, proteome, and metabolite profiling studies will provide an integrated view of the complex and remarkably plastic responses to environmental, developmental, and circadian cues that dictate the diel patterns of CO₂ fixation characteristic of CAM plants.

Calvin Cycle Intermediates

Richard G. Jensen (Retired)

The University of Arizona, Tucson, Arizona, U.S.A.

INTRODUCTION

The intermediates of the Calvin Cycle or the reductive pentose phosphate cycle involved in assimilation of CO₂ during photosynthesis are sugar phosphates. They include ribulose-1,5-bisphosphate (RuBP), 3-phosphoglycerate (PGA), dihydroxyacetone-phosphate, fructose-1,6-bisphosphate, fructose-6-phosphate, erythrose-4-phosphate, sedoheptulose-1,7-bisphosphate (SBP), sedoheptulose-7-phosphate, xylulose-5-phosphate, ribose-5-phosphate, and ribulose-5-phosphate. Although most of these intermediates are also involved in other metabolic pathways, notably glycolysis and the hexose monophosphate shunt, a unique sugar phosphate not involved in other metabolic pathways is RuBP. CO₂ fixation occurs when one molecule of RuBP accepts one CO₂ and forms two molecules of PGA, catalyzed by ribulose biphosphate carboxylase/oxygenase (Rubisco). Measurements of the pool size of RuBP in leaf tissues can indicate mechanisms by which photosynthetic CO₂ fixation is regulated.

IDENTIFICATION AND QUANTITATIVE ANALYSIS OF CALVIN CYCLE INTERMEDIATES

Calvin and his laboratory, in the 1950s, perfected a method of separation of sugar phosphate intermediates using descending two-dimensional paper chromatography, followed by radioautographic identification on X-ray film of spots containing intermediates that became labeled as the result of fixation of ¹⁴CO₂. The spots were cut from paper and inserted into vials for liquid scintillation analysis.^[1,2] This technique as well as separation by thin-layer chromatography are still used by some laboratories. Ion exchange chromatography has also been used to separate the intermediates from plant tissues, such as isolated chloroplasts capable of light-dependent CO₂ fixation.^[3]

Sugar phosphates in protein-free leaf extracts have also been detected using coupled enzyme reactions. On proper addition of purified and active enzyme preparations, reactions are coupled to the oxidation/reduction of NAD⁺/NADH and the change in absorbance is measured at 340 or 366 nm.^[4,5] This approach involves performing proper

preliminary control experiments. An in-depth discussion of this technique is beyond the scope of this article.

With the advent of high-performance anion chromatography (HPAE), rapid separation of the intermediates became possible. On elution, the compounds, radiolabeled by fixation of ¹⁴CO₂, were detected by radioactive monitoring of the online flow. With older methods where the sugar phosphates were unlabeled, the eluant fractions were treated with inorganic phosphatase and the released inorganic phosphate was analyzed by colorimetric methods.^[6]

As sugar phosphates themselves exhibit low ultraviolet (UV) absorbance, much greater ease and sensitivity were obtained by indirect or vacancy UV detection.^[7] The eluant, containing a UV-adsorbing strong acid, was passed over the anion column at constant ionic strength. The sugar phosphates displaced the UV-adsorbing acid and were detected as a vacancy or negative absorbance peak. Using polymer-based anion exchange columns, 0.3 mM trimesic acid (1,3,5-benzenetricarboxylic acid) worked best for sugar monophosphates, whereas 1.5 mM trimesic acid gave the best separation of the sugar bisphosphates. The disadvantage of this technique is that anions, other than the sugar phosphates, such as chloride, perchlorate, bicarbonate, and sulfate, interfered with detection. These anions were significantly eliminated by pretreatment of the sample over Sepralyte SAX minicolumns and sequential elution of the monophosphates by 0.05 N HCl followed by the bisphosphates with 0.15 N HCl. The salt-low fractions containing either the sugar monophosphates or bisphosphates were evaporated to near dryness to remove the HCl, resuspended in a little water, adjusted to about pH 7 with NaOH, and applied separately to the HPAE column.

Sugar phosphates have also been detected by their sugar moiety by pulsed amperometry, which reacts with the oxidizable hydroxyl groups in the presence of 50 mM NaOH or greater. The technique, called high performance anion exchange chromatography, pulsed amperometric detection (HPAE-PAD), can separate both monophosphates and bisphosphates by using a potassium acetate gradient from 400 to 500 mM.^[8] However, phosphoglycolate is not detected as it has no oxidizable hydroxyl group.

Probably the most quantitative detection system for PGA, phosphoglycolate, and RuBP involves HPAE

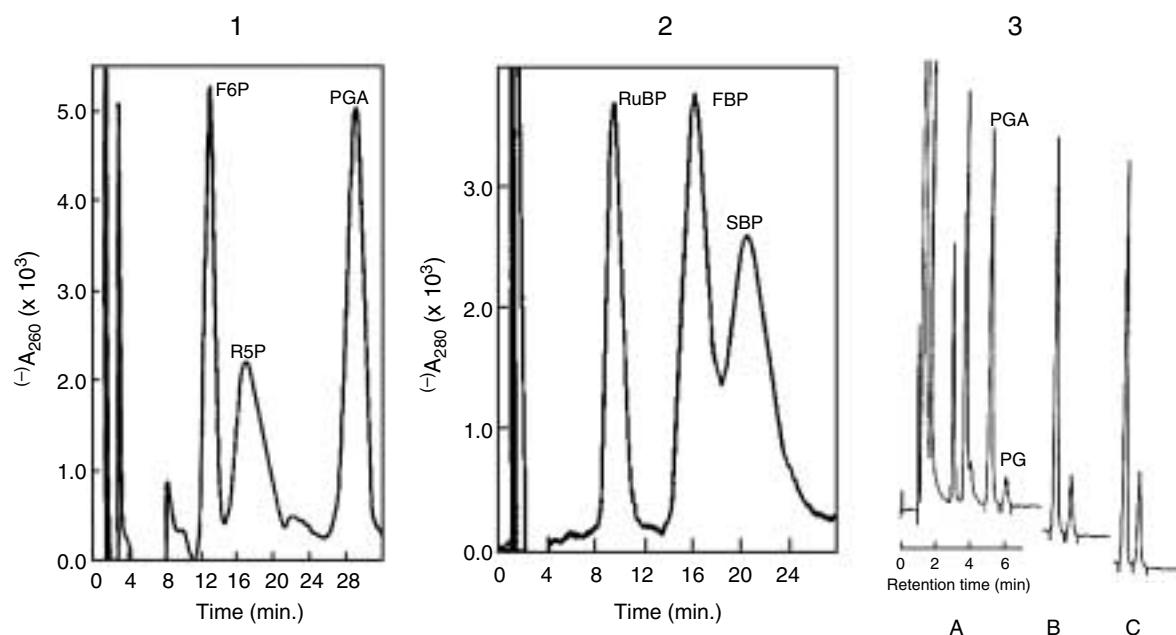

Fig. 1 Elution of Calvin Cycle intermediates during high-performance anion exchange chromatography. Elution of (1) monophosphates with 0.3 mM trimesate and 10 mM borate (pH 8.7) and (2) bisphosphates with 1.5 mM trimesate in 10 mM borate (pH 8.7) was detected by negative absorbance. (From Ref. [7].) In (3), the products of the reaction catalyzed by Rubisco in the presence of different gas mixtures were detected by suppressed conductivity. (A) 21% O₂, 384 μ bar CO₂; (B) 35% O₂, 320 μ bar CO₂; and (C) 50% O₂, 245 μ bar CO₂. As the ratio of O₂ to CO₂ increased, more phosphoglycolate (PG) was formed by the oxygenase activity of the enzyme. (From Refs. [9] and [10].) (View this art in color at www.dekker.com.)

separation followed by determination by suppressed conductivity. The technique detects all anions involved in the Calvin Cycle with peak areas most representative of their amount because of the low baseline noise that can be achieved.^[9,10] The use of these techniques to separate intermediates of the Calvin Cycle and to determine the CO₂/O₂ specificity of Rubisco is illustrated in Fig. 1.

RuBP IS THE MAJOR INTERMEDIATE UNIQUE TO THE CALVIN CYCLE

Of all of the sugar phosphate intermediates, only RuBP and SBP, which are unique to photosynthesis, are located exclusively in the chloroplast. Although important to the operation of the Calvin Cycle, SBP is present in considerably less amounts in the leaf than RuBP and changes in SBP are not directly related to controlling photosynthetic CO₂ fixation. In contrast, the levels of RuBP were estimated to be as high as 12 mM in the chloroplast, which is twofold to fourfold higher than the concentration of RuBP binding sites on Rubisco.^[11] RuBP is, most often, analyzed in the presence of Rubisco, excess ¹⁴CO₂, and Mg²⁺, and the [¹⁴C]PGA product is detected by liquid scintillation counting. To detect RuBP from leaf tissue extracts, especially those containing obnoxious phenolic compounds or interfering amounts of inorganic

phosphatase, the tissue was chilled on ice, homogenized in 10% vol/vol perchloric acid, and centrifuged to remove the particulate protein. RuBP remains quite stable for several hours in cold perchloric. Before analysis, the buffer bicine was added to 0.1 N and sufficient 4 N KOH was added while stirring to bring the pH to 7.8–8.0. The precipitated KClO₄ was removed on centrifugation. The neutralized extract was added to media containing purified tobacco Rubisco, 5 mM MgCl₂, 10 mM NaH¹⁴CO₃, and 50 mM bicine–KOH at pH 7.8–8.0 at room temperature. After reaction for 1 hr, 1 N HCl was added, the samples were dried in scintillation vials to remove gaseous ¹⁴CO₂, and the amount of [¹⁴C]PGA was determined.^[4,5] On lysis of intact spinach chloroplasts, the most direct approach for RuBP analysis used endogenous Rubisco and included 2,6-dichlorophenol-indophenol and carbonyl cyanide *m*-chlorophenylhydrazone to inhibit the continued synthesis of RuBP by the endogenous ribulose-5-phosphate kinase.^[12]

Analysis of RuBP levels in wheat leaf tissue has proven to be an important metabolic indicator of mechanisms by which light and other environmental factors influence CO₂ fixation during photosynthesis of intact plants. The availability of RuBP appeared to limit the rate of CO₂ fixation in the dark or dim light. At higher irradiances, the pool of RuBP quickly reached a maximum, whereas the CO₂ exchange rate and the activation of Rubisco slowly

increased in like manner until the light-dependent point of maximal CO₂ exchange rate was observed with the leaves.^[11] Under high light intensities, the pool of RuBP can be two to four times that of RuBP binding sites on Rubisco. Obviously, as CO₂ fixation increases, the rate of turnover of the RuBP must likewise increase. Yet, as determined in dim to saturating light intensity, the concentration of RuBP quickly reached a maximum well before the rate of CO₂ exchange became maximal. Under these conditions, the photosynthetic rate of CO₂ exchange was limited not by RuBP concentration but by the amount of activation of Rubisco.

The degree to which Rubisco is activated is a function of the degree to which CO₂ has carbamylated some or all of the eight RuBP–substrate binding sites on the protein. Although Rubisco requires CO₂ to activate the enzyme, changes in CO₂ between 100 and 1400 μL/L did not change the level of activation of Rubisco in light.^[13] The importance of activation of RuBP carboxylase in controlling CO₂ assimilation at high temperatures has recently been reported in studies with mature cotton plants.^[14]

CONCLUSION

Many different methods have been developed to measure the Calvin Cycle intermediates. However important these sugar phosphates are to the metabolic recycling of the substrate RuBP, they are also important to other processes in the plant and are to be found throughout the cytosol of the cell. Uniquely, RuBP is found only where Rubisco is located—mainly in the green chloroplast. Measurements of RuBP levels in leaf extracts under various environmental conditions can indicate whether the availability of RuBP—and thus the *rate* of synthesis of RuBP, which requires the reductive power of photosynthesis to make nicotinamide adenine dinucleotide phosphate (NADPH) and energy for adenosine 5c-triphosphate (ATP) synthesis—limits the *rate* of CO₂ fixation, or, whether it is the activation state of Rubisco which is dependent on Rubisco activase and the ATP/adenosine 5c-diphosphate (ADP) ratios. As the photosynthetically driven ATP/ADP ratios increase, Rubisco activase interacts with Rubisco, allowing more sites to be carbamylated and thereby activating CO₂ fixation. Either way, as astutely observed in a Gordon Conference on CO₂ assimilation 20 years ago, “no photosynthesis, no dark CO₂ fixation.”

Canola: Applications in High Performance Lubricants

Duane L. Johnson

Northwestern Agricultural Research Center, Montana State University,
Kalispell, Montana, U.S.A.

INTRODUCTION

Vegetable oils have been used since prehistory in the manufacture of cosmetics and as lamp oils and lubricants. It is as lubricants that vegetable oils became popular at the beginning of the 19th and 20th centuries. Vegetable and animal fats have been used for centuries as a means of reducing friction, whether greasing an axle with lard, lubricating a steam engine with rapeseed oil, or maintaining a modern internal combustion engine. Lubricants really became critical during the Industrial Revolution when heavy machinery became available. With the invention of the diesel engine, vegetable oils became not only lubricants, but also fuels. However, the most popular fuel for the emerging automotive industry in the early 20th century was gasoline. With crude petroleum, fuels and heavy oils were separated. The fraction used for motor oil was typically 4% of each barrel that was too light to make into an asphalt tar and too heavy to burn as fuel. This very low cost material became mineral oil. Automotive manufacturers quickly adopted mineral oils as the basis for lubricating internal combustion engines. Mineral oils per se, however, are not good lubricants and contain metallic salts derived primarily from zinc, lead, and molybdenum.

During the late 1980s and 1990s, in an effort to support agricultural development, the U.S. Department of Agriculture with the National Science Foundation initiated an aggressive program to develop bio-based products. By the early 1990s, petroleum companies began to look at vegetable oils as lubricant base oils and as additives for petroleum motor oils. At the same time, a vegetable-based motor oil concept, which would require no petroleum, emerged. The results of refining a canola-based motor oil have shown it to be equal or superior to synthetic oils in functionality, cost effectiveness, and environmentally nonhazardous.

THE HISTORY OF CANOLA

During the 19th century in the American and Canadian west, steam engines prowled the prairies

and mountains. These engines were typically lubricated with oil derived from European “rapeseed.” Rapeseed production became popular in the Canadian Prairie Provinces and its production would eventually move into the Pacific Northwestern United States. Rapeseed had been known in Europe and Asia as a source of oil used originally as a lamp oil because of its “smokeless” characteristic. As wheeled vehicles became available, rapeseed oil was found to provide critical lubrication as a soap to axles and vehicular joints. With the development of heavy industry in Europe, rapeseed was again reinvented to become a lubricant for machinery. One thing became obvious. Vegetable oils were excellent lubricants. By lubricating moving metal parts, lubricants prevent metal-to-metal contact. This reduces wear and heat among those parts.

It was in the New World, however, that rapeseed would see a significant change in application. During the Second World War, Canada found itself lacking adequate edible oils for its population. A radical research program was initiated to convert the industrial “rapeseed” oil to an edible oil. The result would be an oil low in glucosinalates and very low in erucic acid.^[2] Glucosinalates are toxic alkaloid materials. Erucic acids are long chain fatty acids of 22 carbons in length. They are unsaturated (having a double bond between two carbon atoms) at the 9th carbon and are therefore considered monounsaturated. However, erucic fatty acids are detrimental to human health. A genetic mutation was discovered by Canadian scientists blocking production of erucic acid and increased production of oleic fatty acids—the fatty acid most commonly associated with olive oil. Oleic fatty acids are also unsaturated at position 9 but only have 18 carbons in their chain.

DEVELOPMENT OF MOTOR OIL

Manufacturing motor oil from a vegetable oil requires considerable skill. Vegetables oils, which are composed primarily of saturated fats, such as coconut or palm oil, would be very chemically stable. Unfortunately, they also become solid rather than liquid at relatively high temperatures. This would prevent their use in

temperate climates for a large part of the year. Vegetable oils, which are highly polyunsaturated, such as soybean or sunflower oil, have a very low pour point (they become solid well below 0°C) but are oxidatively unstable. That is, under the heat and pressure in an engine, they begin to cross-link, forming a netlike structure similar to nylons. What was needed was a fatty acid that was relatively oxidatively stable and possessed a low pour point. Two fatty acids were candidates: oleic fatty acids and hydroxy fatty acids. Hydroxy fatty acids (containing a hydroxy group at position 12 in the fatty acid chain) provided better pour point depression but were chemically more reactive. The relative chemical stability of oleic acids provided a better starting point.^[3,5]

Developing motor oil from rapeseed oil or canola oil has taken several basic approaches:^[4]

1. The conversion of the native triacylglyceride (a compound molecule of one glycerin and three fatty acids found in the cells of seeds) to long chain esters. This occurs by cooking refined vegetable oils in the presence of alcohols and metallic catalysts until the glycerin is released and the "free fatty acid" is linked to an alcohol, forming a long chain ester. The esters then form a base oil to which the manufacturer can add ingredients, which add viscosity, lower the pour point (the temperature at which oil stops flowing), antioxidants to prevent cross-polymerization (cross-linking) of the esters and antiwear packages. Another approach is to chemically alter the fatty acid esters to produce branched chain fatty acids called estolides.
2. The second system involves using the basic triacylglyceride molecule native to the plant from which it is derived. In this system, the native oil can be refined by removal of all gums (resins and phospholipids) and can be bleached and deodorized, very much like edible vegetable oils. Typically a package of antioxidants, wear additives, and pour point depressants are added.
3. The third approach is to use a crude and unrefined vegetable oil. The reasoning here being that a crude base oil contains a specific amount of natural antioxidants and pour point depressants. Rather than remove these, manufacture can enhance them. The additives typically are bio-based to maintain the ability of the oil to be nontoxic and biodegradable. Typically, a package of antioxidants, wear additives, and pour point depressants are added.
4. The fourth approach is to use esters of the fatty acids to manufacture hydroxy fatty acids or branched chain fatty acids. The hydroxy fatty acids in turn can be manufactured into various

nylons. These nylons have been used as additives in the production of synthetic motor oils.

All of these options are being researched and developed.

DEVELOPMENT OF HYDRAULIC OILS AND TWO CYCLE OILS

Hydraulic oils must endure extreme temperatures and pressures while maintaining adequate lubricity to protect hydraulic pumps and provide sufficient viscosity to maintain itself in extreme conditions. Like motor oil, vegetable-based hydraulic oils have similar problems to those of motor oils: oxidative stability and pour point depression. Again the better compromise has been to use oleic fatty acids as the starting point for the construction of a viable lubricant oil.^[4,5]

Two cycle oils require the oil and gasoline to be mixed; so both are consumed during combustion. Two cycle oils developed from vegetable oils currently being developed have superior lubricity and require half the concentration of petroleum-based oil. The result is a cleaner burning engine and reduced emissions.^[5]

TESTING OF A MOTOR OIL

Motor oils undergo a rigorous test protocol overseen by the American Petroleum Institute (API). A series of tests must be conducted and approved by the API prior to acceptance by the manufacturers of internal combustion engines.^[2,5] In addition to the basic requirements of the API, each manufacturer may have additional tests prior to recommending the oil in their applications. At this time, no vegetable-based motor oil has been approved and certified by the American Petroleum Institute. However, stringent testing of vegetable motor oils has been performed using API certified protocols. In most cases, the vegetable motor oils have outperformed comparable conventional or synthetic motor oils in these tests.^[5]

EMISSION REDUCTIONS USING VEGETABLE MOTOR OIL

Emissions tests, using protocols recognized by the U.S. Environmental Protection Agency, have demonstrated that the use of some canola-based motor oils significantly reduces various air pollutants such as oxides of nitrogen (NO_x), carbon monoxide, hydrocarbons,

and nonmethane hydrocarbons (VOCs). The mechanism for this reduction is unclear at this time but is believed to be related to the reduced friction created using canola motor oil. This in turn reduces energy lost as heat and increases usable energy as base horsepower. The engine runs cooler and therefore generates lower NO_x, for example, in the combustion chamber. The engines also show an increase in fuel economy as energy is used as work as opposed to waste heat.^[5]

NONTOXICITY

The canola-based motor oils have been evaluated using the acute range finding and acute definitive *Oncorhynchus mykiss* test (EPA/600/4-90/027F), a standard test for toxicity to marine life, and were found to be toxic to fingerling rainbow trout at 7345 ppm as opposed to a refined petroleum oil being toxic to the trout at 0.025 ppm.^[1]

CONCLUSIONS

High performance can be obtained from vegetable oil-based lubricants. Tests using ASTM protocols illustrate that one half in engines using a canola-based motor oil can reduce friction. The reduction in friction means conversion of mass (gasoline) to energy produces less heat and more work. The result is better fuel economy and an increase in base engine horsepower. Canola-based engine oils do not require metallic salts as additives and therefore are nontoxic. They also have been found to significantly reduce air pollution from tailpipes of carbon monoxide, nitrous oxides, hydrocarbons, and nonmethane hydrocarbons (VOCs).

Carotenoids in Photosynthesis

Britta Förster

Barry J. Pogson

Australian National University, Canberra, Australian Capital Territory, Australia

INTRODUCTION

Carotenoids are plant pigments that are essential for the survival and productivity of all photosynthetic organisms. Their function in harvesting light energy complements the role of chlorophylls. The structure and assembly of the photosystems is dependent on the availability of specific carotenoids that assist in correct folding and maintain stability of photosystem proteins. In addition, carotenoids are essential for several of the photoprotective mechanisms employed by plants to effectively dissipate (as heat) excess photon energy absorbed by chlorophyll, thus preventing formation of highly reactive oxygen species. Carotenoids also deactivate singlet oxygen generated in the reaction centers and antennae.

BACKGROUND

Carotenoids are red, orange, and yellow pigments that are found in very diverse organisms, ranging from bacteria to plants and animals that either synthesize the pigments or acquire them through nutrition. There are two main classes—the nonpolar carotenes and the oxygenated xanthophylls. Xanthophylls received their name after the coloration of autumn leaves (xanthos = yellow and phyll = leaf) in 1837.^[1] Carotenoids have been intensively researched for over a century. This article focuses on the involvement and physiological relevance of carotenoids in photosystem II (PSII) of higher plants. In particular, roles of carotenoids in PSII assembly, energy transfer to and from chlorophylls, thermal dissipation of excess absorbed light, and minimization of singlet oxygen generation and its deactivation are discussed.^[2] Carotenoid chemistry and biosynthesis have been reviewed comprehensively elsewhere.^[3]

Light-harvesting and photoprotective mechanisms must be balanced to ensure optimal photoassimilate production for sustained plant growth while preventing lethal free radical damage to the plant. Photon capture and energy transfer from the antenna drive the electron transfer reactions of photosynthesis. Factors that disrupt the balance between these reactions lead to the production of reactive oxygen species, including singlet oxygen

($^1\text{O}_2^*$), superoxide anion radicals (O_2^-), hydroxyl radicals ($\cdot\text{OH}$), and hydrogen peroxide (H_2O_2), which potentially cause oxidative damage to lipids, proteins, and nucleic acids.^[4] Therefore, effective acclimatory mechanisms at whole plant, cellular, and molecular levels are essential to accommodate short- and long-term exposure to potentially photodamaging full sunlight and environmental stresses that can cause plant death or greatly reduced crop yields.

Consequently, complementary and redundant protective mechanisms have evolved that include 1) harmless thermal dissipation of excess energy involving xanthophylls; 2) quenching of triplet chlorophylls by carotenoids; 3) free radical detoxification via antioxidants (e.g., ascorbate, tocopherols, and carotenoids) and antioxidant enzymes such as catalase, superoxide dismutase, and ascorbate peroxidase; 4) down-regulation of light absorption via decreasing light-harvesting antenna size; and 5) repair of photodamage. Carotenoids are known to confer protection against photo-oxidative damage by stabilizing the pigment-protein complexes and membranes, quenching of excited-state chlorophylls and reactive oxygen species, and reduction of the reactive P680^+ in PSII.^[4] The PSII complex is central to understanding these processes, as it is the primary site of stress-induced photoinactivation under most natural conditions.

CAROTENOIDS IN PHOTOSYSTEM ASSEMBLY AND FUNCTION

Six primary photosynthetic pigments are found in the photosystems of higher plants: chlorophyll *a*, chlorophyll *b*, and four almost ubiquitous carotenoids—lutein, β -carotene, violaxanthin, and neoxanthin (Fig. 1). Zeaxanthin and antheraxanthin are two other xanthophylls common in chloroplasts, whereas only a few plant species accumulate additional carotenoids.

The ubiquitous nature of β -carotene in the reaction centers of oxygenic photosynthetic organisms suggests that it fulfills a fundamental, although not yet clearly defined, role. Carotenes are required for quenching chlorophyll triplet states in purple bacterial reaction centers, and their loss results in cell death. In higher plants, β -carotene is unable to effectively quench PSII core chlorophylls, but

Fig. 1 Pigments of higher plant chloroplasts. The chart represents the typical pigment composition in chloroplasts of *Arabidopsis* (μg pigment/g fresh weight) when plants are exposed to moderate light (Ref. 2). Chemical structures are shown next to each pigment. (View this art in color at www.dekker.com.)

it may afford photoprotection by quenching $^1\text{O}_2^*$ or by signalling damage of the D1 reaction center protein that triggers repair of photoinactivated PSII complexes.

The xanthophylls are located in the light-harvesting pigment complexes (LHCs) and the core antenna proteins (Fig. 2), where they act as accessory light-harvesting pigments by absorbing those wavelengths in the visible spectrum not absorbed by chlorophyll. The absorbed energy is then transferred to chlorophyll. The carotenoid-binding sites have been determined using a combination of structural studies, *in vitro* reconstitutions of recombinant proteins, and analyses of pigment-binding to native LHCs.^[5] Four distinct carotenoid-binding sites have been identified in LHCs (L1, L2, N1, V1), but only three of these are occupied in plants grown at moderate light intensities.^[5] In LHCIb (Fig. 2), the L1 and L2 sites are occupied by lutein, although either violaxanthin or zeaxanthin can be accommodated, whereas the N1 site is specific for neoxanthin. The V1 site is proposed to function in high light stress responses by loosely binding violaxanthin, which facilitates deepoxidation to the photoprotective zeaxanthin.^[5] In the minor LHCs (Fig. 2), the L1 site is occupied by lutein and L2 by either violaxanthin or neoxanthin. β -Carotene is typically excluded from LHCs, although it is found in Lhca1, the major LHC of PSI.

Despite the apparent plasticity of carotenoid-binding sites, there are limits to the flexibility of substitutions *in vitro* and *in vivo*, which seem to correlate with specific structural properties of the pigments. Lactucaxanthin, a xanthophyll with two hydroxylated ϵ -rings, cannot support LHC assembly *in vitro*. Mutations resulting in exclusive accumulation of zeaxanthin, a xanthophyll with planar β -rings, are associated with delayed greening in higher plants and decreased photoprotective energy dissipation in algae. These phenotypes probably reflect disrupted LHC assembly due to lack of the nonplanar ϵ -ring of lutein or the epoxidated β -ring of violaxanthin. LHCIb trimers are absent in lutein-deficient plant and algal mutants, suggesting that lutein is compulsory for LHC trimerization.

CAROTENOIDS IN PHOTOPROTECTION

The intensity of light in the middle of a sunny day may exceed a plant's capacity to use the harvested light for photochemistry, which can result in a decrease in the production of photoassimilate (sugars, etc.) by about 65%.^[6] Other environmental factors such as cold reduce this capacity further. The first and critical strategy employed by all plants is to safely utilize and dissipate

Fig. 2 Model of pigment localization and protein subunits in PSII. The major LHC antennae (LHCIIb or Lhcb1–3) and the minor LHC antennae (Lhcb4–6) and PSII core antenna (CP43, CP47) are shown surrounding the PSII reaction center core. PsbS is shown to be associated with the PSII, although its exact location is subject to debate. Bars indicate the distribution of each of the chlorophylls and carotenoids. Carotenoid-binding sites (Ref. 5) are described in the text. Sites of the various types of photoprotection are indicated by arrows; however, the location of some mechanisms (such as $^1\text{Chl}^*$ quenching) is not clear. (View this art in color at www.dekker.com.)

absorbed energy, thereby preventing the formation of free radicals and oxidizing species. Absorption of light energy results in the excitation of chlorophyll from the ground state to its singlet state ($^1\text{Chl}^*$) (Fig. 3). Under optimal conditions this energy is transferred to the PSII reaction center to catalyze the photochemical reactions. However, excess light absorption results in a greater proportion of chlorophyll molecules in excited electronic states, which can be deactivated by heat emission, return to ground state

by emitting fluorescence, or undergo intersystem crossing (i.e., reverse the spin direction of an excited electron) to form triplet state chlorophyll ($^3\text{Chl}^*$). The latter process is nearly an order of magnitude faster than fluorescence emission, and because $^3\text{Chl}^*$ can effectively interact with ground-state molecular oxygen ($^3\text{O}_2$) to generate highly reactive and potentially toxic $^1\text{O}_2^*$, the risk of oxidative damage to nearby organic compounds markedly increases under these conditions.

Carotenoids are able to quench both singlet and triplet excited states of chlorophyll (Fig. 3).^[7] Carotenoids participate in $^1\text{Chl}^*$ deactivation via nonphotochemical quenching (NPQ), a process that thermally dissipates the energy of $^1\text{Chl}^*$. The different components and relative contribution of NPQ to energy dissipation are determined from changes in chlorophyll fluorescence in response to saturating pulses of light.^[8] The predominant component of NPQ is fast; reversible; and requires acidification of the thylakoid lumen, synthesis of specific xanthophylls, and protonation of the PsbS (CP22) protein of PSII. The synthesis of the specific xanthophylls requires activation of the xanthophyll cycle to convert violaxanthin into zeaxanthin and antheraxanthin. The acidification of the thylakoid lumen activates the cycle and results in protonation of lumenally located residues of LHCs and PsbS. The excited-state energy levels of zeaxanthin, antheraxanthin, and lutein, and their proximity to chlorophylls would allow them to efficiently accept excitation energy from $^1\text{Chl}^*$ via Förster–Dexter electron-exchange mechanisms. These mechanistic implications are even more plausible, considering that those carotenoids are clearly necessary for induction and maintenance of NPQ both in vitro and in vivo.^[9] However, an appropriate protein environment, such as the aforementioned protonation, is also required for operation of NPQ in vivo.

The *npq1* mutant and transgenic plants deficient in the high light-induced accumulation of antheraxanthin and zeaxanthin are unable to induce more than 14–60% reversible NPQ, which is essentially eliminated when lutein is absent.^[9] In fact, irrespective of genetic backgrounds, altering lutein levels has an effect on NPQ consistent with lutein contributing to NPQ, particularly in the early phase.

The necessity for the PsbS protein in NPQ has been a key discovery.^[10] Mutations in PsbS that prevent its accumulation or protonation result in almost no NPQ despite accumulation of zeaxanthin.^[10] PsbS is capable of binding zeaxanthin in vitro, which correlates with a characteristic NPQ-induced change in absorbance at 535 nm (ΔA_{535}). Furthermore, the level of NPQ is directly proportional to the amount of PsbS, and PsbS increases up to tenfold in overwintering species subject to cold-induced light stress. This suggests that changes in PsbS levels may be employed for modulation of NPQ levels in

Fig. 3 Photoprotective roles of carotenoids and singlet chlorophyll quenching. Photon absorption raises ground-state chlorophyll (^0Chl) to the excited singlet state ($^1\text{Chl}^*$) energy level. Ideally, this energy is utilized to drive photochemical electron transfer of photosynthesis (Ref. 1). If photon absorption exceeds photosynthetic capacity, $^1\text{Chl}^*$ in the antennae and reaction center dissipates energy via fluorescence at a rate constant of $6 \times 10^7 \text{ s}^{-1}$ corresponding to a lifetime of about 15–20 ps (Ref. 2). Formation of triplet-state chlorophyll ($^3\text{Chl}^*$) competes with fluorescence at a rate constant of $2 \times 10^8 \text{ s}^{-1}$, resulting in a lifetime of about 5 ps. Carotenoids can directly quench $^3\text{Chl}^*$ (Ref. 3), thus preventing $^3\text{Chl}^*$ from reacting with ground-state oxygen ($^3\text{O}_2$) to form the phototoxic singlet oxygen ($^1\text{O}_2^*$). Alternatively, $^1\text{O}_2^*$ can be scavenged directly by carotenoids (Ref. 3). Furthermore, $^1\text{Chl}^*$ energy can be dissipated thermally by certain xanthophylls, which is apparent as nonphotochemical quenching of chlorophyll fluorescence (NPQ) and involves formation of zeaxanthin in the xanthophyll cycle (Ref. 4). (View this art in color at www.dekker.com.)

response to variations in environmental conditions during plant development and growth.

CONCLUSION

Although there is a tendency to focus on the relationship of carotenoids and NPQ in photoprotection (as both are readily measured), sufficient consideration must be given to the fact that carotenoids have a range of significant constitutive functions in preventing oxidative damage by quenching excited triplet states of chlorophyll and scavenging free radicals (Fig. 3). Although all carotenoids can quench chlorophyll triplets *in vitro*, lutein bound to L1 has also been identified as the main site of triplet quenching in reconstituted LHCs.^[7] Zeaxanthin-deficient mutants exhibit enhanced lipid peroxidation and leaf necrosis upon exposure to light or chilling stress (which appears to reflect a role for carotenoids in inhibiting lipid peroxidation, consistent with their localization in the chloroplast and thylakoid membranes), in addition to binding directly to LHC apoproteins.

What is the physiological importance of carotenoids? Plants with altered carotenoid compositions show a wide range of phenotypes from full viability and normal greening to high-susceptibility, bleaching, delayed greening, and semilethality. Even apparently healthy and viable mutants lacking zeaxanthin are reduced in seed production by 30–50% under field conditions,^[11] which constitutes a selective disadvantage. Clearly, optimal carotenoid composition is required to sustain plant fitness and survival.

Cellular Water Relations

George C. Papageorgiou

*Institute of Biology, National Center for Scientific Research Demokritos,
Athens, Greece*

INTRODUCTION

Life originated in the Archaean sea more than three billion years ago and evolved and diversified always in the presence of water. Water is the medium in which the majority of cell reactions take place, and in which nutrients and wastes are imported and exported, a participant in numerous metabolic and biosynthetic reactions, and most significantly, the source of the protons and electrons, which plants use along with light to assimilate carbon dioxide and release molecular oxygen. The oxygen of our atmosphere was produced by photosynthetic bacteria (*cyanobacteria*) during the Proterozoic and Paleozoic eras (approximately 2500–250 million years ago). Water, also, stabilizes native structures of proteins, nucleic acids, lipids, and membranes, it is a constituent of supramolecular complexes, and it is necessary for free energy storage as electrochemical potential across biological membranes and also for regulating solute concentrations in the cytoplasm. Lack or scarcity of water is a severe stress for organisms. However, there exist bacteria, plants, and even animals, which can withstand desiccation and resume metabolic activity upon rehydration.

This entry will examine the interactions of water with cytoplasmic constituents, the transport of water in and out of cells, and the perception and response of cells to water stress.

PHYSICAL PROPERTIES OF CELLULAR WATER

This biological multifunctionality of water is dictated by its physical properties. Its two covalent H–O bonds (length 0.0965 nm; energy 460 kJ/mol) are set at an angle of 104° 35' (in liquid water). This makes water an electric dipole (dipole moment 1.86 D in dioxane; higher in water itself). The dipoles associate by noncovalent H–O bonds (hydrogen bonds; average length 0.177 nm; energy 20 kJ/mol; lifetime ≤ 1 ns) and form transient three-dimensional networks of quasi-tetrahedral structures. Actually, two kinds of nanodomains (approximately eight molecules wide) exist in liquid water: low density water (approximately 0.91 g/ml, stronger H–bonds) and high density water (approximately 1.18 g/ml, weaker H–bonds). Water exchanges rapidly between them and equilibrium depend on the presence of solutes,

macromolecules, and membranes, as well as on temperature and pressure.^[1]

In addition to these atomic scale properties, two bulk properties of liquid water are noteworthy: its large specific heat capacity (4.19 J/g/°C at 25°C) and its large dielectric constant ($D = 87.74$ at 0°C). The first makes it an efficient heat sink, and the second an excellent solvent for electrolytes by suppressing coulombic attractions. Dissociated ions are further stabilized by hydration. Hydronium ($\text{H}_2\text{O} + \text{H}^+ \rightleftharpoons \text{H}_3\text{O}^+$) is the simplest hydrated ion.

Water dissolves nonionic polar molecules (e.g., sugars, proteins, and nucleic acids) by establishing H–bonds to hydroxyl (–OH), carbonyl (>C=O), and various amino groups (–NH₂, >NH, and =N–); it dissolves amphiphilic (part hydrophilic, part hydrophobic) molecules, such as fatty acids and some proteins, by forming hydrogen bonds in the hydrophilic moieties and by forcing hydrophobic moieties to cluster away from the water phase. Water also favors the self-assembly of membrane glycerolipids (amphiphilic molecules) into bilayers by orienting the hydrophilic headgroups to the outside and the hydrophobic acyls to the inside.

The properties of water are greatly modified in the cytoplasm. Diffusible solutes shift its vapor pressure, boiling point, freezing point, and osmotic pressure. These so-called colligative properties depend on total solute concentration and not on individual chemical identities.

Solutes, which modify the three-dimensional structure of water and its solvent properties, are known as cosolvents. Cosolvents that can exist in the cytoplasm at elevated concentrations (typically, several hundred millimolar) without interfering with cell functions are termed as compatible osmolytes. Kosmotropic cosolvents enhance the network structure of water and the chaotropic cosolvents randomize it. Hydrophobic surface patches of proteins and membranes, and hydrophobic ends of amphiphilic molecules behave as kosmotropes; their hydrophilic counterparts as chaotropes. Inorganic ions can also be kosmotropic or chaotropic. For example, in the well-known Hofmeister series

anions are ranked left-to-right by decreasing kosmotropic effectiveness and right-to-left by decreasing chaotropic effectiveness.^[2]

Cosolvent molecules may preferentially bind to or may be excluded from protein surfaces. Preferential cosolvent binding drives some water away from the protein; preferential cosolvent exclusion enables its preferential hydration. Surface hydration favors native (biologically active) conformations of proteins and enzymes.^[3]

Macromolecules exist at low concentrations in the cytoplasm. Collectively, however, they occupy a sizeable fraction of the available space (typically 50–400 mg/ml). This situation, known as macromolecular crowding or volume exclusion, is the source of various nonspecific effects (e.g., steric hindrance and surface electrostatic effects) on the kinetics and the thermodynamic equilibria of chemical reactions in cells.^[4]

Water Transport across Cell Membranes

Water translocates spontaneously through a semi-permeable membrane to equalize the osmotic pressures (Π) on its two sides. In ideal solutions, Π is a linear function of solute concentrations (van't Hoff's law):

$$\Pi = RT \sum_j C_j = RT \sum_j \text{Osm}_j \quad (1)$$

Here, R is the universal gas constant, T the absolute temperature, C_j the molarity of solute j , and Osm_j its osmolarity or osmolality. The summation encompasses all osmotically active molecules and ions present. In nonideal solutions (e.g., in the cytoplasm) Π is a complex function of solute concentrations and can be estimated only experimentally from the freezing point or the vapor pressure depressions that osmoactive solutes cause.

Cell walls (of archaeal, bacterial, fungal, and plant cells) support cell membranes mechanically. In these cells, the cytoplasm is hyperosmotic relative to the ambience. The osmotic pressure difference (turgor; $\Delta\Pi$) relating to internal and external solute molarities (C_i , C_e), or osmolarities and osmolalities (Osm_i , Osm_e) is as follows:

$$\begin{aligned} \Delta\Pi &= (\Pi_i - \Pi_e) = RT(C_i - C_e) \\ &= RT(\text{Osm}_i - \text{Osm}_e) \end{aligned} \quad (2)$$

Water moves through biological membranes basically along two paths: i) Through water-selective protein channels (aquaporins) that allow bidirectional movement of water molecules but exclude ions.^[5] Water movement is passive, nearly unimpeded (activation energy ΔH_{act} approximately 17–25 kJ/mol) and quite

fast (membrane permeability $> 100 \times 10^{-6}$ m/sec). ii) Through the lipid layers of the cell membrane by diffusion. Here, water movement is also bidirectional and passive, but slower (approximately 10×10^{-6} m/sec) and not unimpeded because an activation energy barrier of ΔH_{act} approximately 63 kJ/mol has to be overcome. A minor fraction of water is translocated through solute-specific transporters and channels of the cell membrane.

Cell Volume, Osmolality, and Turgor Pressure Measurements

Cell volumes and cytoplasmic osmolarities are not easy to measure, especially in small bacterial cells. Various microscopic, centrifugal, turbidometric, and molecular probe methods have been applied to these tasks.

Cell volumes can be estimated from light or electron micrographs. Statistical confidence requires a large number of images to be averaged. Centrifugal methods measure packed cell volumes. An average cell volume can be estimated using accurate cell counts and after correcting for extracellular spaces (cell walls, outer membranes, and peptidoglycan) and for nonosmotic intracellular spaces (solid inclusions). Turbidometry correlates osmotically induced cell volume changes to light scattering changes by cell suspensions. Here, the effects of added osmosis on the refractive indices of suspension media need to be corrected. Molecular probes are molecules labeled with radioactive isotopes, uncoupled spins, or fluorophores. Extracellular volumes are estimated using impermeable probes (e.g., C^{14} -inulin) and total volumes with permeable probes (e.g., H^3 -water); internal volumes are estimated from the difference.

A recent method employs osmotically induced changes in phycobilisome-excited chlorophyll a fluorescence (ΔF) for estimating osmotically induced cell volume changes (ΔV) and cytoplasmic osmolalities in cyanobacteria. It is based on the relation

$$\Delta F \propto \Delta V \propto 1/\text{Osm}_e \quad (3)$$

which was verified by measuring cell volume changes with three independent methods (packed cell volumes, turbidometry, and molecular spin probes).^[6,7] An example is shown in Fig. 1.

Osmotic Stress: Perception and Defense

How do plant cells sense osmotic stresses and how do they respond to it? Most of what we know comes from studies with *Escherichia coli*^[8] and *Synechocystis*,^[9] both unicellular prokaryotes, and *Saccharomyces cerevisiae*, a unicellular eukaryote.^[10] However, similar

Fig. 1 External osmolality effects on the volume of cyanobacterium *Synechococcus* cells. Osmotically induced chlorophyll a fluorescence changes (ΔF) were used to estimate relative cell volume changes (ΔV) because it has been established experimentally that both ΔV and ΔF are linearly related to $1/Osm_e$ [Eq. (3)]. Sorbitol (impermeable solute) was used for adjusting Osm_e . In the unshaded areas of the figure $Osm_i > Osm_e$ (i.e., presence of turgor), in the shaded areas $Osm_i = Osm_e$ (i.e., no turgor). Turgor threshold (cytoplasmic osmolality), given by the intersection of the regression lines, was higher in cells cultured in hyperosmotic medium (BG11 + 0.2 M NaCl; panel B) than in cells cultured in normal hypo-osmotic medium (BG11; panel A). The higher cytoplasmic osmolality of the former cells reflects the accumulation of sucrose (the compatible osmolyte of *Synechococcus*) (From Ref.^[7].)

sensing and response devices exist in plants and animals, as well as in other bacteria.

Plant cells sense osmolarity upshifts and downshifts by the mechanical force generated at the lipid-protein interfaces of cell membranes. Transporter proteins (with characteristic protein kinase activities) sense osmolarity upshifts. Mechanosensitive channel proteins sense osmolarity downshifts. Transporters import specific, compatible osmolytes into cells, to maintain $\Delta Osm > 0$ and to prevent water outflow. Osmolyte translocation occurs against concentration gradients and is powered by ATP hydrolysis, or by the dissipation of pre-existent transmembrane H^+ or Na^+ concentration gradients. Mechanosensitive channels open to allow passive exportation of size-selected cosolutes. This depresses ΔOsm and prevents cell swelling.

To more persistent hyperosmotic stresses (and to other stresses that cause cytoplasmic water deficit such as drought, hypersalinity, and low temperature), cells respond by upregulating and downregulating large

numbers of genes. This involves communication of the stress signal from protein sensors of the cell membrane to genomic DNA via interaction with histidine kinase networks. Long-term defenses against hyperosmolarity involve de novo syntheses of species-specific compatible organic osmolytes, as well as the transcriptional and posttranscriptional regulation of aquaporin genes.

CONCLUSIONS

Cellular water is important for tuning the physical properties of cytoplasm, as a structural constituent in supramolecular assemblies of biomolecules, and as a reactant in numerous metabolic and biosynthetic reactions of plant cells, including photosynthesis. To maintain homeostasis, cells developed elaborate mechanisms for sensing deviations in water content and for correcting them by regulating the importation and exportation of water.

Cereal Sprouting

C. W. Wrigley

Food Science and Wheat Australia CRC, North Ryde, Sydney, Australia

INTRODUCTION

Rain at harvest time causes several problems for the cereal grain farmer. In addition to difficulty in drying the grain for storage, rain brings the possibility that the grain may start to germinate. This event is likely to make the harvested grain unsuitable for most types of utilization, thereby drastically reducing its market value.

Severe sprouting is visually evident by the presence of roots and shoots emerging from the germ of the cereal grain, but significant damage may be done before there are visual signs of damage, by the development of hydrolytic enzymes, especially alpha-amylase. Testing for the production of these enzymes is thus an important part of evaluating grain quality at harvest. If such damage is detected, the rain-damaged grain must be segregated, so as to maintain the quality of the sound grain with which it might otherwise be mixed.

There are further possibilities for overcoming the problems caused by sprouting. These include the breeding of varieties that have built-in dormancy to provide tolerance to these effects of wet harvest conditions. In addition, there are possibilities of predicting situations where there are increased risks of sprout damage, based on combinations of variety and climate (mainly moisture and temperature).

SEED MORPHOLOGY AND PHYSIOLOGY

Seed or Grain?

A seed is a plant's way of forming another plant. For this purpose, the seed is provided with the following essential anatomical parts (Fig. 1):

- An embryo (germ) from which the new plant will form.
- A store of nutrients (starch and protein in the endosperm of the cereal grain) to nurture the emerging plant until its own photosynthesis can take over.
- An outer layer (the bran of the cereal grain) to protect the seed against damage.

The great advantage of the seed as a means of perpetuating the species is that it can remain dormant (resting unchanged) for long periods of time. In this way, the seed awaits the "rainy day" (a suitable combination of moisture and temperature) when the conditions are conducive for it to commence the germination process that will start it on its way to producing another plant. This process starts with the swelling of the germ as it takes up moisture, followed by the splitting of the germ covering to allow the roots and shoots to emerge and elongate, seeking soil and light, respectively. Long ago, mankind found the cereal seed to be an important answer to his need for nutrition, based on the two important attributes, namely, nutrients suited to the diet of humans (and of animals) and storage for long periods of time without loss of nutritional value. The consequent rise in the growing of grain crops changed early man from a hunter-gatherer to an agriculturalist, with the advantages of fixed residence and spare time to develop cultural pursuits. Consequently, we regard the "seed," with its prime function to perpetuate the plant, as a "grain," whose function is the provision of food for man and beast.

The Germination Process

Germination is essential for the role as "seed," but it may not suit the "grain" role. This is because important biochemical changes have commenced in the germinating seed, even before the anatomical changes become evident.^[1] These biochemical changes include the production of hydrolytic enzymes, the agents that have the physiological function of breaking down the stored nutrients to simpler compounds that can be used to produce new tissues for plant growth, in particular the emerging roots and shoots.

The most significant of these enzymes is alpha-amylase, the primary enzyme involved in reducing starch (a polymer of the monosaccharide glucose) to the component simple sugars for transport to the growing embryo. Figure 2 shows how amylase attack has "eaten away" at a starch granule during germination. Protease action is also needed during germination to break down the stored proteins of the endosperm, providing amino acids for protein synthesis in the embryo.

Fig. 1 The anatomy of a wheat grain, as shown in the scanning electron microscope, dorsal and ventral (crease) views. The germ (embryo) is seen as a bulge at the lower right of the dorsal view (at left). (View this art in color at www.dekker.com.)

Dormancy

Ideally, there is a significant lag period (dormancy) before germination commences in the newly harvested grain. However, it is not unusual for the dormancy period to be short or absent, with the consequence that germination may commence even before the grain is harvested if it gets wet. This is illustrated in Fig. 3; the grains in the wheat head on the left have sprouted, whereas the variety at right has shown adequate dormancy. Barley grains are shown in Fig. 4 in varying degrees of sprout damage.^[2]

Fig. 2 Scanning electron micrograph of a wheat starch granule that has been attacked by amylase during germination. Small starch granules can also be seen. Amylase action has accentuated the layers of deposition in the eroded starch granule. The eroded starch granule is about 20 micrometers across the wide dimension.

PROCESSING PROBLEMS OF SPROUTING

Sprouting is a major problem for wheat. Even if there are no visible signs of roots and shoots, the production of alpha-amylase due to incipient sprouting causes processing problems for food products such as bread (sticky crumb and difficulty in slicing), noodles (poor color and disintegration of structure), and Chinese steamed breads (poor crumb structure). Rye grain is especially susceptible to sprout damage, causing difficulty in the production of rye breads.

For barley, germinated grain is unsuitable for malting and brewing, the premium use of barley. Uniform germination of all barley grains is needed for the malting process to be successful. A germination percentage of over 95% is generally required for sound malting barley, but this quality requirement may not be met for germinated barley. Even if rain damage has been only minor, the affected barley is likely to have a shortened storage life due to a premature drop in germination percentage. This is illustrated in Fig. 5, which shows that the germination rate falls during storage, depending on the moisture and temperature conditions. Incipient sprouting

Fig. 3 Grains in the wheat head at left have germinated, seen by the protrusion of roots and shoots, following the head being exposed to rain. In contrast, grains in the head on the right have shown adequate dormancy to tolerate the effects of the rain. (View this art in color at www.dekker.com.)

Fig. 4 Barley grains showing various degrees of visible sprouting, seen as roots and shoots emerging from the germ end of the grains. (Adapted from Fitzsimmons and Wrigley, Ref. 2.) (View this art in color at www.dekker.com.)

Fig. 5 The rate of germination decreases during the storage of malting quality for barley.^[8] The rate of this loss is greater for barley that has undergone incipient sprouting at harvest.

accelerates the rate of this loss of germination, with consequent loss of value because the grain must be used for animal feed instead of for malting.

Premature sprouting also occurs in other cereals, including maize, oats, and rice, although the economic consequences are not so serious as they are for the processing of wheat, rye, and barley. Nevertheless, seed viability during storage is reduced for germinated grain.

TESTING FOR SPROUT DAMAGE

Traditionally, sprout damage has been detected by visual inspection, by the appearance of a swollen or split covering on the germ or in the extreme by the appearance of roots and shoots. Inspection standards have specified minimum proportions of such grains for a grain load to qualify for specific grades. However, this basis of sprout evaluation ignores the basic nature of the problem, namely, the enzymes of germination.

Accordingly, various tests have been developed to determine the activity of alpha-amylase, either on the starch of the sample or on an added substrate. Tests of the former category involve milling a representative sample

Fig. 6 Falling Number equipment. A suspension of milled grain is mixed with water in a long glass tube immersed in boiling water, using the vertical movement of a plunger. After 60 seconds of mixing, the plunger is raised and allowed to fall under its own weight. Falling time is long for a sound sample but is short if the amylase of sprouted grain has hydrolyzed the starch of the suspended grain particles. (View this art in color at www.dekker.com.)

of grain and heating it to accelerate the action of the amylase, followed by some form of measurement of the viscosity of the heated suspension. In the Falling Number test,^[3] remaining starch viscosity is determined by timing the fall of a plunger through the suspension of milled grain (Fig. 6). Changes in viscosity are measured by the power required to stir the suspension in the Stirring Number test, which uses the Rapid Visco Analyzer^[4] (Fig. 7).

In other test systems, the amylase enzyme is extracted from the milled grain for direct analysis^[5] or by immunoassay.^[6] This latter method, based on the reaction of antibodies specific to the alpha-amylase of cereal grains (Fig. 8), is rapid (about five minutes) and can be used in the field (literally) without the need for additional equipment.

REMEDIES FOR SPROUT DAMAGE

Breeding for Increased Dormancy

Genetic sources of tolerance to sprout damage are available, as is indicated by the fact that the degree of dormancy varies among genotypes of the various cereals. It has therefore been a priority of plant breeders to incorporate genes for dormancy in varieties by cross-breeding, especially in regions where sprout damage is a frequent occurrence. In red-grained wheats, which have a reputation for greater dormancy than white-grained varieties, dormancy is associated with genes for red coloration

Fig. 7 The Rapid Visco Analyzer, used to determine Stirring Number values. A suspension of milled grain is placed in a disposable cup, clamped in a heating block. The apparent viscosity of the suspension is measured continuously during stirring. A low viscosity after three minutes indicates that the sample is sprouted. (View this art in color at www.dekker.com.)

Fig. 8 The WheatRite test cassette for immunoassay of amylase in sprouted grain. An extract of crushed grain is spotted onto the card, which is then closed to permit immunochromatography to take place. The degree of sprout damage is indicated by the intensity of a colored band appearing in the window of the closed card. (View this art in color at www.dekker.com.)

of the bran layers, located on the Group 3 chromosomes, together with at least one other gene.^[7,8] Genetic research is thus discovering the genetic basis of dormancy in wheat and barley, thereby assisting breeders to select for tolerance to sprout damage more efficiently.

Prediction of Problems Due to Sprouting

A knowledge of local weather conditions just before grain delivery is an obvious means for the staff of a mill or grain elevator to be forewarned that grain delivered from some local areas may be sprout damaged. Longer-term prediction involves risk assessment based on predicted climate patterns obtained from historical climate data. In both of these cases, predictions should also take into account the sprouting susceptibility of the varieties involved.

A further aspect of the value of prediction relates to the storage of malting barley. If the rate of fall of viability can be predicted for various consignments, then the grain with

the shortest “safe” storage life can be used before the grain that is sound, with consequent longer storage life. This form of prediction involves assessing the degree of sprout damage and using this measure in a mathematical model that reflects the rate of loss of germination rate, depending on the conditions of storage, especially temperature and moisture.^[9] Another factor that may be relevant is the variety involved, because barleys may differ in the rate of loss of viability.

CONCLUSION

Sprouting damage has long been a problem, especially in climates where wet harvest conditions are common. For this reason, considerable research effort has been expended on breeding genotypes that have longer dormancy and thus better tolerance to sprout damage. These efforts have already provided valuable results for many varieties, but the breeder must balance this genetic trait against many other breeding objectives. As more efficient procedures become available to select for sprout tolerance, tolerant varieties will become more common. Possibilities for such breeding methods are likely to come from the identification of molecular markers and their use in screening for such benefits.^[10] In the meantime, the problem of sprouted grain will become less severe with the implementation of better methods of testing and prediction.

Chemical Weed Control

Don W. Morishita

University of Idaho, Twin Falls, Idaho, U.S.A.

INTRODUCTION

Herbicides are chemicals used for the control of weeds or other unwanted vegetation. Most herbicides in use today are synthetically derived organic compounds. A few herbicides are derived from naturally occurring chemicals found in plants. The Weed Science Society of America recognizes 315 herbicides that have been developed over the years. Herbicides are just one of many types of pesticides and represent about 60% of the pesticides used in the United States. Other pesticides include insecticides, fungicides, bactericides, nematocides, rodenticides, as well as others. The greatest use of chemical weed control is in crop production. In addition, herbicides are used to control weeds growing in turf grass, as in golf courses and parks, ornamental flowerbeds, pastures, rangeland, forests, aquatic areas, and industrial sites. The types of herbicide used in these different areas vary widely, as do the methods of their use.

Herbicides affect plant growth in many ways. Some herbicides are applied only to plant foliage, some only to soil, and some are applied only to water for controlling unwanted aquatic vegetation. Herbicides also can vary in how long they persist in the environment. Herbicides that persist in the soil for long periods are used only in areas where long-term weed control is desired. Herbicides that break down rapidly typically are used in situations where residual activity of the herbicide is undesirable (e.g., a persistent herbicide used to control crop weeds may be undesirable if it takes so long to break down that it could injure the crop subsequently grown in the same field).

There are several advantages and disadvantages to the use of herbicides. From an agricultural food production standpoint, herbicides provide more economical weed control, reduce human labor requirements, allow for increased farming acreage per person, can reduce the number of tillage operations and soil erosion, and permit weed control where cultivation is impossible. They can also be beneficial for increasing aesthetic and land value through removal of unwanted vegetation. Herbicides, like other pesticides, are often criticized for their impact on the environment and potential injury to humans and other animals. When misused, herbicides can contaminate the

environment, injure non-target vegetation, and persist for periods longer than desired. When use properly and judiciously, herbicides provide many environmental and economical benefits.

This article discusses the history and use of herbicides, and briefly explains how herbicides affect plant growth and behave in the environment, and how governmental regulation of herbicides ensures their safety.

HISTORY OF HERBICIDES

The use of chemicals for the control of vegetation dates back hundreds of years. Sodium chloride (table salt) is probably the oldest known chemical used as a herbicide.^[1] Historical reports of Romans using salt in 146 B.C. to sack Carthage indicate the earliest use of a chemical to kill plants. In this case, the Romans used salt to prevent crop growth. From 1937 to 1950, salt was used for controlling weeds on Kansas highway rights-of-way at rates of up to 20 tons per acre.^[2] Other inorganic chemicals were used as herbicides. One was calcium carbonate (lime), recommended for controlling horsetail (*Equisetum* sp.) in Germany as early as 1840. Other inorganic chemicals used as herbicides prior to 1940 included arsenical compounds such as sodium arsenite, sodium chlorate, and sodium borate. From 1927 to 1935, 4 million pounds of sodium chlorate were used in the state of Idaho alone for controlling perennial weeds such as field bindweed (*Convolvulus arvensis*) and Canada thistle (*Cirsium arvense*).^[2] Other chemicals used as herbicides prior to the 1940s included sulfuric acid, copper sulfate, carbon bisulfide, salt of dinitrophenol, iron sulfate, ammonium sulfate, and kerosene.

Sinox, a precursor to dinoseb, was the first synthetically produced organic herbicide. A major breakthrough was the production of 2,4-D, discovered in 1941 and originally tested as a fungicide and insecticide.^[1] Soon after, it was discovered that 2,4-D could selectively kill broadleaf or dicotyledonous plants without hurting grass or monocotyledonous plants. The discovery of 2,4-D is considered by many to be the beginning of modern herbicides. One of the most widely used herbicides in the world today continues to be 2,4-D.^[3]

CLASSIFICATION OF HERBICIDES

The ways herbicides are used and how they kill weeds vary greatly. Consequently, herbicides are classified many different ways.^[1,4-7] The two most common classifications are based on the herbicide's chemical structure and its mode of action. Herbicides with similar chemical structures are grouped into a common chemical family. The structure of a herbicide influences how it will act in plants and in the environment. For example, metsulfuron and tribenuron are two sulfonylurea herbicides used for broadleaf weed control in cereal crops^[8] (Fig. 1). However, slight differences in their chemical structure alter not only which weed species they control, but also how long they persist and how much they may leach or move in the soil. A sensitive broadleaf crop such as canola can be planted 60 days after tribenuron application. If metsulfuron is used, canola cannot be planted for as long as 22 months after application. Metsulfuron also has a higher potential for moving in the soil compared to tribenuron^[9] (Table 1).

Herbicides classified in the same chemical family typically have the same mode of action. The mode of action is defined as the sequence of events beginning with introduction of the herbicide into the environment through the death of the plant.^[1] Weed scientists also refer to a mechanism of action, relating to the primary biochemical

Fig. 1 Structural similarity between metsulfuron (top) and tribenuron (bottom). Although these two herbicides have only slight differences in chemical structure, metsulfuron persists in the soil about three times longer and controls many weeds that tribenuron does not. Tribenuron is used extensively in cereal grain production, whereas metsulfuron is used in cereal grain production, rangeland, and noncrop areas. (View this art in color at www.dekker.com.)

or biophysical process leading to plant death.^[1] The location in the plant where herbicides exert their toxicity at the cellular level is called the site of action.

Herbicides can also be classified based on whether they selectively kill weeds and whether they translocate in the plant. Some herbicides (like 2,4-D) are classified as selective because they control weeds in cereal crops without injuring the crop. Nonselective herbicides such as glyphosate will injure or kill nearly all plants regardless of species. Herbicide selectivity may also be dependent on factors such as plant health, environmental conditions, and application rate, timing, and method.

Herbicides such as 2,4-D and glyphosate are also classified as systemic herbicides because they are taken up by the plant after they are applied, and move or translocate to a site of action in the plant that causes injury or death to the plant. Nonsystemic herbicides are called contact herbicides. Bromoxynil and paraquat are two examples of contact herbicides. A contact herbicide, once taken up by the plant, is not translocated in order to injure or kill the plant.

HOW HERBICIDES KILL WEEDS

Some herbicides are applied to the foliage to kill weeds, whereas other herbicides control weeds only when they are applied to the soil. Other herbicides control weeds when they are applied to the foliage and/or the soil. Glyphosate and 2,4-D are both foliar-applied herbicides and have little or no effect on plants when applied to the soil. Metolachlor and trifluralin are two examples of soil-applied herbicides, both of which have little or no effect on plants when applied to the foliage. Soil-applied herbicides kill weeds as they germinate and begin to grow in the soil. Picloram and atrazine are two examples of herbicides that have both foliar and soil activity.

As previously mentioned, herbicides kill plants in many different ways. The mode of action of herbicides is sometimes broadly categorized into the following: plant growth regulators, seedling growth inhibitors, photosynthetic inhibitors, amino acid synthesis inhibitors, lipid synthesis inhibitors, and cell membrane disruptors. Some examples of herbicides and their modes of action are listed in Table 1. Once a herbicide is applied to plant foliage or to the soil, it must be absorbed, or taken up, by the plant. If it is a systemic herbicide, it must be translocated to a site of action. If it is a contact herbicide, the site of action will be very close to where the herbicide was absorbed. A plant that is tolerant of the herbicide is usually able to break down or metabolize it into a nontoxic form. Sometimes, repeated use of herbicides with the same mode of action can lead to the development of herbicide-resistant weeds. These weeds are able to tolerate more than normal amounts of herbicide.

Table 1 Common herbicides' mode of action, persistence,^a and relative mobility^b in soil

Herbicide	Product name(s)	Mode of action	Persistence	Mobility in soil
2,4-D	Many names	Plant growth regulator (synthetic auxin)	Short	Moderate
Atrazine	Aatrex, other names	Photosynthesis inhibitor (PS II inhibition)	Moderate	High
Glyphosate	Roundup, other names	Amino acid synthesis inhibitor (EPSP synthase inhibition)	Moderate	Extremely low
Metsulfuron	Ally, Escort	Amino acid synthesis inhibitor (ALS inhibitor)	Moderate	High
Metolachlor	Dual II, other names	Seedling growth inhibitor (lipid synthesis inhibitor)	Moderate	High
Paraquat	Gramoxone, other names	Photosynthesis inhibitor/cell (membrane disruptor)	Persistent	Very low
Picloram	Tordon	Plant growth regulator (synthetic auxin)	Moderate	Very high
Tribenuron	Express	Amino acid synthesis inhibitor (ALS inhibitor)	Short	Moderate
Trifluralin	Treflan, other names	Seedling growth inhibitor (microtubule assembly inhibition)	Moderate	Very low

^aPersistence is categorized based on a pesticide's half-life (i.e., the time required for a pesticide to degrade to half its original concentration). Pesticides categorized as Short have less than a 30-day half-life; Moderate indicates a 30- to 100-day half-life; Persistent indicates more than a 100-day half-life.

^bPesticide mobility ratings are based on an empirically derived Groundwater Ubiquity Score (GUS). Pesticides with a GUS less than 0.1 are considered to have an extremely low potential to move toward groundwater. Values of 1.0–2.0 are low; 2.0–3.0 are moderate; 3.0–4.0 are high; and values greater than 4.0 have very high potential to move toward groundwater.

HERBICIDE REGULATION

In order for a herbicide or any other pesticide to become available for use in the United States, it must be registered by the Environmental Protection Agency (EPA), which follows criteria established by the Food Quality Protection Act. The EPA requires a set of rigorous tests to ensure that a pesticide will be safe to use and not harm people, animals, or the environment. Manufacturers must prove that a herbicide can be used to perform its intended function without reasonable adverse effects on the environment.^[1]

CONCLUSION

Herbicides have been and continue to be an important tool for successful integrated weed management. However, it must be remembered that herbicides are not the only method of controlling weeds. The most successful weed management programs utilize integrated weed management practices—preventive, cultural, mechanical, biological, and chemical control. The use of herbicides for controlling weeds has reduced dependency on hand labor, and allowed land managers to utilize more land. Herbicides will continue to be an important tool for controlling weeds. However, overreliance on chemicals for weed control increases the risk of environmental contamination, selection for herbicide-resistant weeds, and likelihood of failure.

Chlorophylls

Robert D. Willows

Macquarie University, Sydney, Australia

INTRODUCTION

Chlorophylls are the pigments that make plants green. Chlorophylls are arguably the most important compounds on earth, because they are required for the harvesting and transduction of light energy in photosynthesis. The structures and spectra of chlorophylls, the details of how chlorophylls are synthesized, the challenges faced by plants in synthesizing chlorophylls, and the degradation of chlorophylls will be discussed.

STRUCTURE OF CHLOROPHYLLS FOUND IN PLANTS

The chlorophylls belong to a class of compounds known as tetrapyrroles, which include other pigment molecules such as heme and vitamin B₁₂. Chlorophylls are distinguished from other tetrapyrroles by the presence of a centrally coordinated magnesium and a fifth isocyclic ring. Chlorophyll *a* and chlorophyll *b* (Fig. 1.) are the major types of chlorophylls found in plants; they have a characteristic green color due to strong absorbance of blue and red light. Chlorophylls also show a characteristic red fluorescence when light is absorbed. The spectral properties are essential for the function of chlorophyll in harvesting light energy and in the transduction of that light energy for photosynthesis.

The ratio of chlorophyll *a* to *b* varies from 2.0–2.8 for shade-adapted plants to 3.5–4.9 for plants adapted to full-sun conditions. The variation in chlorophyll *a/b* ratio is due to differences in the ratio of photosystem I (PSI) and photosystem II (PSII) and the size and composition of the light harvesting complexes (LHCs) associated with each photosystem. The photosystems contain chlorophyll *a* but not chlorophyll *b*. In contrast the LHCs contain significant amounts of chlorophyll *b*. Shade-adapted plants have more LHCs and thus have lower chlorophyll *a/b* ratios than sun-adapted plants.^[1,2]

A number of spectral variants of chlorophyll *a* are detected in vivo. These spectral differences result from chlorophyll molecules in different environments within LHCs and photosystems. Other minor chlorophyll derivatives have also been reported, with the most important

ones being chlorophyll *a'*, found in the PSI reaction center, and pheophytin, which is found in the PSII reaction center. Other organisms such as algae, cyanobacteria, and photosynthetic bacteria have other types of chlorophylls or bacteriochlorophylls within their LHCs and photosystems.^[3]

BIOSYNTHESIS OF CHLOROPHYLLS

Chlorophyll is synthesized within the chloroplast of plants and algae, and most of the chlorophyll biosynthetic enzymes are encoded by the nuclear genome. Despite the complete sequencing of a number of plant, algal, and photosynthetic bacterial genomes, not all of the genes involved in chlorophyll biosynthesis have been positively identified. Thus, although many of the details of chlorophyll biosynthesis have been elucidated, many gaps in our knowledge remain. Figs. 2–4 show an overview of the chlorophyll biosynthetic pathway. The interesting and novel reactions in each section of the pathway are discussed below.

The tetrapyrrole ring system is synthesized from eight molecules of 5-aminolevulinic acid (ALA). ALA is the universal precursor of all tetrapyrroles and there are two known pathways for the synthesis of ALA, as shown in Fig. 2. The most common pathway for ALA biosynthesis in nature is the C-5 pathway found in plants, archaea, and most bacteria. Glutamyl-tRNA and glutamate-1-semialdehyde are the two intermediates in this pathway. The glutamyl-tRNA is also used for protein biosynthesis. The Shemin pathway, which biosynthesizes ALA from glycine and succinate, was discovered first but is only found in α -proteobacteria and most non-photosynthetic eukaryotes.

Both heme and chlorophyll have a common biosynthetic route from ALA to protoporphyrin IX, as shown in Fig. 3. ALA dehydratase, also known as porphobilinogen synthase, catalyzes the condensation of two molecules of aminolevulinic acid to form the monopyrrole porphobilinogen. Four porphobilinogens are then condensed to form a linear tetrapyrrole called hydroxymethylbilane, a reaction catalyzed by hydroxymethylbilane synthase, which is also known as porphobilinogen deaminase.

Fig. 1 Absorbance spectra and structures of chlorophyll *a* (solid line) and chlorophyll *b* (dotted line). Spectra are in ether and are normalized based on extinction coefficients given by Ref. 2.

This enzyme has a covalently-attached dipyrrole cofactor. Porphobilinogen is added sequentially to this cofactor so that a linear hexapyrrole forms as an intermediate on the enzyme before release of hydroxymethylbilane and regeneration of the enzyme. Hydroxymethylbilane is unstable and will cyclize non-enzymatically to uroporphyrinogen I, which is non-functional. The enzyme uroporphyrinogen III synthase is required to cyclize hydroxymethylbilane to produce uroporphyrinogen III, in which ring IV is inverted relative to the other pyrrole rings. Porphobilinogen can be readily condensed to form uroporphyrinogen isomers of which 50% are isomer III. Isomer III was probably scavenged by the earliest organisms before they were able to synthesize their own tetrapyrroles. When organisms subsequently evolved to synthesize their own tetrapyrroles, they would have had to evolve a mechanism for synthesizing isomer III. Uroporphyrinogen decarboxylase converts uroporphyrinogen III to coproporphyrinogen III, which is then converted to the last colorless intermediate protoporphyrinogen IX by coproporphyrinogen oxidase.^[4]

Protoporphyrinogen oxidase converts protoporphyrinogen to protoporphyrin IX, the first colored intermediate in the pathway. Protoporphyrinogen oxidase is the primary target of the diphenyl ether class of herbicides, which inhibits the protoporphyrinogen oxidase found in both mitochondria and chloroplasts. As a consequence, protoporphyrinogen accumulates and moves into the cytosol where it is oxidized to protoporphyrin IX. Protoporphyrin IX accumulation results in photo-oxidative damage and cell death. The potential to cause photo-oxidative damage by the colored intermediates in chlo-

rophyll biosynthesis highlights the challenges faced by plants in synthesizing chlorophyll from protoporphyrinogen onwards.^[5,6]

A metal ion is then inserted into protoporphyrin IX by a metal ion chelatase. When Fe^{2+} is inserted by the enzyme ferrochelatase, heme is the end product. When Mg^{2+} is inserted by magnesium chelatase, chlorophyll will be the end product. Thus, insertion of Mg^{2+} by magnesium chelatase represents a commitment to chlorophyll biosynthesis, as shown in Fig. 4. Magnesium chelatase is a complex enzyme consisting of three subunits and belongs to a class of proteins known as AAA+ molecular machines. This enzyme hydrolyzes ATP and the mechanism appears to have similarities to some molecular chaperons. After Mg^{2+} insertion, an S-adenosylmethionine-dependent O-methyltransferase adds a methyl group to the 13-propionate sidechain. Molecular oxygen is incorporated when ring V is formed by an oxidative cyclase whose genes have yet to be positively identified. The next step in the pathway is the reduction of ring IV, which can be catalyzed by two types of enzyme, both known as protochlorophyllide oxidoreductases (POR). The more ancient of the two types of POR has not been found in flowering plants but occurs in almost all other photosynthetic organisms, including gymnosperms and algae. This POR has structural similarities to nitrogenase, with three different protein subunits encoded by the chloroplast genome. The second type of POR is found in all land plants and algae. It is a single subunit enzyme that requires light and reduced nicotinamide adenine dinucleotide phosphate (NADPH) to catalyze the reduction of ring IV to produce a chlorin. This requirement for light appears to be an important developmental adaptation for angiosperms. The reduction of the vinyl group on ring II occurs at either this stage or at some stage

from protoporphyrin IX onwards. The enzyme responsible for this reduction has not been identified. The final step in chlorophyll *a* synthesis is esterification of the alcohol phytol onto the remaining propionate sidechain of chlorophyllide *a* to make chlorophyll *a* by chlorophyll synthase. Chlorophyll *a* can then be converted to chlorophyll *b* by chlorophyll *a* oxygenase. Chlorophyll *b* can be converted back to chlorophyll *a* via chlorophyllide *b* and chlorophyllide *a*. However, the enzymes responsible for this conversion have not been identified.^[3]

REGULATION OF CHLOROPHYLL BIOSYNTHESIS

Chlorophyll itself, and the intermediates in the pathway from protoporphyrin IX onwards, are phototoxic when not bound to protein in a way that allows absorbed light energy to be dissipated or transduced. When pigments are irradiated in the presence of molecular oxygen, highly

reactive singlet oxygen is produced. To limit the formation of singlet oxygen, the biosynthesis of chlorophyll is tightly regulated and is also coordinated with synthesis of LHC and photosystem proteins. This regulation and coordination occurs by both feedback inhibition of enzyme activities as well as regulation of the quantities of key enzymes in the pathway. Some of the key regulatory features of chlorophyll biosynthesis are described below. However, we are still far from understanding the entire regulatory network.^[7]

ALA biosynthesis is the primary regulatory point in the pathway, because feeding ALA results in accumulation of intermediates. Evidence exists for feedback inhibition of ALA biosynthesis in plants by heme and the magnesium containing tetrapyrroles. In greening seedlings, light activates production of ALA biosynthetic enzymes as well as other enzymes in the pathway, and in some species, light causes the rapid degradation of one POR isozyme while activating the synthesis of a second POR isozyme. Light also activates the transcription of magnesium chelatase genes and a circadian rhythm controls the transcription of these genes. In addition to these controls,

S-adenosylmethionine:magnesium protoporphyrin IX O-methyltransferase; c. magnesium protoporphyrin IX monomethylester oxidative cyclase; d. 8-vinyl reductase; e. protochlorophyllide oxidoreductase; f. chlorophyll synthase.

phytochrome and cytokinins have also been implicated in the regulation of the quantity of chlorophyll biosynthetic enzymes or mRNA.^[5-7]

The chlorophyll biosynthetic intermediates, Mg-protoporphyrin IX and Mg-protoporphyrin IX monomethyl ester, are directly involved in the transcriptional regulation of LHCs. This finding links chlorophyll biosynthesis to the regulation of pigment-binding protein synthesis and is likely to be important in coordination of these two processes.^[8,9]

DEGRADATION

The color change of leaves in autumn is due to degradation of chlorophyll to colorless compounds when leaves senesce. This decolorization is essential so that plants can recover the protein nitrogen from the leaves. Chlorophyll is phototoxic and can produce singlet oxygen when not associated with LHCs or photosystems. Thus, in

order to recover the protein from senescing leaves, the chlorophyll must be degraded to colorless compounds so that the protein nitrogen can be efficiently recovered. This degradation is an ordered process involving removal of the centrally coordinated magnesium and opening of the tetrapyrrole ring by a monooxygenase.^[10]

CONCLUSION

Chlorophyll biosynthesis and degradation are complex processes that are vital for the growth and development of photosynthetic organisms, although not yet fully understood. The current focus of research into these processes aims to 1) identify of all of the genes/enzymes involved; 2) provide a structural and mechanistic understanding of the enzymes and regulatory proteins; and 3) determine the regulatory mechanisms by which they are coordinated with other cellular and developmental processes.

Chloroplast Genomes: Architecture of Ancestors

Klaus V. Kowallik

Institut für Botanik, Heinrich-Heine-University, Düsseldorf, Germany

INTRODUCTION

The closest relatives of chloroplasts (plastids) are free living cyanobacteria, which some 1.5–1.8 billion years ago were transformed into chloroplasts following endocytotic (endosymbiotic) events. In contrast to their evolutionary progenitors, chloroplasts almost exclusively perform oxygenic photosynthesis to the benefit of their hosts; i.e., they transform light into chemical energy while releasing oxygen from their water splitting complex and they export photosynthate. It is therefore conceivable that the evolutionary distance between a free living cyanobacterium and a chloroplast is laid down in their genomes, thereby reflecting evolutionary pathways of chloroplasts and allowing us to define ancestral vs. derived characters in chloroplast genomes by analyzing their gene complements and gene orders.

According to current sequencing data, extant cyanobacteria differ in their genomic complexity by a factor of >4 (1.694 protein coding genes for *Prochlorococcus marinus*, 7.281 for *Nostoc commune*; www.jgi.doe.gov./JGI-microbial/html/index.html). In contrast, photosynthetic chloroplasts contain in their genomes between 100 and 220 protein coding genes that account for only few per cent of a cyanobacterial genome. The massive postendosymbiotic loss of genetic information from the evolving chloroplast genome to the host nucleus affected all kinds of gene categories, including even those whose products are required for photosynthesis. Equipped with a presequence that allows the products of nuclear genes to be reimported into chloroplasts, most chloroplast proteins are now encoded in the nuclear genome. Moreover, the vast majority of cyanobacterial genes relocated to the nucleus are targeted to components other than the chloroplast.^[1]

GENOMIC COMPLEXITY OF ANCESTRAL CHLOROPLAST GENOMES

Molecular phylogenies based upon concatenated protein sequences from chloroplast genomes common to plastids of all major evolutionary lineages (46 genes, of which 41 can be used for multiple alignments) are indicative of a single successful endosymbiotic event,

thus rendering all extant plastids monophyletic.^[2,3] Apart from an early offspring of the Glaucocystophyceae with plastids (cyanoplasts) still surrounded by a residual peptidoglycan layer, photosynthetic eukaryotes split into a red and green lineage probably >1.2 billion years ago, with an early diversification of filamentous red algae into forms almost identical to modern species.^[4] One may assume that the streamlining process of the ancestral cyanobacterial genome was already advanced at that time. What finally remained within the “pre-red” and “pre-green” lineage is fundamental to our understanding of chloroplast genome evolution in the red and green lineages we know today.

Inherited from their cyanobacterial ancestor is the circular confirmation of all known chloroplast genomes together with a duplicated set of the ribosomal RNA operon [16SrRNA-trnI(gau)-trnA(ugc)-23SrRNA-5.8SrRNA], usually in inverted orientation (inverted repeat, IR; Fig. 1). This IR separates a small single copy sequence from a large single copy sequence. Both strands of the genome code for a complete set of tRNAs and for proteins frequently translated from a large mRNA transcribed from gene clusters or operons as in eubacteria. Similar to cyanobacteria, and contrary to eukaryotic genomes, noncoding regions are restricted to spacer regions and, if present, to group I and group II introns in green algae and land plants. These introns are mostly of secondary origin. The sizes of nontranslated spacer regions tend to enlarge in the more advanced chloroplast genomes of land plants. In contrast, introns in red algal plastids and their evolutionary offspring (chlorophyll *a* + *c*-containing “Chromophytes” that received their chloroplasts from a red alga through secondary endosymbiosis, i.e., heterokont algae including brown algae and diatoms, Prymnesiophytes, Cryptophytes, and probably the human parasitic Apicomplexa) are rare or even missing. Only one proven exception for an ancient group I intron within the anticodon of the trnL(u!aa) gene can be regarded as being transmitted from the cyanobacterial ancestor through all chloroplast lineages.^[6] Species-specific lack of this intron therefore reflects a derived character for this tRNA gene, even if it occurred in ancestral cp genomes like that of the red alga *Porphyra purpurea*.^[7]

As expected from an evolutionary point of view, the highest degree of genomic complexity is found in red

Fig. 1 Gene map of the 119.7-kb chloroplast genome of the diatom *Odontella sinensis* showing genes and gene clusters transcribed from both strands.^[5] Also indicated are the inverted repeats (IRa, IRb) containing the ribosomal rRNA operons, as well as the large and small single copy regions (LSC, SSC). Transcription direction is clockwise inside and counter-clockwise outside the circle. Genes typical for red algae and thus reflecting the ancestral condition, while missing from green algal and land plant chloroplast genomes, are marked by arrow heads. Transfer RNAs are written in the single letter code with their anticodons in brackets.

algal plastids that contain some 220 protein genes, followed by the genomes of complex plastids with a red algal ancestry. During the transformation process of the red alga into a complex plastid, the eukaryotic endosymbiont lost some 60–80 genes from its plastid genome, mostly by lateral transfer to the nucleus of the second host. Yet chromophyte plastids still contain some 50 protein-coding genes that are missing in chloroplast genomes of green plants, which therefore reflect the most advanced state (Table 1). Altogether, red algal plastids contain about twice as many genes as green algae and land plants. These additional genes code for subunits of ribosomes, constituents of all thylakoid-intrinsic photosystem (PS) complexes (PS I,

PS II, electron transport chain, ATPase), phycobilins, components of the chloroplast import/export machinery (secA, secY), chaperonins (HSP60, HSP70), subunits for protein processing/degradation as well as for tRNA synthetases, aminotransferases, and regulatory subunits of various enzyme complexes involved in primary chloroplast metabolism (DNA replication, chlorophyll and carotenoid biosynthesis, CO₂ fixation, glycolysis, nitrogen metabolism). They are either transcribed individually or, for stoichiometric reasons and genetic control, are decoded from multigene complexes (operons). Notably, the ribosomal super operon in red algae, made up of 26 genes, which was inherited from cyanobacteria as a fusion product of two independent

Table 1 Gene categories from chloroplast genomes of two primary evolutionary lineages (red algae: *Porphyra purpurea*, accession no. U38804; green plants: *Nephroselmis olivacea*–Prasinophyte, accession no. AF137379; *Oryza sativa*, accession no. operons, is retained in all algal groups that gained their chloroplasts from red algae, without any further modification,^[8] thus reflecting the ancestry and evolutionary affiliation between red algal and Chromophyte plastids.

CHLOROPLAST GENOMES ANCESTRAL TO ANGIOSPERMS

With the full information available from green algal and land plant chloroplast genomes we are able to also identify ancestral characters within the rather conserved chlorophyll *a* + *b* lineage. The early split into a chlorophytic and charophytic lineage (the sister group to land plants) occurred within the Prasinophytes. Chloroplast genomes of these flagellated unicellular green algae contain genes that still reflect a red algal sistership (RNA components of RNaseE and RNaseP, *ycf62*) as they are missing from all other green plants.^[9] Also ancestral within the green lineage (and partially also among reds) are plastid genes coding for light-independent chlorophyll biosynthesis (*chlB*, *L*, *N*), which are modifications of an ancestral nitrogen-fixing complex and which only in angiosperms have been replaced by a strict light requiring nuclear encoded enzyme.^[10]

CONCLUSIONS

The rapidly increasing amount of information from fully sequenced chloroplast genomes of all major evolutionary lineages favors of a single origin of all known chloroplasts, irrespective of their pigment composition

and ultrastructure, from a single cyanobacterial ancestor. Secondary endosymbioses involving different hosts and red or green algae as endosymbionts gave rise to the majority of algal classes, notably to those with chlorophyll *a* + *c*-containing plastids. Supported by the fossil record, extant red algae from within the Bangiophyceae contain the most ancestral chloroplast genomes known among all phototrophs, followed by those algae that received their chloroplasts from endosymbiotic red algae. A high number of genes as well as conserved gene clusters of cyanobacterial origin are considered ancestral in chloroplast genomes, contrary to those of green algae and land plants that reflect the most advanced condition in chloroplast genome evolution. With the sequence information of additional chloroplast genomes to come, we will soon be able to reconstruct the genomic complexity of the last common ancestor of chloroplasts and to use the full information contained therein to reconstruct the true phylogeny of extant phototrophs, replacing the many misleading phylogenetic trees based upon single gene phylogenies. We may also be able to respond to the open question whether chloroplast genome evolution occurred mainly by loss of information or whether horizontal transfer of xenogenous DNA from eubacteria or other sources into chloroplasts may have contributed to chloroplast genomes in certain lineages.

Chromosome Banding

Takashi R. Endo

Kyoto University, Kyoto, Japan

INTRODUCTION

A chromosome is a discrete body carrying many genes and is composed of DNA and protein. Treatment of chromosomes with alkali or phosphate buffer, followed by staining with Giemsa stain, produces a pattern of bands along the chromosomes. The bands are regarded to represent constitutive heterochromatin, which is composed of repetitive DNA and is highly condensed. C-banding and N-banding are the most commonly used methods for the identification of individual chromosomes and chromosomal structural changes in plants. The power of chromosome banding will be enhanced when it is combined with *in situ* hybridization.

The particular chromosome complement termed “karyotype” is specific to each species. A karyotype is defined by the number and morphology of the chromosomes. The morphology of a chromosome is characterized by the absolute size, position of centromere, and the presence or absence of nucleolar and secondary constrictions. However, the karyotype allows only a few chromosomes of unusual size or shape to be identified unequivocally.

BACKGROUND INFORMATION

In the early 1970s, several chromosome-banding techniques were first developed in mammals. The techniques termed G-, C-, N-, R-, and Q-banding involve treatments with trypsin, alkali, or phosphate buffer, followed by staining with Giemsa or a fluorochrome dye to produce a pattern of bands along the chromosomes.^[1] The nature of the bands is regarded to be related to constitutive heterochromatin, which is composed of repetitive DNA and is highly condensed. These chromosome-banding techniques are very powerful tools for the identification of chromosomes and chromosomal structural changes. Among different chromosome banding techniques, G-banding is usually the method of choice for the investigation of human chromosomes, because G-banded preparations contain many bands.

Stimulated by the success in chromosome banding for human and animal chromosomes, cytogeneticists started to apply the same banding methods to plant chromosomes in the 1970s. G-banding does not produce bands to a

useful extent in plants. C-banding and N-banding produce distinct bands in many plant species, although not as many as G-bands in animals. At present, these have been the most commonly used methods for the identification of individual chromosomes and chromosomal structural changes in plants, especially in species with large chromosomes, such as rye, barley, wheat, onion, broad bean, and anemone.^[2]

C-BANDING

C-bands were first described as pericentric bands, corresponding to the satellite DNA regions in mammalian species, after the treatment of preparations for *in situ* hybridization. The bands were originally termed C-bands because of their correlation with the centromeric heterochromatin. However, C-banding in plants produces bands not only in pericentric regions but also in terminal and interstitial regions of chromosomes (Fig. 1). Several procedures have been developed for staining constitutive heterochromatin in plants. The C-banding procedure includes an alkali treatment, usually in a barium hydroxide solution ($\text{Ba}(\text{H})_2$), incubation in $2 \times \text{SSC}$ (standard saline citrate) solution, and then staining with Giemsa stain that contains Azur, eosin, and Methylene Blue (Leishman's stain or Wright stain containing only eosin and Methylene Blue is also used). C-banding in plants does not always produce pericentric bands and is not the only technique that differentially stains constitutive heterochromatin. Therefore, C-banding might be best described as a Giemsa banding method that selectively stains most regions of constitutive heterochromatin after treatment with a barium hydroxide solution followed by incubation in $2 \times \text{SSC}$.^[2]

C-bands are regarded as corresponding to constitutive heterochromatin regions containing a mass of repetitive DNA sequences of various kinds.^[3] The nature of action of the chemicals in C-banding is as follows: The hydrochloric acid (or acetic acid) treatment depurinates the chromosomes halfway without degrading all of the DNA; the alkali treatment denatures the DNA, which aids solubilization; incubation in warm SSC breaks the sugar-phosphate backbone and DNA fragments pass into solution. Giemsa staining looks like a precipitation reaction

Fig. 1 C-banding and N-banding of barley and rye. Note both methods produce very similar banding patterns in barley, but in rye N-banding produces only a few of the bands produced by C-banding.

on the part of the chromosome that still retains the constitution of the highly compacted heterochromatin.^[1] Banding patterns produced by different C-banding methods are basically the same, although some minor bands do not appear or are enhanced depending on the procedures used.^[4]

C-banding allows geneticists to construct accurate idiograms for comparing the karyotypes of different plant species and varieties. C-band karyotyping was conducted in the aneuploid series of common wheat (*Triticum aestivum*, $2n = 6x = 42$) to identify individual wheat chromosomes based on their particular banding patterns.^[5] The genome evolution of wheat and its related wild species was further analyzed by C-banding beyond the genome analysis based on meiotic chromosome pairing.^[6] C-banding further allows the screening for deficient chromosomes in the progeny of a certain line of common wheat in which chromosomal breakage occurs by a genetic mechanism, and a series of deletion stocks have been produced in common wheat.^[7]

N-BANDING

N-banding was developed as a simple, one-step banding technique to localize nucleolus organizers in animal and plant chromosomes. However, this method was found to stain differentially the regions of constitutive heterochromatin, not nucleolus organizers, in cereal species. N-banding involves incubation in a hot sodium dihydrogenphosphate (NaH_2PO_4) solution.^[2] The N-banding pattern is very similar to that generated by in situ hybridization with a probe of satellite DNA, $(\text{GAA})_m(\text{GAG})_n$.^[8] The N- and C-banding patterns look similar in some species but are very different in other species (Fig. 1). All the N-bands appear to be included in the C-bands. Probably, C-banding can differentially stain various types of heterochromatin concurrently.

Chromosome banding is important in crop science because it allows us to identify the chromosomal constitution of interspecies hybrids, alien addition lines, and derivative lines containing alien chromosomal

Fig. 2 Sequential C-banding and genomic in situ hybridization (GISH) of reciprocal translocations between rye chromosome 1R and wheat chromosome 7D (shown by arrows). C-banding allows the identification of the chromosomes involved in the translocation. Rye chromosomal segments fluoresce brightly by GISH. (View this art in color at www.dekker.com.)

segments. In situ hybridization, the latest technique of molecular cytogenetics, allows the detection of a sequence of interest, such as ribosomal DNA sequences. If highly repetitive DNA sequences are present in large blocks in the genome of an organism, their presence can also be detected as bands by in situ hybridization. In situ hybridization banding is potentially powerful for karyotyping in plants; however, C- and N-banding are still more suitable methods of karyotype analysis in plants because they produce more bands than in situ hybridization.

The power of chromosome banding will be enhanced when it is combined with in situ hybridization. By genomic in situ hybridization chromosomes of one genome can be distinguished from those of another genome, but it is impossible to identify individual chromosomes. For analysis in wheat, when C- or N-banding is followed by in situ hybridization,^[9] chromosome banding can identify individual chromosomes and the subsequent in situ hybridization shows the DNA nature of the chromosomes, such as SAT-chromosomes containing a nucleolus organizer region and alien chromosomes containing different types of repetitive DNA sequences. The sequential chromosome banding and in situ hybridization technique is now used to pinpoint the break points of wheat-alien chromosome translocations^[10] (Fig. 2).

Chromosome Manipulation and Crop Improvement

Adam J. Lukaszewski

University of California, Riverside, California, U.S.A.

INTRODUCTION

Chromosomes carry most of the genetic information of a cell. Any genetic experiment or a breeding effort involves, de facto, a degree of chromosome manipulation. However, in some situations, especially when interspecific or intergeneric hybrids are made for breeding purposes, special steps must be taken to induce chromosomes to perform some unusual feats and generate unusual variants.

WHAT IS CHROMOSOME ENGINEERING?

An amazing array of techniques and approaches to chromosome manipulation have been devised and tried in research, but they may not lead to the development of successful crops. The criterion for this section, therefore, is successful utilization of the chromosome constructs in commercial agriculture. Conscious chromosome manipulation in crop improvement was termed “chromosome engineering” by its pioneer, E. R. Sears.^[1] The term refers to a series of actions leading to the introgression into a crop species of a fragment of a chromosome carrying a desirable characteristic, most often a disease or pest resistance locus. Usually, the donors are wild relatives. The practical limits to such introgressions are set by the ability of the donor and recipient species to hybridize and to produce hybrids with at least trace fertility. Somatic cell fusion, while promising to expand the boundaries of wide hybridization and already used successfully in potato breeding,^[2] is yet to prove itself in commercial agriculture.

The gene pools of wild relatives of crops are not adapted to agriculture. Therefore, the amount of the introgressed chromatin is of primary concern so that as little as possible of the undomesticated gene pool is transferred along with the targeted locus. Theoretically, single loci can be transferred, but such goals are unrealistic. Often, the process of introgression is frustrated by tight linkages that introduce undesirable characteristics or eliminate desirable loci and may require repeated cycles of backcrosses and selection to remedy.^[3] Pleasant surprises also happen, such as the yield-enhancing effects of two alien introgressions into wheat.^[4]

In diploids, introgressions from wild relatives are standard, if challenging, breeding strategies. Many desirable characteristics have been introduced in this fashion into such crops as barley, maize, potato, rice, soybeans, tomato, and many others.^[5] Some unusual chromosome behavior has been observed along the way, such as apparent absence of chiasma interference in wide hybrids of rice or a change in the distribution of recombination in wide hybrids of grasses, but the procedures are driven strictly by breeding demands. Once the hybrids are made, they do not require any special protocols.

WHEAT ENGINEERING

The situation is more complex in wheat. Wheat is an allopolyploid, composed of three closely related genomes. To ensure diploid-like behavior in meiosis, and only bivalent pairing guarantees chromosome stability, wheat evolved a genetic system that controls the stringency of recombination.^[6] The stringency criteria are so high that even homologues in intervarietal hybrids may be unable to pair. Under these conditions, there is practically no wheat-alien chromosome pairing. To force it, the pairing control system has to be disabled. This is done by the removal of the main locus, *Ph1*, either by a deletion or nullisomy for chromosome 5B or by making use of its dominant suppressors.

Practical chromosome engineering in wheat is illustrated in Fig. 1. An alien chromosome with the targeted locus is introgressed into its proper (homoeologous) position in one of the genomes by the use of monosomics. This introgression is combined with the *Ph1* mutation or a suppressor, and recombinant wheat-alien chromosomes are recovered in the progeny. Usually, these primary recombinants are single breakpoint translocations. They appear in two configurations: with wheat telomeres and alien centromeres and vice versa. The primary recombinants are tested for the locations of the breakpoints and the presence of the target locus. From each configuration, a chromosome is selected that carries the targeted locus and has the breakpoint as close to it as possible. These two chromosomes are combined in one plant with the *Ph1* locus. This permits only homologous recombination. The only region of homology shared by the two recombinants

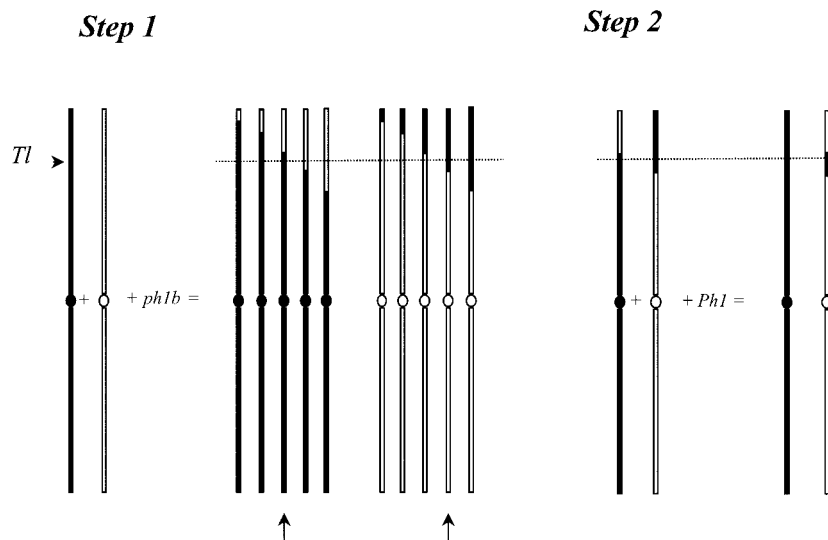

Fig. 1 A two-step approach to engineering intercalary alien transfers into wheat. In Step 1, a donor alien (solid black) and a recipient wheat (open white) chromosome are induced to pair and recombine by the absence of the *Ph1* locus, and two classes of single breakpoint translocations are recovered. From each class, recombinants with the target locus (*Tl*) and the closest possible breakpoint are selected (arrows). In Step 2, the two selected recombinants are combined in one plant. In the presence of wild-type *Ph1*, only homologous recombination is permitted. A crossover in the overlapping region of homology produces a wheat chromosome with an intercalary alien introgression that carries *Tl* and a normal donor chromosome.

is between the two breakpoints: A crossover within that segment produces a secondary recombinant, a chromosome of wheat with an intercalary segment of alien chromatin, and a normal donor chromosome.

PRIMARY RECOMBINANT CHROMOSOMES

The precision of this approach depends on the number of primary recombinant chromosomes available and the precision of breakpoint mapping. Larger populations of primary recombinants offer higher probability of breakpoints close to the targeted locus. The number of available recombinants is a function of the pairing frequency of the donor and recipient chromosomes and the size of screened populations. Because pairing of alien chromosomes with wheat can be very low even in the absence of *Ph1*, the screened populations may have to be very large to eventually generate small intercalary transfers. For example, if the targeted locus in the final chromosome is to be flanked by no more than 1 cM of alien chromatin, and the donor and the recipient pair 1% of the time, 29,956 progeny must be screened for a 95% probability of recovery of the two necessary breakpoints.

Very high numbers of the primary recombinants are not necessarily advantageous. With the current marker technology, high-precision breakpoint mapping is possible, if

costly. However, even if the positions of tightly spaced breakpoints can accurately be resolved, and the best two are selected to be combined into an intercalary introgression, the probability of a crossover in their shared segment of homology may be too low to be practically useful. In fact, the contrasting structure of the two primary recombinants may prevent them from forming any chiasmata, even if sufficient homology exists. No practical limits for the chiasma establishment under such conditions have been determined, but the author observed a threefold reduction in the crossover frequencies in pairs of selected primary recombinants, relative to the frequencies inferred on the basis of their breakpoint positions.

Once a series of primary recombinant chromosomes have been produced, any higher-order recombinants can be generated, depending on the practical demands. Four breakpoint translocations were produced in an attempt to remedy the quality defect of the 1RS.1BL wheat-rye translocation in wheat.^[7] Primary recombinants can also be used in homoeologous recombination to direct the crossovers into proximal locations that would not be easily accessible in the first round of recombination, thereby extending the range of chromosome locations accessible to manipulation.

The limit of this engineering approach is set by chromosome affinity. If there is no meiotic pairing of the donor with the recipient, the recombination approach will

Fig. 2 Whole-arm translocations of the same rye chromosome (1R) with each of the group-1 chromosomes of wheat (1A, 1B, 1D). From all possible combinations of random fusion of centric fission products, only compensating translocations, that is, those involving the short arm of rye (1RS) with the long arms of wheat (1AL, 1BL, and 1DL) and the short arms of wheat (1AS, 1BS, and 1DS) with the long arm of rye (1RL), were selected.

not succeed. Such recalcitrant chromosomes may still be engineered but with considerably less precision. This is done by chromosome fragmentation, either centric fission-fusion where at least the recipient can be selected or by completely random processes of chromosome breakage and reunion of broken fragments.

FISSION-FUSION

The centric fission–fusion approach exploits a tendency of unpaired chromosomes in meiosis to break across the centromeres. From a range of random fission-fusion products of a donor and a recipient, compensating whole-arm translocations can be selected (Fig. 2). One of the most successful alien introgressions in wheat, the 1RS.1BL wheat-rye translocation, must have originated by centric fission-fusion.

Irradiation of plants or pollen offers the means of introgressing chromosome fragments smaller than whole arms. The fragmentation approach uses brute force to break chromosomes and relies on the DNA repair mechanisms to fuse the broken fragments into new chromosomes. No affinity of the chromosomes is required, but the resulting translocation still must compensate the

absence of the original recipient chromosome or it will not be accepted in agriculture. Built into this approach is an assumption, or hope, that a large enough scale offers a sensible chance of finding compensating translocations that carry the targeted loci from the donors. Given the astronomical numbers of possible breakpoint positions and fusion combinations, the fragmentation approach does not offer realistic chances for successful transfers. With few exceptions,^[8] chromosome translocations produced in this fashion are noncompensating and have not been widely utilized in practical plant breeding.^[9] However, the fragmentation approach lures like a lottery: It teases with a large payoff for a low investment. On the other hand, introgressions based on recombination, if done with sufficient care, offer a high probability of success but can be extremely laborious.

Chromosomes of crop species can be engineered to produce duplications of small segments of the genome. This is accomplished by combining certain reciprocal translocations into double translocation homozygotes. In barley, some of such duplications produced up to 35% yield increases.^[10] It is doubtful that this approach will be used on a wider scale as very few crops have large enough collections of chromosome translocations to suit this purpose, and no efforts to produce them are apparent.

CONCLUSION

The techniques of molecular biology will likely have a major impact on future chromosome manipulation approaches in plant breeding. Already, genetic maps and sets of DNA markers increase the precision of chromosome engineering. Perhaps the techniques of gene identification, cloning, and transformation will eventually eliminate all need for painstaking assembly of chromosome pieces into viable constructs. However, it is likely that in their search for new sources of variation, breeders will keep probing the fringes of the possible. Such fringes do not offer sufficient economic incentives for routine applications of sophisticated and expensive techniques. Therefore, the quest will probably continue even if the details of the approaches change.

Chromosome Rearrangements

Tomás Naranjo

Universidad Complutense, Madrid, Spain

INTRODUCTION

Chromosome rearrangements and polyploidy have produced a huge variation in the number, size, and morphology of chromosomes among, and often within, plant taxa. Structural chromosome modifications invariably occur in all species. These changes appear in one or a few individuals and occasionally become fixed in a given population. Some chromosome rearrangements may accompany the origin of new species or be shared by related species that inherited them from a common ancestor. Cytogenetic studies that detect and explain the origin and evolutionary implications of chromosome rearrangements are considered in this report, with special emphasis on Triticeae, a tribe of the family *Poaceae* (*Gramineae*) with diploid and polyploid species and chromosome rearrangements at the intraspecific, specific, and supraspecific levels.

IDENTIFICATION OF CHROMOSOMAL ABERRATIONS

Identification of structural changes is a prerequisite for understanding their effect and implication on genome evolution. Multivalent configurations at metaphase I were evidence for the evolution of multiple translocation complexes in the genera *Oenothera* and *Rhoeo*. Translocations accumulated during the evolution of these genera are maintained in heterozygous condition because of the action of lethal genes or mechanisms in the gametophyte that prevent gametes with a particular chromosome set from participating in fertilization. However, chromosome rearrangements are usually fixed in homozygous condition and do not require additional mechanisms to become permanent. Other cytogenetic approaches permit the identification of these structural changes. In some species, the chromosome structure has been studied using chromosome banding techniques.^[1] Pairing data between chromosomes from related (homoeologous) genomes at metaphase I in interspecific hybrids (Fig. 1) provides information on chromosome structural differentiation.^[2] The fluorescence in situ hybridization (FISH) technique reveals the physical location and organization of DNA sequences on chromosomes. A variant of FISH, genomic

in situ hybridization (GISH), permits visualization of entire genomes and allows identification of intergenomic chromosome exchanges (Fig. 2) produced after allopolyploid formation.^[3] Finally, linkage and gene order in genomes with variable degrees of relatedness may be compared from the construction of genetic maps.^[4]

TRITICEAE AS A MODEL FOR STUDYING CHROMOSOME REARRANGEMENTS

The tribe Triticeae contains about 500 diploid and polyploid species, including the agronomically important crops, wheat, barley, and rye. Diploid species of the tribe diverged from an ancestral species with $2n=14$ chromosomes. Autopolyploids and allopolyploids appeared in a subsequent evolutionary step. Common bread wheat, *Triticum aestivum*, is an allohexaploid species ($2n=6x=42$, genome AABBDD) that arose from the hybridization between tetraploid wheat *T. turgidum* ($2n=4x=28$, AABB) and *Aegilops tauschii* (DD). Hybridization between *T. urartu* (AA) and the donor species of the B genome gave rise to *T. turgidum*. Development of engineered nullisomic-tetrasomic lines of bread wheat as well as wheat-alien addition and substitution lines helped identify homoeologous chromosomes. Comparative genome analysis based on homoeologous pairing revealed that the D genome of wheat and most of the A and B genome chromosomes preserve the ancestral arrangement. Two interchanges involving chromosome arms 5AL/4AL and 4AL/7BS, and a large pericentric inversion of chromosome 4A that occurred during the evolution of wheat were detected.^[3] These rearrangements are present in *T. turgidum*, which inherited the 5AL/4AL translocation from *T. urartu*. Comparative mapping demonstrated the conserved synteny of wheat chromosomes only disrupted by the above mentioned rearrangements in addition to a paracentric inversion of 4AL.^[4] GISH analysis confirmed the absence of translocations between homoeologous chromosomes.^[5]

T. timophevii (A¹A¹GG), another tetraploid species formed from the hybridization between *T. urartu* and *Ae. speltoides*, also inherited the 4AL/5AL translocation from *T. urartu*. Tetraploid wheats share no other evolutionary chromosome rearrangement, although four

species-specific translocations, 6A^L/1GS, 1GS/4GS, 4GS/4A^L, and 4A^L/3A^L, are known in *T. timopheevii*.^[3,6] Structural chromosome differences suggest that *T. turgidum* and *T. timopheevii* originated from two independent hybridization events. Several landraces and wild populations of tetraploid wheats have additional chromosome modifications, whose histories may be traced. For instance, the karyotypic diversity of wild populations of *T. timopheevii* in different geographical regions suggests that the center of origin and the center of primary diversity of this species is in Iraq.^[7]

Diploid species show a variable number of chromosome rearrangements relative to wheat.^[8] Genomes of *Ae. umbellulata* and *Secale cereale* (rye) have eleven and seven rearrangements, respectively—mainly translocations. It needs to be determined whether two inversions detected in *Hordeum vulgare* (barley) and another two in *H. bulbosum* are species-specific. *Ae. longissima*, *T. urartu*, and *T. monococcum* have one translocation each, and *Ae. speltoides*, *Ae. sharonensis*, and *Ae. tauschii* show no structural modification. Rye and *Ae. umbellulata* have an interchange between chromosomes 4/5 similar to the 4AL/5AL translocation of the genus *Triticum*. However, these translocations arose independently, because the D genome, which is more closely related to the A genome than to the genomes of rye or *Ae. umbellulata*, has no translocations. Dissimilar numbers of rearrangements, either in outbreeders such as rye and *Ae. speltoides*, or in predominantly self-pollinated species such as *Ae. umbellulata* or *Ae. sharonensis*, indicate no relationships between structural chromosome differentiation and the reproductive system. The translocation present in *Ae. longissima* could be the primary cause of the reproductive isolation that led to the formation of this species. The

Fig. 2 Intergenomic translocations in *T. timopheevii* chromosomes detected by GISH. (From Ref. 6 by permission of NRC Research Press.) (View this art in color at www.dekker.com.)

same process could have occurred in the differentiation of the A genome of the genus *Triticum*. Likewise, rearrangements present in rye most likely accumulated during the evolution of the genus *Secale*. However, chromosome differentiation is not a prerequisite for divergence of diploid species among the Triticeae. The genera *Hordeum* and *Secale* and the *Triticum-Aegilops* group are representative members of separate lineages in the tribe Triticeae, and originated in that order and are not parallel to the accumulation of rearrangements.

The highly conserved structure of the diploid progenitors of polyploid wheats contrasts with the number—three and four, respectively—of evolutionary chromosome rearrangements produced in tetraploid wheats. All these structural changes had to arise in the primitive tetraploids, because transient structures of their sequence were not found. The formation of new polyploids is often accompanied by extensive genomic modifications within a short period of time. Evolutionary chromosome rearrangements of tetraploid wheats may represent a fraction of the overall genomic reorganization that occurred immediately after polyploidization. Data from comparative mapping support a high rate of chromosome rearrangements following the whole-genome replication that occurred in the ancestors of *Brassica* and maize. Some of these changes could be involved in the subsequent reduction of the basic chromosome number.

ORIGIN OF CHROMOSOME REARRANGEMENTS

Intergenomic translocations also exist in polyploids from other taxa such as *Avena* or *Nicotiana*. Recombination between homoeologous chromosomes in the primitive

polyploid has been suggested as a possible origin of such translocations. However, this is not the case in polyploid wheats, where evolutionary intergenomic rearrangements involve nonhomoeologous chromosomes. Both intergenomic and intragenomic rearrangements could have a similar origin. The position of the breakpoints at or near the centromere in many intraspecific chromosome rearrangements of tetraploid wheats^[9] contrasts with the intercalary or distal position of evolutionary rearrangements. This nonrandom distribution may reflect different mechanisms generating each type of chromosome modification. Translocations with centromeric breakpoint may arise by rejoining the arms of nonhomologous chromosomes that misdivide simultaneously at anaphase I after failure of synapsis or recombination. Another possibility is that translocations derive from the effect of gametocidal genes, which cause chromosomal breaks in the gametophyte. Most breakpoints are noncentromeric, although centromeric breaks also occur. The broken chromosomes can rejoin to produce translocated chromosomes. Finally, transposable elements may mediate the production of chromosome rearrangements. Transposable elements have been found to be associated with chromosomal rearrangements such as deletions, duplications, inversions, and translocations in different species. Homologous recombination between elements at different locations and alternative transposition have been proposed as two possible mechanisms by which chromosome rearrangements may occur.^[10]

FUTURE PROSPECTS

The cytogenetic approaches used in the last 15 years reveal that intraspecific and evolutionary chromosome rearrangements occurred in diploid and polyploid species from different plant taxa. Among diploids, very distant species preserve their ancestral chromosome structure, although others accumulate several chromosome rearrangements. Thus, chromosome rearrangements are not a prerequisite for speciation. By contrast, speciation caused by polyploidy is often accompanied by structural chromosome differentiation.

An immediate aim in the study of chromosome rearrangements is the determination of the DNA sequence at the breakpoints. This may help to explain the origin of rearrangements and phenomena such as their accumulation in some chromosomes, as in wheat chromosome 4A, or their recurrence, as in the translocation between chromosomes 4/5 in Triticeae. On the other hand, structural

changes may modify the topological arrangement of chromatin in the nucleus. The consequences that chromosome rearrangements may have for gene function and its evolutionary implications should be the focus of new studies.

Chromosome Structure and Evolution

Ingo Schubert
Andreas Houben

Institute for Plant Genetics and Crop Plant Research, Gatersleben, Germany

INTRODUCTION

Plants share with other eukaryotes the basic structural organization of chromosomes and their subdivision into functional domains, such as telomeres, centromeres, nucleolus organizers, euchromatin, and heterochromatin.^[1] The same holds true for the primary and secondary events that contribute to evolutionary alteration of number, size, shape, and content of chromosomes.^[2] Constraints restricting the variability of chromosome size are indicated.

CHROMOSOME STRUCTURE

Plant nuclear chromosomes, like those of other eukaryotes, are composed of DNA, RNA, and proteins forming the chromatin. They consist of one linear DNA double helix per unreplicated chromosome (or per sister chromatid after reduplication during S-Phase of the cell cycle). The DNA double helix encoding the genetic information is wound approximately 1.75 turns, corresponding to approximately 160–200 base pairs (bp), around octamers of two molecules each of the histones H2A, H2B, H3, and H4—the nucleosomal core—while the linking stretches of DNA are usually associated with histone H1. This “bead on a string” structure represents the thin chromatin fibril that in turn is hierarchically structured by coils, loops, and/or spirals eventually resulting in the most dense “transport” form that becomes visible microscopically as individual chromosomes during nuclear division. This structuring, for which the precise mechanism is not yet known, yields a condensation by approximately 5 orders of magnitude from naked DNA to mitotic chromosomes (Fig. 1a).

Post-translational modifications of specific amino acids of nucleosomal histones (acetylation, methylation, phosphorylation, and ubiquitination) are involved in regulation of several nuclear processes (“epigenetic histone code.”^[3]).

Each diploid species is characterized by a specific set of chromosome pairs that may vary considerably in number ($2n = 4$ to >100), size (<1 – $>10 \mu\text{m}$), and shape (symmetric/symmetric arm length, with/without satellites; see Fig. 1b). The chromosome complement of an orga-

nism—the karyotype—may consist of chromosomes that are similar or different in size and/or morphology.

Although the estimated number of genes in higher eukaryotes is similar (between approximately 20,000 to 60,000), the DNA content of (unreplicated) nuclear plant genomes may vary from approximately 1.5×10^2 Megabase pairs (Mbp) in *Arabidopsis* to $>10^5$ Mbp in some *Fritillaria* species. This high variability is due mainly to the varying content of tandem and dispersed repetitive sequences. The latter are represented mainly by redundant, potentially mobile transposon and retrotransposon sequences. These rapidly evolving sequences have a major impact on chromosome evolution, and probably also on speciation and regulation processes. Discussion of the main structurally and functionally distinct domains of chromosomes (Fig. 1c) follows.

Telomeres

The chromosome ends, called telomeres, are responsible for stable maintenance of linear chromosomes.^[4] Highly conserved TTTAGGG tandem repeats represent the typical telomeric sequences of all plant phyla. In some Asparagales these repeats are substituted with the vertebrate-specific sequence TTAGGG_n and in Alliaceae they are secondarily lost during evolution, as are the insect repeats TTAGG_n in Diptera. Canonical telomeric repeats form single-stranded 3'-overhangs that pair into proximal double-stranded regions generating a “T-loop.” The terminal T-loops are stabilized by telomere-binding proteins, thus preventing exonucleolytic degradation and recombination between DNA ends that occur during repair of internal double-strand breaks. Because all known DNA-polymerases need RNA-primers to add deoxy-nucleotides in the 5' to 3' direction, each replication cycle results in the shortening of linear DNA molecules. This shortening is compensated by a reverse transcriptase—the telomerase—that, according to an internal complementary RNA-template, adds telomeric repeats to the 3' DNA ends (Fig. 1d). In the absence of telomerase, telomeres may, in some cases, become extended by nonreciprocal recombination (conversion). However, this has not yet been reported for plants. Frequently, telomeric sequences are proximally followed by species-specific subtelomeric tandem repeats.

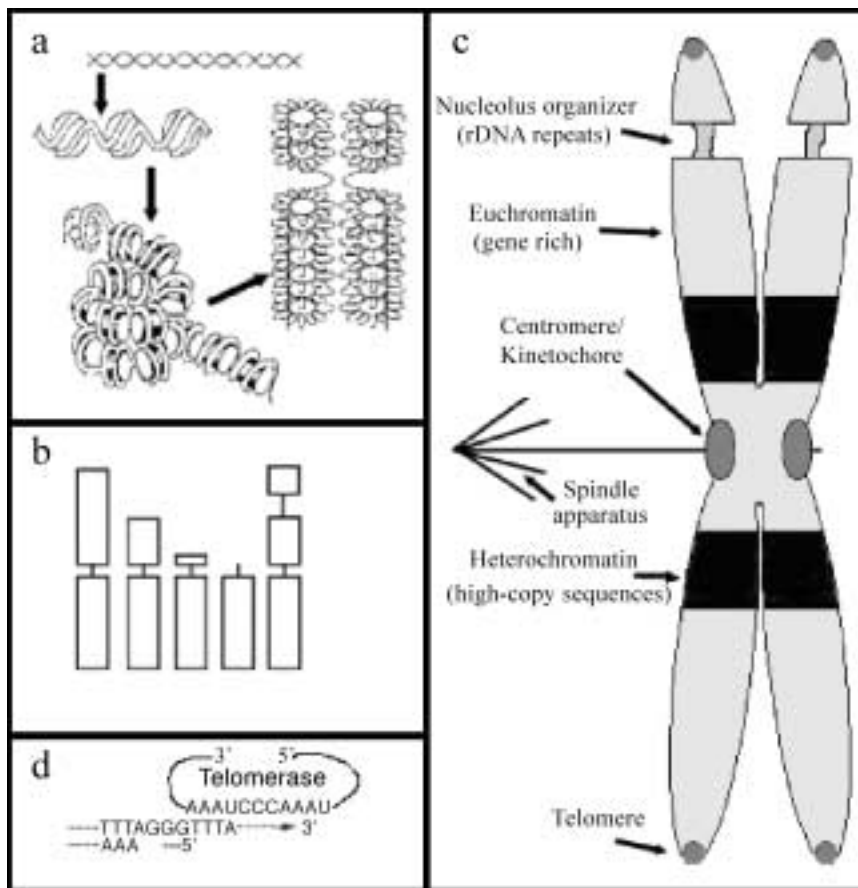

Fig. 1 Structure of eukaryotic chromosomes. a) Structural condensation from naked DNA into metaphase chromosomes. b) Types of chromosome morphology from left to right: metacentric; submetacentric; acrocentric; telocentric; and metacentric chromosome with satellite, separated from its arm by the nucleolus-organizing secondary constriction. c) Schematic presentation of a metaphase chromosome and its domains. d) Elongation of terminal telomeric sequence repeats according to the complementary internal RNA component of the reverse transcriptase “telomerase.”

Centromeres

Another domain of eukaryotic chromosomes essential for their stable inheritance is the centromere,^[5,6] the primary construction of monocentric chromosomes. (Some plant

genera, e.g., *Luzula*, possess poly- or holocentric chromosomes, with centromeres not restricted to a single site on the chromosome.) At the centromeres >20 highly conserved proteins are permanently or transiently (during the nuclear divisions) assembled within the kinetochore

Fig. 2 Different types of chromosome rearrangements. a) Alteration of chromosome number by reversible fusion of telocentric into bi-armed metacentric chromosomes without (extensive) loss of sequences (centromeres: black, telomeres: triangles). b) Basic mechanisms of primary structural chromosome rearrangements. c) “Breakage-fusion-bridge” cycle of dicentric chromosomes (resulting from asymmetric chromosome translocations) may secondarily yield deletions (top, right) and duplications and inversions (bottom, right) due to random disruption of chromosome bridges during nuclear divisions until the breakage products become stabilized by the gain of telomeric sequences at the broken ends. d) Secondary chromosome rearrangements (bottom, right) arising by crossover (x) between homologous regions of translocation chromosomes within a meiotic multivalent (□) in individuals heterozygous for two translocations. (As a second recombination product, the ancestral karyotype is reconstituted. Compare top and bottom left.) e) Alteration of diploid chromosome number by meiotic mis-segregation from a meiotic multivalent (□) of individuals heterozygous for two translocations between one bi-armed and two one-armed chromosomes. When the two bi-armed translocation chromosomes segregate into one gamete and the remaining four one-armed chromosomes segregate into the other, chromosome numbers alter into $n - 1$ and $n + 1$ simultaneously, accompanied by only minor deletions or duplications (□), respectively.

Fig. 2

complex. Distinct kinetochoric proteins are responsible for the onset of nuclear division (anaphase-promoting complex), for cohesion of sister chromatids at centromeres until anaphase, and for correct segregation of sister chromatids (mitosis, meiosis II) or homologous chromosomes (meiosis I) into the daughter nuclei via interaction with the fibers of the spindle apparatus.

In contrast to telomeres, centromeres are not specified by highly conserved DNA sequences. Tandem repeats (and in cereals, also “gypsy-type” retroelements) often occur at centromeres, and bind centromere-specific histone H3 variants. Nevertheless, their functional importance is unclear because they are not present in all centromeres/neocentromeres of rearranged chromosomes. Therefore, an epigenetic mechanism for kinetochore assembly cannot be excluded.

Nucleolus Organizers

Nucleolus organizing regions (NORs) occur on one or several chromosome pairs of a complement and harbor the most redundant genes (up to 10,000 copies per locus). They encode the transcription units for the large ribosomal rRNA fractions (5.8S, 18S, 25S RNA). If not at terminal position or suppressed by “nucleolar dominance,” they are visible as achromatic threads—the “secondary constrictions,” separating the distal “satellite” from the remaining chromosome arm (Fig. 1b,c)—and form a nucleolus, where ribosomes are synthesized, in interphase nuclei. Specific proteins of active NORs can be visualized by silver staining.

Heterochromatin

Heterochromatin forms the most dense structures of interphase nuclei. It represents late replicating, genetically inert, or transcriptionally inactive chromatin. On dividing chromosomes, heterochromatin is made visible by various techniques yielding species-specific band patterns, mostly around centromeres but also at interstitial and/or terminal positions. In addition to constitutive heterochromatin, sex chromosomes or entire parental chromosome sets may appear as “facultative” heterochromatin (not yet found in plants). Constitutive heterochromatin of large genomes often consists of highly methylated tandem-repetitive DNA sequences associated with heterochromatin-specific proteins and nucleosomal histones H3 and H4, showing a low level of lysine acetylation. Lysine 4 of H3 is regularly less intensely and lysine 9 mostly more intensely dimethylated in heterochromatin than in euchromatin domains. Within small genomes (e.g., that of *Arabidopsis*) heterochromatin is restricted mainly to pericentromeric regions, containing many of the potentially mobile sequences (transposons, retrotransposons) in addition to

tandem repeats, and inactive rDNA. Heterochromatin is rarely involved in meiotic recombination but it represents “hot spots” for structural chromosome aberrations if repair of DNA damage interferes with replication. Positioning of genes into or close to heterochromatin may lead to suppression of their transcription (position effect) via “heterochromatinization.”

Heterochromatin represents the most variable chromosomal domain with a high potential for evolutionary alteration and epigenetic modification of nuclear processes such as replication, transcription, repair, and recombination.

Euchromatin

Euchromatin is of less dense structure in interphase nuclei, replicates earlier than heterochromatin, and is enriched in genes (approximately 1 gene/5 kilobase pairs (kb) in *Arabidopsis*). It contains higher levels of acetylated histones and H3 di-methylated at lysine 4. Euchromatin of large plant genomes may harbor considerable amounts ($\geq 90\%$) of diverse repetitive sequences, in particular retroelements, interspersed between genes/gene clusters. Such sequences are inactivated by DNA di-methylation and associated with H3 methylated at lysine 9. As to both features, euchromatin of large plant genomes resembles the pericentromeric heterochromatin of the small *Arabidopsis* genome.

CHROMOSOME EVOLUTION

During evolution, the number, shape, size, and content of chromosomes may change according to mechanisms similar in principle for all eukaryotes.

Primary Rearrangements

Apart from interspecific hybridization, adding chromosome complements or single chromosomes to that of a host spindle disturbances may result in poly- or aneuploid chromosome numbers.

At the euploid level, chromosome number, size, and shape may change due to fusion of telocentrics resulting in metacentric chromosomes. This is reversible if centromeric and telomeric sequences from both telocentrics persist within the fusion chromosome^[7] (Fig. 2a). Otherwise, centric fission may yield stable telocentrics when telomeric sequences are patched to the breakpoints.

Size and/or morphology also may be modified by reciprocal translocations, para-/pericentric inversions, interstitial or terminal deletions (tolerable only when dispensable/multiple sequences are involved), or by sequence insertions into breaks (Fig. 2b). Such “primary” structural rearrangements usually reflect misrepair of

DNA damage, particularly during nonhomologous end-joining of double-strand breaks.

Sequence amplification/deletion may also occur via “replication slippage” or due to unequal (out-of-frame) recombination (meiotic crossover, somatic sister chromatid exchange) between (partially) homologous sequences. Chromosomes may “grow” by active dispersion of retroelements or “shrink” by excision of transposons or exonucleolytic degradation of break ends during repair processes.

Secondary Rearrangements

Unstable products of primary rearrangements, e.g., dicentric chromosomes (resulting from asymmetric translocations), or ring chromosomes (resulting from intrachromosomal translocations), may initiate “breakage-fusion-bridge” cycles and eventually yield stable chromosomes with further inversions, duplications, or deletions^[7] (Fig. 2c).

Even stable primarily reconstructed chromosomes may cause secondary rearrangements by meiotic crossover between homologous regions of translocation chromosomes when combined in heterozygous condition^[7] (Fig. 2d).

Mis-segregation from meiotic multivalents within individuals heterozygous for two whole-arm translocations involving one meta- and two acrocentric chromosomes may alter the euploid chromosome number of a complement simultaneously in both directions^[8] (Fig. 2e). In principle, all types of chromosome modification may contribute individually or in combination to chromosome evolution. However, comparative mapping, chromosome banding, and/or painting often revealed preferences for specific types of modifications during the chromosomal evolution of related groups of organisms.

Tolerance Limits for Chromosome Evolution

Finally, there are apparently upper and lower (species-specific) tolerance limits for chromosome size. Chromosome arms longer than half of the spindle axis dimension at telophase yield disturbances during nuclear divisions, caused by incomplete separation of the corresponding sister chromatid arms.^[9]

On the other hand, chromosomes falling below a lower size limit (<1% of the genome) frequently do not

segregate correctly during meiosis (even if an original centromere is present), and thus are not transmitted to the progeny.^[10] Although the reason for this behavior (e.g., lack of homologous pairing or need for a minimal “lateral support” of centromeres) is not yet evident, it bears severe consequences for the construction of artificial mini-chromosomes.

Circadian Clock in Plants

C. Robertson McClung

Dartmouth College, Hanover, New Hampshire, U.S.A.

INTRODUCTION

The circadian clock is an endogenous oscillator that drives rhythms with periods of approximately 24 hours. By definition, these circadian (*circa*, approximately; *dies*, day) rhythms persist in constant conditions and reflect the activity of an endogenous biological clock. Plants are richly rhythmic and the circadian clock regulates a number of key metabolic pathways and stress responses. In addition, the circadian clock plays a critical role in the photoperiodic regulation of the transition to flowering in many species.

AN OVERVIEW OF THE CIRCADIAN SYSTEM

The circadian clock has a number of defining characteristics.^[1,2] The period of the rhythm is approximately—but seldom exactly—24 hours. The clock is self-sustaining, meaning that oscillations persist in constant conditions. Environmental time cues entrain the clock, synchronizing it with the local daily cycle. Thus, the circadian system consists of three components: input pathways that entrain the clock, the central oscillator (clock), and output pathways to generate overt rhythms (Fig. 1).

OUTPUTS: RHYTHMIC PROCESSES IN PLANTS

Many plant processes exhibit circadian oscillations. The earliest described rhythms were in leaf movement.^[1,2] These are often seen in legumes, in which they are generated by a specialized organ called the pulvinus. Circadian-gated fluxes of ions and water cause cells in the extensor and flexor regions of the pulvinus to swell in antiphase (i.e., 180° out of phase) to drive a circadian oscillation in leaf position. These leaf movements may have adaptive value in regulating perception of photoperiodic light signals.^[2] *Arabidopsis thaliana* lacks a pulvinus, but displays rhythms in cell elongation, and thus in growth rate. For example, there is a circadian rhythm in the elongation rate of the abaxial and adaxial cells of the

petiole that confers an oscillation in position of cotyledons and leaves. Similarly, there are oscillations in the elongation rates of the hypocotyl and the inflorescence stem. Such rhythms are easily monitored by video imaging.^[1,2] Other physiological properties—such as stomatal aperture and conductance, the rate of CO₂ assimilation, and the activities of enzymes of the Calvin cycle—are also regulated by the clock in some species.^[2] Examples of rhythmic processes of *Arabidopsis* are shown in Fig. 2.

The circadian clock controls the expression of many plant genes. Rhythms in mRNA abundance are observed in 5–10% of all genes, and the peaks in mRNA abundance for different genes occur at distinct circadian phases.^[3] Because circadian regulation of transcription underlies the rhythmic expression of many genes, it seems likely that the clock directly regulates the expression of transcription factors; the different transcription factors then coordinately confer circadian expression patterns on suites of genes.^[2] For example, 23 genes encoding enzymes of phenylpropanoid biosynthesis are coordinately regulated, oscillating with mRNA peaks about 4 hr before subjective dawn.^[3] Oscillating together with these genes is PRODUCTION OF ANTHOCYANIN PIGMENT 1 (*PAP1*), which encodes a Myb domain transcription factor shown to regulate the transcription of several genes encoding enzymes of the pathway. This offers the likely scenario that the clock regulates *PAP1* expression, which in turn regulates the entire phenylpropanoid biosynthetic pathway.

Although nuclear run-on experiments have been employed to demonstrate circadian regulation of transcription, the current method of choice is the measurement of light production from plant promoter::firefly luciferase gene fusions (Fig. 2C). Using this approach, a number of promoters have been characterized and it is now possible to select a promoter to drive transcription at essentially any circadian phase of choice.^[2]

The timing of flowering in many species is photoperiodic, and circadian timekeeping is essential for photoperiodic time measurement. Many mutations that affect circadian rhythms in gene expression and leaf movement also affect flowering timing.^[4] *CONSTANS* (*CO*) encodes a Zn finger transcription factor that plays a key role in the integration of circadian timekeeping and day-length

Fig. 1 A simplified scheme illustrating the three components of the circadian system. (View this art in color at www.dekker.com.)

peak in the light. Post-transcriptional regulation of CO activity by light is required for the transcriptional activation of FLOWERING LOCUS T (*FT*), a CO target gene whose expression is sufficient to induce flowering.^[5] Thus, in long days CO is activated, *FT* is transcribed, and flowering is promoted.

perception.^[5] *CO* mRNA abundance oscillates and the phase of the peak in *CO* mRNA varies with photoperiod such that only in long days does *CO* mRNA abundance

ENTRAINMENT (INPUT)

Any biological circadian clock must be reset in response to the local daily cycle. For example, imbibition (the hydration of the dry seed) will synchronize the clocks

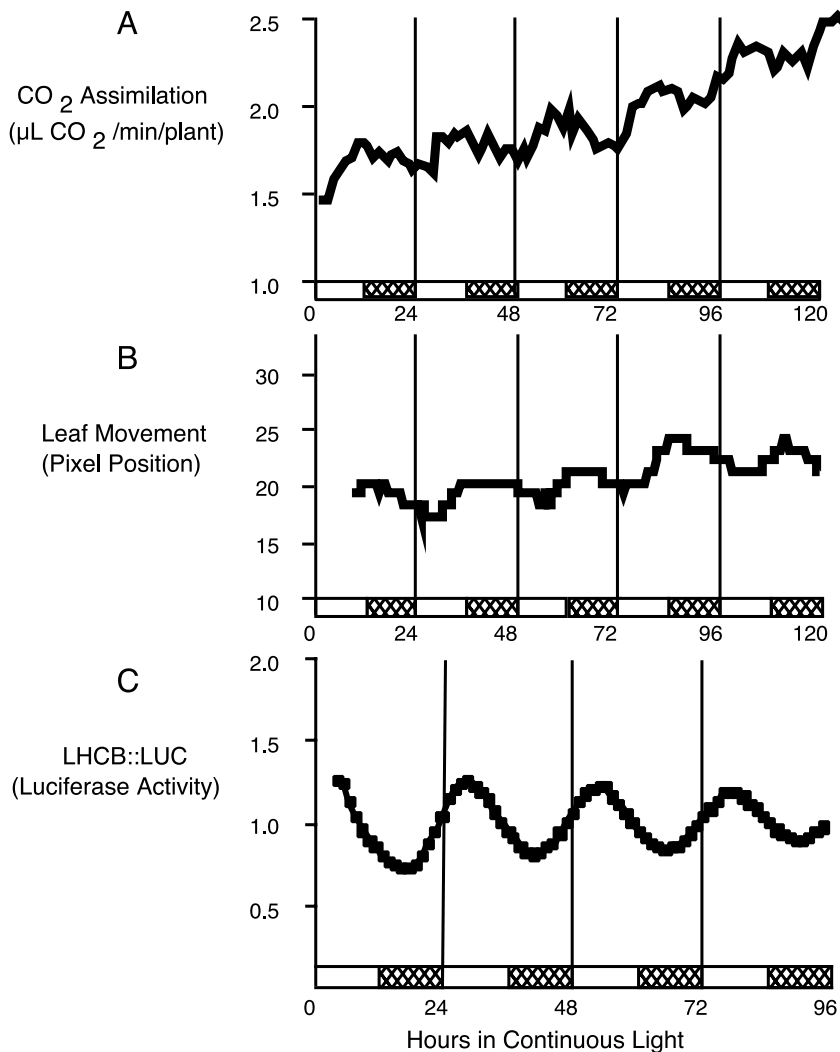

Fig. 2 Typical clock outputs in *Arabidopsis thaliana*. A. CO₂ assimilation; B. Leaf (cotyledon) movement; C. Transcription of the LIGHT-HARVESTING CHLOROPHYLL a/b BINDING PROTEIN gene (*LHCb*) as measured by luciferase (*luc*) activity in seedlings transformed with *LHCb::LUC* transcriptional gene fusions. For each assay, wild type seedlings (Accession Columbia) were grown in a light–dark (12–12) cycle and then transferred into continuous light at *T* = 0. The entraining light–dark regimen is indicated by the bars underneath each graph, where open bars indicate subjective day and the hatched bars indicate subjective night.

in a population of seedlings.^[2] The most common stimuli that entrain the circadian clock are light and temperature. Little is known of the mechanism by which temperature is perceived and the signal is transmitted to the clock. Considerably more is known about photoperception and the clock. Plants have a number of photoreceptors. Both phytochromes (PHY, sensitive to red/far-red light, and also to blue light) and cryptochromes (CRY, sensitive to blue light) provide light signals to establish period length and phase and to entrain the clock.^[6] The sensitivity of the clock to entraining stimuli varies at different times of day. Typically, light prior to dawn advances and light after dusk delays the phase of the clock, whereas light at midday has little effect. The abundance of PHY and CRY photoreceptors is itself a clock output^[7] and light signaling is modulated (gated) by the clock, providing at least part of the mechanistic explanation of how the clock modulates its own sensitivity to light.

Additional plant photoreceptors are known. The phototropins do not seem to provide input to the circadian clock. However, other potential photoreceptors may provide input to the clock. Three LOV (light, oxygen, voltage) DOMAIN KELCH PROTEINS [LKP, also called ZEITLUPE, (ZTL), FLAVIN-BINDING, KELCH REPEAT, F-BOX (FKF), or ADAGIO (ADO)] contain the LOV domain, which may function in photoreception.^[2,6] Misexpression (loss of function or overexpression) of these proteins confers circadian defects. Kelch repeats allow protein–protein interactions, whereas the F-box is a motif that allows the targeting of other specific proteins for ubiquitination and degradation by the proteasome, suggesting a role for these proteins in the light-regulated degradation of circadian oscillators or in input or output pathway components.

Several other components have been implicated in circadian photoperception. Loss of EARLY FLOWERING 3 (*ELF3*) function results in early flowering, hypocotyl elongation, and conditional arrhythmicity in continuous light.^[2,6] *ELF3* is clock-regulated; both transcript and protein accumulation peak at dusk. *ELF3* encodes a nuclear protein that interacts with PHYB and is a negative modulator of PHYB signaling to the clock. *GIGANTEA* (*GI*) is another clock-controlled gene implicated in PHYB-mediated light input. *gi* mutants are altered in the leaf movement and gene expression rhythms of multiple genes.^[2,6] The period-shortening effect of *gi-1* on gene expression rhythms is less severe in extended dark than in continuous light. The extension of period length seen in light of decreasing fluence is less pronounced in *gi-1* than in wild type, which indicates that *GI* acts in light input. *gi* mutants are late-flowering—opposite to the early-flowering phenotype of *elf3* and *phyB* null alleles.

Perhaps *GI* and *ELF3* mediate *PHYB* signaling to the clock, but their effects on flowering time are mediated through another signaling pathway.

THE OSCILLATOR: INTERLOCKED NEGATIVE AND POSITIVE FEEDBACK LOOPS

Circadian oscillators typically are composed of two interconnected feedback loops, one positive and one negative.^[8] With the determination of the complete sequence of the Arabidopsis and rice genomes, no obvious orthologs to most known clock proteins can be found, demonstrating that at least part of the plant clock mechanism is novel. Key oscillator components include two single Myb domain transcription factors: CIRCADIAN CLOCK ASSOCIATED 1 (*CCA1*) and LATE ELONGATED HYPOCOTYL (*LHY*), and TIMING OF CAB EXPRESSION 1 [also called ARABIDOPSIS PSEUDO-RESPONSE-REGULATOR 1 (*TOC1/APRR1*)].

mRNA abundances of *CCA1*, *LHY*, and *TOC1* oscillate. If oscillation is necessary for clock function—as would be predicted for a clock component—then clamping mRNA or protein abundance at either high or low levels should eliminate clock function. Indeed, overexpression of any of these three genes results in arrhythmicity of multiple clock outputs.^[2,9] Although loss of *CCA1* or of *LHY* function shortens the period of mRNA oscillation in multiple clock-controlled genes, the plants retain rhythmicity. However, the double *cca1 lhy* mutant is arrhythmic in leaf movement, which is consistent with *CCA1* and *LHY* playing necessary, albeit redundant, roles for sustained oscillator function.^[10,11] Loss of *TOC1* function shortens the period length, suggesting that another component plays a partially overlapping role with *TOC1* in clock function. The identification of this component is a key goal. *CCA1* overexpression results in reduced accumulation of *TOC1* mRNA, indicating that *CCA1* is a negative regulator of *TOC1*. Loss of *TOC1* function reduces accumulation of *CCA1* mRNA, suggesting that *TOC1* is a negative regulator of *CCA1*.^[10] Thus *CCA1*, *LHY*, and *TOC1* compose a negative feedback loop of the sort found in other circadian oscillators (Fig. 3).^[2,9,12] *TOC1* is a member of a family of five *APRR* genes. mRNA abundance of the other four members also oscillates. However, whether these genes play roles in input pathways or in the oscillator itself—or simply represent clock outputs—remains to be established.^[2]

Another link to other circadian oscillators is the role of phosphorylation by casein kinase 2 (*CK2*). Binding of *CCA1* to its recognition site in clock-regulated

Fig. 3 A model of an Arabidopsis circadian system. Light input to the clock occurs via PHY and CRY, whose expression is clock regulated. In addition, light signaling to the clock is gated by the clock-regulated activity of ELF3 and GI. ZTL binds to PHYB and CRY1, and may mediate their degradation. At least some PHYB signaling occurs via PHYTOCHROME-INTERACTING FACTOR 3 (PIF3)—which binds to CCA1 and LHY promoters and possibly to other targets in the clock—and activates transcription when bound by PHYB. A central oscillator with a number of oscillator components is illustrated. CCA1 and LHY are phosphorylated by CK2, which is required for binding of CCA1 to the *LHCB* promoter. A family of TOC1 related ARABIDOPSIS PSEUDO-RESPONSE REGULATORS (APRRs) may function within the oscillator or as input (or output) pathway components. Output pathways may emanate from any of the putative oscillator components. (View this art in color at www.dekker.com)

promoters requires its phosphorylation by CK2.^[2] CK2 abundance is not clock-regulated. Nonetheless, misregulation of CK2 disrupts clock function. Proteolytic degradation has been shown to play important roles in other clock systems; phosphorylation is also required for substrate recognition by F-box proteins such as the LKP family. The degradation of clock components in response to environmental time cues may be a critical step in plant oscillator function, and may also contribute to resetting the clock.

CONCLUSION

The plant circadian clock is composed of a negative feedback loop in which one component (TOC1) is a positive regulator of a second component (CCA1 and LHY) which, in turn, negatively regulates the expression of the first component. The clock is entrained to environmental time cues via input pathways that monitor environmental stimuli such as light and temperature. The clock regulates its sensitivity by regulating the expression and activity of input pathway components. Multiple

output pathways emanate from oscillator components to drive overtly rhythmic processes.

Citrus Canker

Rui Pereira Leite Júnior

IAPAR, Londrina, Parana, Brazil

INTRODUCTION

Asiatic citrus canker (canker A), caused by the bacterium *Xanthomonas axonopodis* pv. *citri*, is one of the most important diseases of citrus. The disease probably originated in Southeast Asia and continues to increase its geographic distribution around the world despite the quarantine regulations imposed by several countries. Citrus canker has been reported in almost all of the major citrus-growing areas of Southeast Asia, North America, and South America.^[1,2] In general, the pathogen becomes established and disease may be severe in regions where temperatures and precipitation are high during the growing season.

Other forms of canker have been reported on citrus. Cancrosis B, caused by strain B of *X. axonopodis* pv. *aurantifolii* (= *X. campestris* pv. *citri* strain B), occurs on lemons in Argentina, Paraguay, and Uruguay.^[1] The disease also affects other *Citrus* spp., such as Mexican lime (*C. aurantifolia*), Pummelo (*C. grandis*), and sour orange (*C. aurantium*). Cancrosis B infects leaves, fruits, and twigs causing lesions similar to, but smaller than, those of canker A. Cancrosis C, caused by the strain C of *X. axonopodis* pv. *aurantifolii* (= *X. campestris* pv. *citri* strain C), was reported on Mexican lime in the State of São Paulo, Brazil.^[3] *X. axonopodis* pv. *aurantifolii* strain C is pathogenic only to Mexican lime and does not occur on other *Citrus* spp. Symptoms are identical to those of canker A. Atypical forms of canker A have been reported on Mexican lime in several countries in the Middle East.

SYMPTOMS

Citrus canker may occur on all above-ground parts of the citrus tree. Symptoms of this disease are very characteristic, but may vary depending on the citrus cultivar, organ affected, and age of the tissue at infection. Citrus canker symptoms appear within 10 days of inoculation as pin-point, raised, cream-colored spots <1 mm in diameter. Foliar lesions are circular and tend to be similar in size (Fig. 1), because tissues are susceptible for only a short time allowing only one infection period. Galleries of the citrus leaf miner (*Phyllocnistis citrella*) can be infection courts for *X. axonopodis* pv. *citri*, increasing the number of lesions on infected

tissues. Lesions developing from leaf-miner galleries usually coalesce to form large, irregular lesions. Lesions are raised on both sides of citrus leaves and later become corky and crateriform, with raised margins and sunken centers. Older lesions become brown and are surrounded by a characteristic yellow halo.

Canker lesions on fruits and stems are similar to those on leaves (Figs. 2 and 3). However, lesions on fruits tend to be larger, with the central part more crateriform and having a spongy center. Citrus canker may cause fruits to crack as they enlarge and develop thicker rinds. Infected fruits usually drop before they reach maturity. Unlike foliar lesions, lesions on fruits vary in size because fruits are susceptible for a longer time, and infection may occur at different stages of fruit development. Cankers on stems are more common on highly susceptible citrus cultivars, and such lesions may coalesce, girdling and killing the stems.

CAUSAL AGENT

X. axonopodis pv. *citri* (Hasse) Vaut. [= *X. campestris* pv. *citri* (Hasse) Dye] is gram negative with single and straight, rod-shaped cells. The bacterium is motile by a single polar flagellum and is strictly aerobic. Colonies on nutrient agar medium are smooth, circular, raised, and yellow. The yellow color is due to the pigment xanthomonadin, which is a characteristic brominated aryl polyene present in most xanthomonads. The optimum temperature for growth is 28–30°C, with growth at minimum and maximum temperatures of 5°C and 35°C, respectively.

X. axonopodis pv. *citri* can be identified based on serology, bacteriophage typing, fatty acid profile analysis, polymerase chain reaction-based methods, and DNA analysis. The bacterium can also be differentiated from strains of *X. axonopodis* causing other forms of citrus canker by pathogenicity tests on different susceptible and resistant citrus hosts.

DISEASE CYCLE

Although *X. axonopodis* pv. *citri* has a large host range among members of the Rutaceae family with

Fig. 1 Lesions of citrus canker on leaf of sweet orange. (View this art in color at www.dekker.com.)

artificial inoculation, apart from *Citrus* spp., only *Poncirus trifoliata* and its hybrids are susceptible enough to be of epidemiological significance.^[1] The bacterium does not have the capability for long-term survival in plant debris, weeds, or soil.^[4,5] *X. axonopodis* pv. *citri* may survive a few days in soil and a few months in infected, decomposing plant debris.^[6]

The primary source of inoculum for *X. axonopodis* pv. *citri* is active lesions on leaves, fruits, and stems.

Fig. 2 Lesions of citrus canker on fruits of sweet orange. (View this art in color at www.dekker.com.)

Fig. 3 Lesions of citrus canker on stem of *Poncirus trifoliata*. (View this art in color at www.dekker.com.)

In the presence of free moisture on the lesions, the bacteria ooze out and can be spread to infect new growth. The bacterium has been detected in concentrations of 1×10^6 to 1×10^9 colony-forming units per milliliter in rain water collected from the foliage of infected citrus trees.^[7]

Wind-driven rain is the main dispersal mechanism of *X. axonopodis* pv. *citri* over short distances, i.e., among trees within an orchard. Wind speeds higher than 8 m/sec favor the entry of the bacterium through natural openings such as stomata, lenticels, or wounds.^[1] Dispersal over longer distances may occur with hurricanes, storms, and tornadoes. However, worldwide dissemination probably occurs with infected planting material, such as budwood, rootstock seedlings or nursery trees, and fruits. Harvesting boxes and others tools used in the handling of diseased fruits and plants has also been implicated in the long-distance spread of the bacterium.

Leaves and stems are more susceptible to infection within 40 days after initiation of growth. The most important period for fruit infection is within 90 days after petal fall.^[1] Mature leaves, stems, and fruits are resistant to canker, though infection may occur through wounds caused by thorns, insects, and other abrasives.

CONTROL

Measures to prevent the introduction, establishment, and dispersal of *X. axonopodis* pv. *citri* have been enforced in several countries where citrus canker is not endemic or is present in confined locations. When *X. axonopodis* pv. *citri* is introduced into an area, elimination of inoculum by removal and destruction of infected and exposed trees is employed. Eradication of citrus canker was successful in Australia, Mozambique, New Zealand, South Africa, the United States, and Zimbabwe in the first half of the 1900s.^[1] However, due to reintroduction of the bacterium, eradication programs are again currently underway in Florida and Brazil.^[6]

In regions where citrus canker is endemic, integrated disease management strategies are being employed.^[6] The integrated management of canker combines practices such as choice of planting site, planting of healthy nursery trees, use of more resistant citrus cultivars, windbreaks, leaf-miner control, and copper sprays.^[6] The choice of planting site should take into account not only the agronomic and climatic aspects for cultivation of citrus, but also should avoid environmental conditions favorable for citrus canker development.^[1,8] Places exposed to strong winds should be avoided and new orchards should be planted only in areas without recent occurrences of citrus canker.^[1] Production and commercialization of *X. axonopodis* pv. *citri*-free nursery trees has been a regulatory requirement in areas of endemic citrus canker, because young citrus trees are highly susceptible.^[1] A major component of the integrated management of citrus canker is the prohibition of planting highly susceptible citrus cultivars. Combining moderately resistant citrus cultivars,^[1,9] with other control measures may eventually eliminate citrus canker from citrus groves. The use of windbreaks is probably the most effective measure for managing the disease on susceptible citrus cultivars and has been implemented in several regions where canker is endemic.^[1,6,9] Windbreaks will reduce the dispersal of the pathogen in the orchard during wind-driven rain and may prevent wounds on the above-ground parts of the citrus tree that are important sites for penetration of the bacterium in the plant tissue.^[1,6,9] Application of copper-based bactericides have been effective in protecting the new flushes and fruits from infection by *X. axonopodis* pv. *citri*. However, the success of copper-based compounds depends on the susceptibility of the citrus cultivar, environmental conditions, and adoption of other control practices.^[1,9,10] Control of citrus canker on less-susceptible citrus cultivars may be achieved with two to three copper sprays, whereas susceptible or highly susceptible cultivars may require more sprays and other control practices to provide acceptable disease control.^[1,9,10]

CONCLUSIONS

Citrus canker is one of the most important diseases of citrus worldwide. The incidence of citrus canker has increased in recent years and outbreaks have been reported in major citrus-growing areas of Argentina, Brazil, and Florida. Programs based exclusively on exclusion, quarantine restrictions, and eradication have not contained the pathogen, nor eliminated it from areas where it was introduced. There is a need for more effective measures to prevent and suppress the occurrence of citrus canker. Integrated management approaches have been implemented successfully in some citrus-growing areas and hold great potential for effective prevention and suppression of citrus canker in the future.

Classification and Identification of Nematodes

James G. Baldwin

University of California, Riverside, California, U.S.A.

INTRODUCTION

Although nematodes (Phylum Nematoda) are the most abundant multicellular organisms on Earth, plant parasites probably include less than 1% of all nematode species, and only a few hundred principal species are responsible for the billions of dollars of crop losses annually. However, a broad perspective of nematode classification is pertinent to agriculture. Many species that are not plant parasites nevertheless impact crops. For example, soil microbivore nematodes are a critical component of the soil ecosystem and play a crucial role in regulating nutrient recycling. Furthermore, some entomo pathogenic nematodes are biocontrol agents for insect pests.

CLASSIFICATION

All plant parasites feed by a protrusible stylet or spear, and this puncturing tool has arisen independently in three highly divergent orders, Tylenchida, Dorylaimida, and Triplonchida (Table 1); all of these orders also include nonplant parasites that use stylet or spear adaptations to feed on fungi, algae, or small soil organisms.^[1]

GOALS AND TOOLS OF CLASSIFICATION

A goal of taxonomy is to develop a classification that reflects the evolutionary (phylogenetic) history of nematodes, because such a system is sure to have the greatest predictive value for extending knowledge (including pathogenicity) about well-known model species to newly-discovered or less-studied taxa. A predictive classification also serves as the basic tenet of science: repeatability. In contrast, past nematode classification systems often have been largely arbitrary or based on convergent ecological behaviors or typological approaches to morphological characters. Often these morphological characters have been too few, and their homology and polarity inadequately understood to infer patterns of evolution. In

many cases, these classifications have been fragmented and contradictory across practical fields of plant pathology, parasitology, medicine, entomology, and ecology.

New tools and methodologies, are now testing, integrating, and sometimes challenging extant classification systems using computer-based algorithms for integrating large matrices of phylogenetically informative novel characters from molecules, fine structure, and comparative development.^[2] Molecular-based phylogenetic analyses, while substantially congruent with morphological phylogenetic analyses, are the impetus for revised classification systems that realistically place plant parasites within their nonparasitic context. Whereas most have considered nematodes to include two classes, Secernentea and Adenophorea (Table 1), new characters are resurrecting old challenges of Adenophorea as an evolutionary unit, and may thus lead to its elimination from classification systems.^[2] New morphological and molecular characters also justify removal of trichodorid plant parasites, formerly in the Dorylaimida, into the Triplonchida, which is closely aligned with enoplids, a group largely comprising aquatic and marine nematodes.^[2-4]

Advances in a phylogenetic classification of nematodes require knowledge of new characters and inclusion of far more representative taxa in phylogenetic analyses. This is particularly true for the Tylenchida, the order including the majority of crop parasites (Table 1). Although molecular tools have been applied in tylenchid diagnostics and toward resolving phylogenetic relationships of limited groups of genera or species, large-scale molecular-based phylogenies of the order are still being developed and are presently unlikely to resolve some of the more problematic families for revised classification.^[5,6] Monophyly (sharing a unique evolutionary history) of Heteroderinae, including cyst (e.g., *Heterodera*, *Globodera*) and root knot (*Meloidogyne*) nematodes is challenged, as is the monophyly of Pratylenchidae. An issue of particular significance is whether Tylenchina share a unique evolutionary history with all Aphelenchina, and how these are best represented in classification, since new phylogenetically informative characters have only been considered for a few representatives in the latter.

Table 1 Overview of extant higher classification of some important plant-parasitic nematodes

Class—SECERNENTEA
Order—TYLENCHIDA ^a
Suborder—TYLENCHINA
Superfamily—TYLENCHOIDEA
Family—ANGUINIDAE
<i>Anguina</i> —seed gall
<i>Ditylenchus</i> —stem and bulb
Family—BELONOLAIMIDAE
<i>Tylenchorhynchus</i> —stunt
<i>Belonolaimus</i> —sting
Family—PRATYLENCHIDAE
<i>Pratylenchus</i> —lesion
<i>Radopholus</i> —burrowing
<i>Hirschmanniella</i>
<i>Nacobbus</i> —false root knot
Family—HOPLOLAIMIDAE
<i>Hoplolaimus</i> —lance
<i>Helicotylenchus</i> —spiral
<i>Rotylenchus</i> —spiral
<i>Rotylenchulus</i> —reniform
Family—HETERODERIDAE
<i>Heterodera</i> —cyst
<i>Globodera</i> —cyst
<i>Meloidogyne</i> —root knot
Superfamily—CRICONEMATOIDEA
Family—CRICONEMATIDAE
<i>Criconemoides</i> —ring
<i>Macroposthonia</i> —ring
<i>Hemicycliophora</i> —sheath
Family—TYLENCHULIDAE
<i>Tylenchulus</i> —citrus
Suborder—APHELENCHINA ^b
Superfamily—APHELENCHOIDOIDEA
Family—APHELENCHOIDIDAE
<i>Aphelenchoides</i> —foliar
Family—PARASITAPHELENCHIDAE
<i>Bursaphelenchus</i> —pinewood
<i>Rhadinaphelenchus</i> —red ring
Class—ADENOPHOREA ^c
Order—DORYLAIMIDA
Suborder DORYLAIMINA
Superfamily—DORYLAIMOIDEA
Family—Longidoridae
<i>Longidorus</i> —needle
<i>Xiphinema</i> —dagger
Order TRIPLONCHIDA ^c
Suborder DIPHTHEROPHORINA
Superfamily Trichodoroidea
Family—Trichodoridae
<i>Trichodorus</i> —stubby root

^aAdapted from Ref. 9. See Ref. 10 for a more recent classification of Tylenchida.

^bMany consider Aphenchina to be in a distinct order, Aphenchida. For a detailed classification see Ref. 11.

^cSee Refs. 2–4 for a discussion of Triplonchida relative to Dorylaimida and related issues of monophyly of Adenophorea.

DIAGNOSTICS

Where the goal of classification is to reflect evolutionary history, the assigned level/rank of higher taxonomic categories takes on less importance than the overall relationships reflected by the nesting of those categories. What is not arbitrary, however, is “species,” a category widely understood to be the fundamental evolutionary clade but with considerable discussion as to both the ideal of a species as a real entity and practical operational approaches for recognizing species.^[7] In practice, most species of nematodes have been delimited by morphological uniqueness. The result often has been confusion in failing to recognize cryptic species (morphologically similar but evolutionarily independent), or to recognize intraspecific polymorphism or frequent hybridization. Yet, meaningful repeatable research with predictive power requires minimizing errors in recognizing and recovering true species.^[7]

A wide range of morphological and molecular tools may be useful toward discovering the evolutionary units of species, and once species are recognized with some certainty, practical tools for routine diagnosis often can be developed. Ideally, these tools are morphological characters, molecular markers, or behaviors (i.e., host range) that are easily scored and so perfectly congruent with “true species” that they represent a shortcut to identification.

On the most practical level, diagnosis of plant disease caused by soil nematodes requires special consideration, because typical symptoms include general poor health, chlorosis, sensitivity to drought, and increased vulnerability to additional diseases. Such symptoms are often ambiguous and can be attributed to factors other than nematodes. In field crops, patches of distressed plants among a general pattern of otherwise healthy plants may be indicative of parasitic nematodes. In many cases, diagnosis is aided by special knowledge of vulnerability of a particular crop to a certain nematode; such recognition can narrow the diagnostic process to a few simple tests. For example, evaluation of the cause of unthrifty patches of soybean plants might always include the possibility of the soybean cyst nematode. Similarly, heavily galled tomato roots or badly distorted carrot roots are a strong indicator of the presence of one or more species of root-knot nematode. In these cases, diagnostic confirmation involves isolating nematodes from roots and surrounding soil using a combination of washing and sieving. Sometimes the isolation procedure involves centrifugation to separate nematodes from soil particles, and perhaps (depending on the species) it may be practical to dissect individual nematodes directly from roots. Nematodes collected in a small dish typically then are examined with a compound microscope and the diagnosis is made based on specific morphology of the nematode. We have noted that new tools are emerging to complement morphological diagnosis, but important challenges remain.

SHORTCOMINGS OF DIAGNOSTIC TECHNIQUES

Extant diagnostic techniques have important limitations. For example, perineal patterns, host ranges, or esterase electrophoresis patterns have been used to diagnose *Meloidogyne* species; unfortunately, because of intraspecific variability, any one criterion falls short of certainty. Similarly, molecular markers such as ITS region or D2/D3 regions of 28S rDNA are often developed based on limited screening, with the possibly faulty assumption that these characters are congruent with species. The difficulties of recognizing species are illustrated by the long controversy related to the burrowing nematode *Radopholus similis*. This species, as currently defined,^[8] includes geographically limited isolates that attack citrus, and widespread isolates that do not. Although there has been a long search for morphological, karyotypical, biochemical and behavioral markers to separate this host polymorphism and define separate species (i.e., *R. similis* and *R. citrophilus*), ITS and D2/D3 examination of globally distributed isolates was used to vindicate their placement, regardless of host range, in a single species. Conversely, one burrowing nematode isolate from Australia, while morphologically similar to *R. similis*, had unique molecular markers (35 autapomorphies) and did not share a clade with *R. similis*.^[8]

In agricultural nematology, there is sometimes a conflict of goals between those that would define and diagnose species as an evolutionary unit and those that seek a practical diagnosis to predict host range and pathogenicity for management strategies, including crop rotation, host resistance, or quarantine. In the latter case, the ideal is a marker, not necessarily for species as evolutionary unit, but whatever unit (including sub- or super-specific) is linked to a particular host range or pathogenicity. With advances in genomics, we anticipate that in addition to reliable markers for species diagnosis, it ultimately will be feasible to independently diagnose isolates for particular genetic markers for pathogenicity. Presently, for example, quarantines designed to protect citrus target the species *R. similis*, but we anticipate a future in which quarantines can be focused at those isolates of *R. similis* that are pathogenic to citrus.

Presently, for most taxa, morphological diagnosis of species is the primary option, and for others it remains the benchmark for evaluating the diagnostic effectiveness of molecular and other markers. However, new tools bring promise of classifications that reflect evolution, support research on models to understand pathways for pathogenicity, and more specifically diagnose and manage crop disease agents.

Classification and Nomenclature of Plant Pathogenic Bacteria

John M. Young

Landcare Research, Auckland, New Zealand

INTRODUCTION

Fundamental to bacterial taxonomy is the interdependence of classification, nomenclature (naming), and identification. Without identified strains it is impossible to perform comparative taxonomy to classify and to name taxa. Without the establishment of phenotypic descriptions, bacterial strains cannot be allocated to taxa and novel taxa cannot be recognized.

The Approved Lists of Bacterial Names recognizes only the names of bacterial species for which there are modern descriptions permitting species to be distinguished from one other, and at least one extant strain that can be accepted as the type, or name-bearing, strain. In 2002, 5806 bacterial species in about 1094 genera were recognized. Plant pathogenic bacteria are recorded in 132 species in 29 genera. Within these taxa are several hundred pathogens, many recognized as pathovars (see below) that are, to some degree, specific to their host plant species and genera.

APPROACHES TO CLASSIFICATION

Classification is the ordering of bacteria into natural groups. Different approaches lead to different classifications and hence, to different nomenclature. Phenetic classifications (those based on the overall similarities and differences between bacteria) and phylogenetic classifications (those based on the inferred ancestral relationships of bacteria) of plant pathogenic bacteria have been discussed in detail elsewhere.^[1] Polyphasic classification, based on a consensus of data gathered by all available methods that would be consistent with phylogenetic classification, has been suggested to be the best approach to bacterial classification.^[2] Where several methods are employed in taxonomic studies, as in the polyphasic approach, there is an assumption that there will be a concurrence of groupings resulting from the different methods of study.^[3,4] However, in practice, where comprehensive studies of species have been made, this assumption is not always borne out.^[5]

With the refinement of bacterial classification offered by the development of molecular methods and the recog-

nition of previously unacknowledged bacterial diversity, a phylogenetic species concept that emphasizes DNA–DNA reassociation values has become the standard for species definition. In a recent revision, a species concept was proposed that took account of both DNA–DNA reassociation and phenotypic studies.^[4] A protocol for generic characterization emphasized the need for clarity of descriptions based on phenotypic properties at the level of genera, the impracticability of defining genera solely on the basis of phylogenetic data, and the priority of phenotypic characterization over phylogenetic inference.^[3]

IDENTIFICATION

The rapid and reliable identification of isolates may be the most important task in taxonomy. Strains of taxa (species and genera) that were described using older technologies, and for which determinative keys were developed, can still be readily identified.^[6,7] A problem arises for strains of taxa based on genomic and multiple-character methods alone, because they cannot readily be allocated to their genus or species due to a lack of determinative tests. There are now many named species found on plant surfaces that, if isolated from a plant other than their host, would be almost impossible to identify directly according to the most recent nomenclature.

Molecular techniques have greatly improved detection and identification of some organisms, because they provide probes that are specific at generic, specific, and lower levels. Probes are now regularly made that can identify bacterial pathogens as specific pathovars. There is now a choice of many probes with different levels of sensitivity that can be used to establish the presence of specified bacteria as clonal groups, infrasubspecies, and higher taxonomic groups.^[7] Most importantly, molecular probes are now available to identify phytoplasmas or mycoplasma-like organisms that cannot yet be cultivated. Probes have been developed as antibodies, DNA oligonucleotides, and polymerase chain reaction (PCR) primers that can be used to amplify specific DNA sequences in target organisms. Their use is restricted to the identification of

the particular organism for which the probe is designed and do not permit the identification of bacterial isolates in general. The search now is for a universal character or small set of characters, revealed in a single analytic step or by a small number of steps, that identifies species and genera that have been comprehensively classified by phenetic or polyphasic methods.

MISUNDERSTANDINGS OF BACTERIAL NOMENCLATURE

Type Strains Are Not Necessarily Typical

For the publication of a valid bacterial species name, *The International Code of Nomenclature of Bacteria* requires proposal of a name, a description of the taxon, and the designation of a nomenclatural type strain. The type strain should not be expected to be representative of the taxon as a whole and it is not necessarily the most typical or representative strain of the taxon. Mistakes can be expected when taxa are being tested for the presence or absence of small numbers of characters, and deductions are made based on the type strain alone.

Names of Taxa Are Not Necessarily Descriptive

For bacteria, there has been a strong tradition of proposing names that are descriptive of a significant character of the taxon. Descriptive terms necessarily refer to one or a few characters, often regulated by small numbers of genes and therefore not present in all members of the taxon (e.g., not all members of *Agrobacterium tumefaciens* cause tumors, and not all members of *Xanthomonas* are yellow). In many cases, revisions of descriptions, especially of species, result in complete or almost complete dissociation between a taxon's description and the descriptive element shown by the name. Indeed, as the extent of bacterial heterogeneity becomes more apparent, the expectation that the members of taxa established using natural phenetic or polyphasic classifications will share more than a small number of common characters diminishes. This caution should also be applied to special purpose names such as those of pathovars. Pathovar names, commonly ascribed on the basis of the host plant from which the pathogen was first isolated, can become misleading as a wider host range of the pathogen may be realized.^[1]

Species Can Have Several Valid Names

Formal revisions of bacterial classification regularly lead to changes in the names of bacterial species and genera. Although any taxon that is based on the same type strain

can have only one name, subdivisions and amalgamations of taxa mean that there can be several valid names applied to taxa, from which a choice may be made. Revisions can sometimes produce incomplete and unsatisfactory nomenclature. No error is committed provided names are chosen, even those not based on the most recent classification, that are legitimate and validly published.^[5,8]

PATHOVARS

Historically, many names of plant pathogens were applied to bacterial populations that could not be classified as species and so could not be included in the *Approved Lists*. After 1980, pathogens were therefore classified in a special purpose classification at the infrasubspecies level, as pathovars. The International Society for Plant Pathology proposed that pathovars be named according to nomenclatural standards^[9,10] complementary to *The International Code of Nomenclature of Bacteria*. Pathovar classification and nomenclature is based on the capacity of particular bacterial populations to cause distinctive disease syndromes in plants in nature, or refers to their distinct host ranges. Such populations are characterized by their pathogenicity mechanisms (implying distinct combinations of pathogenicity genes).^[1,12]

There is ample evidence to show that many pathovars are specific to relatively small numbers of host species and genera.^[13] Some of these are highly virulent, with proved, well-adapted mechanisms of pathogenicity. However, some pathovars, e.g., *Pseudomonas syringae* pv. *syringae*, are represented by diverse populations of strains varying in degrees of virulence, with wide and sometimes overlapping host ranges.^[1] Furthermore, it is possible, even likely, that pathovars such as *P. syringae* pv. *lachrymans* and *Xanthomonas campestris* pv. *alfalfae* do not have the pathogenic specificity attributed to them. There may be examples in *Xanthomonas* of weak pathogens with wide host ranges, which has resulted in proposals for new pathovar names that are in fact synonyms.^[13]

CONCLUSION

Bacterial classification can be based on a number of taxonomic models, each leading to different interpretations and to nomenclature with differing utility. Phylogenetic, phenetic, and polyphasic classifications vie in claims to being the most natural and therefore offering the best nomenclature. Recently, molecular data, particularly selected DNA sequence data, has led to the subdivision of existing genera. However, such revisions

commonly do not take account of conflicts arising with analyses of alternative databases. Although there are examples of more than one complete chromosomal sequence representative of one species or genus, the extent of heterogeneity between such sequences points to a complexity that may not lead to simple bacterial classifications. Furthermore, taxonomic revisions sometimes fail to take account of the need of practising bacteriologists for stable nomenclature, for whom evolutionary classifications give rise to taxa that are difficult to identify, and therefore, to nomenclature that is of marginal utility. The wider use of special purpose nomenclature may be needed increasingly as natural classification becomes divorced from bacterial groups of applied interest to mankind.

Coevolution of Insects and Plants

M. Deane Bowers

University of Colorado, Boulder, Colorado, U.S.A.

INTRODUCTION

This article briefly outlines the development of the concept of coevolution since it was first proposed in 1964. It touches on both criticisms of and support for the theory. Several examples of coevolution are given, including both pollination and herbivory. These examples include the parsnip webworms and their parsnip host-plants, flea beetles and their hostplants, yucca moths and yucca, and fig wasps and figs.

WHAT IS COEVOLUTION?

The term “coevolution” was first used in a historic paper on butterflies and their host plants published by Ehrlich and Raven.^[1] They defined coevolution as “patterns of interactions between two major groups of organisms with a close and evident ecological relationship.” They used data on larval host plants of related butterfly taxa to suggest that chemical compounds in plants (so-called secondary compounds, natural products, secondary metabolites, or allelochemicals) were important in the specialization of butterfly taxa on particular plant taxa, as well as in the evolutionary diversification of both butterflies and angiosperms.

As formulated by Ehrlich and Raven,^[1] the process of coevolution involves reciprocal selection by plants on their insect herbivores and by insect herbivores on their host plants. They proposed the following sequence of events: 1) Plants produce novel secondary metabolites by mutation or recombination; 2) these compounds reduce the suitability of the plant as food for insects; 3) as a result, the plants “escape” from these insects and are able to undergo evolutionary radiation into a new adaptive zone; 4) by mutation or recombination, insects evolve resistance to these secondary metabolites; 5) these adapted insects are able to use a host plant unavailable to other herbivores and thus enter a new adaptive zone in which they are able to undergo their own evolutionary radiation. This reciprocal selective process can continue, resulting in the evolutionary diversification of plants, including secondary compounds, and their insect herbivores.

Over the years, authors have argued about the definition of coevolution, whether they believed that the

system they were describing was a coevolved one, and even whether coevolution occurred at all.^[2] More recently, the term coevolution was more precisely defined as “an evolutionary change in a trait of the individuals in one population in response to a trait of the individuals of a second population followed by an evolutionary response by the second population to the change in the first.”^[3] This definition more specifically defines the requirements of both specificity and reciprocity: Each trait evolves in response to the other and both traits evolve.

Coevolutionary interactions may be classified as pairwise (=specific) or diffuse. Pairwise interactions are those involving only two species (or populations) or sets of pairs of species (or populations). Such pairwise interactions follow well from Janzen’s definition above. However, if the requirement of specificity is less stringently applied, one or more species or populations may evolve in response to a trait or set of traits in several species, resulting in diffuse coevolution. At some point it may be impossible to distinguish diffuse coevolution, as so broadly defined, from evolution; however, the distinction lies in the reciprocity of the interactions.

Coevolution between insects and plants may include parasitic relationships such as herbivory and frugivory, as well as mutualistic relationships such as pollination and seed dispersal. While coevolutionary theory has traditionally been built on the view of insects as herbivores,^[1] more recently there is increasing evidence from studies of pollination and other mutualistic interactions.

SOME ARGUMENTS AGAINST COEVOLUTION

Criticisms of coevolutionary theory and its importance in shaping the interactions between insects and plants range from rejection of coevolution^[2] to evidence that hostplant chemistry, predators, sequential colonization, or biogeography have played the more significant role.^[4,5] One common criticism pertains to an important tenet of the theory, that of reciprocal selection. Reciprocal selection requires that insects act as selective agents on their hostplants. Some authors believe that insect herbivory does not influence plant evolution because it rarely (if

ever) reduces plant fitness.^[2] This lack of influence is attributed to several factors, including the rarity of insects relative to their host plants, low mean levels of damage by herbivorous insects (5–15%), and the greater importance of bacterial and fungal pathogens in influencing plant evolution.

SOME EVIDENCE FOR COEVOLUTION

While not all researchers may agree that coevolution is one of the most important processes in generating the diversity of organisms, there are examples of insects and plants that may demonstrate the role of coevolution in producing these interactions. They range from mutualisms such as pollination to predation and parasitism such as herbivory. The possibilities provided by molecular techniques have generated a great deal of interest because they can provide data (DNA sequences) that are not linked to the interaction, as may be the case with some (though not necessarily all) morphological characters.

Several different systems of insects and plants have been used to assess the role of coevolution in the interactions of insects and plants, including herbivores and plants, pollinators and plants, and dispersal agents and plants. In addition, different means of assessing the role of coevolutionary processes in these interactions were used. For example, Berenbaum^[6] used a combination of direct empirical evidence coupled with information from the literature to argue that species of the carrot family, the Apiaceae, and certain insect herbivores feeding on these plants provide a premier example of coevolution. This coevolutionary relationship, she suggested, was mediated by a group of secondary compounds called furanocoumarins. Since her first paper in 1983, substantial evidence has been accumulated by Berenbaum and others that supports the ideas she originally developed,^[6] and evidence for coevolution has been reported for other relationships among different species, as well.

In an effort to combine these ideas of reciprocal adaptive radiation with the emerging field of phylogenetics, Mitter and Brooks^[7] suggested that coevolutionary interactions between groups of organisms might be evident in the existence of parallel phylogenies of the interacting groups (=parallel cladogenesis). That is, if two groups of interacting organisms (such as a certain group of plants and their associated pollinators or herbivores) have reciprocally affected each other's evolution, i.e., coevolved, then this will be reflected in phylogenetic trees that mirror each other. Such methods provide a historical approach to answering the question of whether groups of organisms have coevolved.

Yucca moths (*Tegiticula*, family Prodoxidae) and yucca (*Yucca*, family Agavaceae) have a mutualistic

relationship in which the female moths use specialized mouthparts to collect pollen from *Yucca* flowers, which they actively transfer to the stigma of a flower in another inflorescence. Before transfer of the pollen, the females oviposit into the ovary of the flower and the larvae eat some of the resulting seeds. Thus the yuccas need the moths for pollen transfer and moths need the yuccas as food for their progeny. Phylogenetic analyses of both *Yucca* and *Tegiticula*, however, indicate that this relationship arose as the result of yucca moths colonizing a partially diversified set of host taxa rather than parallel cladogenesis.^[8]

Figs (*Ficus*, Moraceae) are pollinated and fed upon by members of the wasp family Agaonidae (Chalcidoidea: Hymenoptera). Oviposition in the fig is typically linked with pollination of the fig flowers. Some of the fig flowers are pollinated, producing seeds and food for the next generation of fig wasps, while others serve as larval food. As with yucca moths, there may be "cheaters" who take advantage of the system, using the resource for food, but not pollinating the flowers. Females of pollinating species exhibit a set of morphological adaptations for using figs, and these pollinators may be actively pollinating, that is storing pollen in thoracic pockets and depositing it on the stigma, or passively pollinating, that is, there is no active pollination behavior.^[9] This system is considered a good example of coevolution because there is evidence for parallel cladogenesis between figs and their pollinators (as well as parasites), as well as for reciprocity in the evolution of interacting traits.^[9]

Beetles in the monophyletic leaf-beetle genus *Phyllotribica* (Galerucinae: Chrysomelidae) feed primarily on a genus of mints, the skull-caps, *Scutellaria* (Lamiaceae). Larvae are root feeders and adults are leaf and flower feeders, and both life stages are very specialized in their feeding habits: One species of beetle feeds on a single host species in both larval and adult stages (with a couple of exceptions).^[10] Comparison of the phylogenetic hypotheses generated by use of morphological characters for the beetles and from published data for the host plants indicate almost complete concordance, suggesting that the relationship of these beetles and their hostplants is a premier example of coevolution between insects and their hostplants.^[10]

CONCLUSION

While the number of good examples of coevolution is still relatively few, those described thus far have been important in shaping our current thinking about evolution in a broad sense, as have those that have not shown evidence of coevolution. In his book, Thompson^[8] argues that coevolution may not be detected in particular

populations because there is a geographic mosaic of coevolution in which some populations of interacting species are coevolving, while others are not. Such a structure would make identification of coevolving taxa more challenging. Nonetheless, the identification and study of such taxa may be crucial to our understanding of population and community dynamics, population and evolutionary genetics, as well as the process of coevolution itself.

Columbian Exchange: The Role of Analogue Crops in the Adoption and Dissemination of Exotic Cultigens

David E. Williams

International Plant Genetic Resources Institute, Cali, Colombia

INTRODUCTION

The violent collision of cultures that began with Christopher Columbus's landfall in 1492 set off an unprecedented and sustained intercontinental exchange of crops that has enriched and altered agricultural systems and diets worldwide. Native American crops such as the potato, maize, tomato, cacao, cassava, and tobacco have had an immeasurable impact upon the rest of the world, while Old World crops such as coffee, sugar cane, bananas, wheat, and rice now constitute the basis of the agricultural economies of many countries in the Americas. During the initial exchanges that accompanied the European conquest of the Americas, dozens of staple crops from both hemispheres quickly became established on foreign soil where in many cases they soon became more important and more widespread than in their land of origin. Other crops were much slower in gaining acceptance. Crops such as the Andean pseudocereals, quinoa and amaranth, have still not achieved significant acceptance beyond their areas of origin despite concerted efforts to promote their undisputed agronomic and nutritional qualities. Some local cultigens, particularly in the Americas, were so overwhelmed by the advent of the exotic crops and farming systems that their use declined nearly to the point of extinction. How can we explain such variation in the acceptance of crops involved in the Columbian exchange?

ANALOGUE CROPS

Clearly, absence of pests and diseases and climatic suitability were important factors favoring adoption.^[1–3] Various biological, agricultural, and socioeconomic factors have been proposed as causes of marginalization of native crops in the Americas following the Columbian exchange.^[4,5] However, among the many historical and cultural factors affecting crop and food acceptance, the preexistence of analogue crops in both hemispheres offers a partial explanation, at least in some cases. Analogue crops are pairs of species that were independently

domesticated, usually on separate continents, but which share important traits of appearance, management, and/or use and are therefore somewhat “familiar” to farmers and consumers upon introduction. Analogous crop pairs typically pertain to the same botanical family and sometimes the same genus. Some analogue crops are botanically unrelated yet occupy similar niches in the agroecosystems and/or cuisines of their respective homelands (see [Table 1](#)).

The similarity of introduced crops to their native analogues was often sufficient incentive for adoption. When maize was first introduced to Africa and Central Asia, it was certainly recognized as a relative of the native sorghum, whose plant it strongly resembles, thereby facilitating its widespread adoption. However, sorghum and the other African and Asian millets did not have the same impact in the Americas where they are cultivated on a limited scale for fodder and birdseed. After maize, the potato and tomato claim the largest tonnage of New World crops produced in the Old World. Once the initial European prejudices against these solanaceous introductions were overcome, the Andean tuber was found to be well adapted to the cool conditions of northern Europe and, as a starchy food, the potato combined well with the fatty meats, butter, and cream of the Western diet. Meanwhile, the sweet but acidic fruit of the tomato became so appreciated that it is now the most widely eaten “vegetable” in the world.

Of the grain legumes, common beans (*Phaseolus*) from the Americas and cowpeas (*Vigna*) from Asia are perfect analogues, so similar in morphology and use that they were all classified by Linnaeus in 1753 within the genus *Phaseolus* before more modern taxonomists determined that they pertain to distinct genera endemic to different hemispheres.^[6] Today, cowpeas and common beans have either replaced or are grown alongside one another throughout the world. In contrast, distinct species of grain lupines (*Lupinus*) were independently domesticated in the Old and New Worlds, yet neither found acceptance across the Atlantic.

Another legume, the peanut (*Arachis hypogaea*), experienced seemingly instantaneous acceptance as soon as

it was introduced from South America into West Africa around 1500. West Africa is home to the Bambara groundnut (*Vigna subterranea*), the peanut's analogue. Both crops are geocarpic (i.e., fruits formed underground) and produce high-calorie seeds with similar culinary properties. The larger size and yield of the American peanut caused it to displace its African analogue in many areas. In Asia, the peanut has another analogue, the soybean (*Glycine max*), both species being valued as oilseeds. Following its early introduction, the peanut became fully integrated into traditional Asian farming systems and cuisines, and China and India are currently the world's biggest peanut producers. The soybean, on the other hand, gained widespread acceptance in the New World only in the past few decades but has become one of the most important commodity crops in the United States, Brazil, Paraguay, Bolivia, and elsewhere. However, despite its phenomenal recent expansion, the soybean is grown in the Americas exclusively as a cash crop and has not entered the local cuisines except as a "hidden" ingredient in the form of soy oil, protein meal, or animal feed. Ironically, large-scale expansion for soybean production in southwestern Brazil and adjacent regions of Bolivia and Paraguay is transforming the natural ecosystems that are home to the peanut's closest wild relatives and threatens these unique genetic resources, some still undiscovered, with extinction.^[7]

The Columbian exchange of root crops is notable for its relative lack of analogue species. The physical similarities between the plants of the South American potato and the Old World poisonous nightshades evidently delayed the acceptance of the tuber in Europe. While the "Irish" and sweet potatoes (*Solanum tuberosum* and *Ipomoea batatas*) eventually received wide acceptance throughout the world, numerous other domesticated Andean root and tuber crops (e.g., *Oxalis*, *Tropaeolum*, *Ullucus*, *Lepidium*, *Arracacia*, *Canna*, etc.) have not, and their use is currently in decline even in their area of origin.^[8] The widespread adoption of cassava (*Manihot*) in Africa and Asia was not replicated in the Americas by the Old World yams (*Dioscorea* spp.).^[9,10] In contrast, the domesticated aroids of Asia (*Colocasia*) and America (*Xanthosoma*) are perfect analogues and today are commonly grown together throughout the lowland tropics where, in some places such as West Africa and the Caribbean, the exotic cultigen has assumed greater importance than its native analogue.^[6]

The New World squashes, pumpkins, and gourds (*Cucurbita* spp.) turned out to be a fair trade for their Old World analogues, the melons and cucumber (*Citrullus* and *Cucumis*); all these crops are now widely cultivated across the globe.

The quest for spices and condiments was one of the primary objectives of Columbus's first voyage.^[11] While unsuccessful in finding a shorter route to the source of black pepper (*Piper nigrum*) as hoped, he did encounter the red peppers (*Capsicum* spp.), which quickly became one of the most widely cultivated crop genera, particularly *C. annuum*.^[12] Black pepper, on the other hand, has made limited inroads in tropical America, where it is cultivated commercially only in Brazil. An interesting pair of analogue crops are the Old World coriander (*Coriandrum sativum*) and the New World culantro (*Eryngium foetidum*), both domesticated umbelliferous herbs with nearly identical flavors. In Central America and the Caribbean, the two herbs are often used interchangeably.

Of the perennial fruit crops, grapes were well known to people on both sides of the Atlantic before Columbus's time, but the European wine grape (*Vitis vinifera*) was assiduously planted throughout the New World by early colonists and missionaries. In the late 1800s, when the aphid pest *Phylloxera* began decimating vineyards around the world, American *Vitis* species began traveling abroad as resistant rootstocks and today are used almost exclusively wherever commercial grapes are produced.^[10] Walnuts (*Juglans*) have analogue species in both hemispheres, yet commercial groves of English walnut (*Juglans regia*) in North America are grafted onto rootstocks of the hardier American species, *Juglans hindsii*. Roseaceous fruits such as apples and cherries (*Malus* and *Prunus*) have native species on both sides of the Atlantic, but only the Old World apples and cherries successfully made the transoceanic trip. Although no apples were domesticated in the Americas, there was a domesticated applelike hawthorn (*Crataegus pubescens*) in Mexico and a domesticated black cherry (*Prunus serotina*) in Mexico and the Andes, but these crops have mostly remained confined to their areas of origin.^[13] Major Old World fruit crops without analogues are the banana and plantain, citrus, and mango, all of which have made impressive inroads in the Americas. New World fruits with worldwide diffusion include the pineapple and, more recently, the avocado, for which there are no Old World analogues.

Different species of cotton (*Gossypium*) were cultivated in each hemisphere for some 5000 years before the advent of the Columbian exchange. After the long-staple cottons from the New World (*Gossypium hirsutum* and *Gossypium barbadense*) were introduced to Asia and Africa, they almost entirely displaced their short-staple analogues (*Gossypium herbaceum* and *Gossypium arboreum*).^[7,14] The analogous pair of botanically unrelated stimulating beverage crops, coffee (*Coffea*) and cacao (*Theobroma*), participated reciprocally in the Columbian exchange and eventually established themselves as major

^aExplanation of symbols:

- **NW > OW** = New World crop adopted in the Old World.
- **OW > NW** = Old World crop adopted in the New World.
- Numbers indicate degree of adoption and diffusion of crop in the new hemisphere: 1 = limited, 2 = significant, 3 = widespread, '–' = not adopted.
- Parentheses () around numbers indicate delayed adoption or diffusion.

commodity crops on opposite ends of the earth from their areas of origin.^[14] Even illicit crops such as the opium poppy (*Papaver somniferum*) and coca (*Erythroxylum coca*) can be regarded as analogues. However, while the Asian opium poppy is now cultivated illegally in significant quantities in Mexico, Guatemala, and Colombia, it is difficult to explain why coca cultivation has never expanded beyond its traditional area of production in northwestern South America. The high-value narcotics derived from both plants are now consumed worldwide in both licit and illicit forms.

CONCLUSION

The Columbian exchange of crops was influenced by the existence of analogue crops, and an examination of their effect can help us understand the different degrees of adoption and diffusion of those crops. However, as shown by the examples presented above, the presence of native analogues didn't always favor the adoption of introduced crops, and sometimes the opposite was the case where the native analogues served to delay or even prevent the adoption of the exotic species. Nor were analogous crop pairs always reciprocally adopted: Sometimes the exchange was unidirectional when only one of the analogues found acceptance abroad. Moreover, many crops without analogues were readily adopted and prospered in their new environment. The identification of analogue pairs and the determination of their effect on the adoption and dispersal of one another require interpretation on a case-by-case basis. By and large, however, the presence of analogous crop pairs has tended to favor their post-Columbian adoption.

The far-reaching impact of the Columbian exchange has been one of incalculable benefit to world agriculture, diet, and cuisine. The Columbian exchange marked the beginning of an ongoing process of global movement of crop germplasm resulting in a strong interdependence between all nations in terms of the plant genetic resources upon which the world's food security and agricultural sustainability depend. With no more crop species becoming available beyond those that we already know, the need to maintain and increase the international exchange of existing crop genetic resources is now more important than ever for ensuring the future well-being of farmers and consumers everywhere.

Commercial Micropropagation

M. C. Gopinathan

E.I.D. Parry Ltd., Bangalore, India

C

INTRODUCTION

Cultivation of plants for ornamental purpose is a wide spread activity throughout the world. Growing and trading flowers and live plants has become a big industry. The world consumption of floriculture products is estimated to be \$50 billion. In most of these crops, the availability of planting material is a major limiting factor. Although several of them can be propagated easily, there are others that have no known form of vegetative propagation. Even in cases where traditional methods work, the rate of multiplication is either slow or limited. Further, occurrence of various viral diseases and their transmittance through conventional methods of multiplication make floriculture a high risk industry. Development of plant tissue culture methods such as micropropagation has enabled floriculture industry to tide over these problems associated with plant propagation. The advantages and limitations of commercial micropropagation are briefly discussed in this article.

MICROPROPAGATION

Plant Propagation by tissue culture began with Morel and Martin,^[1] who demonstrated the elimination of virus from Dahlia stock through shoot apex culture. Morel's group successfully extended this to other crops, eventually including a Cymbidium mosaic virus-infected Cymbidium orchid.^[2] Morel observed the emergence of many plantlets from a single explant in his early experiments. Most orchids reproduce very slowly. Orchid propagators quickly adopted Morel's technique as a commercial practice. Success of rapid propagation of orchids resulted in the application of these techniques to other ornamental crops.

COMMERCIAL MICROPROPAGATION

The ability to control plant propagation and growth provided a big stimulus to entrepreneurs in both horticultural

and agriculture. Producers of nursery planting materials saw this as a big business opportunity. This stimulated fast development of commercial *in vitro* propagation in the early 1970s. At the same time the term "micropropagation" denoting vegetative propagation or cloning of plants in sterile environment, was coined. The 1970s and 1980s were decades of boom for micropropagation industry worldwide. This was facilitated not only by the technological improvements but also by the dedicated work of a large number of scientists, researchers, and technicians. Today, the list of plants that can be propagated by tissue culture has expanded considerably.^[3-10]

There has been a steady increase in the number of commercial micropropagation laboratories since the beginning of 1970s. These companies are both small- and medium-size, some of which are privately held and others of which are owned by large corporations.^[11] The globalization of micropropagation industry has been active during the 1980s and commercial laboratories were primarily located in the United States, the United Kingdom, Australia, Belgium, Canada, France, Israel, Italy, Japan, The Netherlands, Taiwan, Korea, Malaysia, Thailand, and China. Micropropagation is generally more expensive than conventional propagation because of the high cost of technology and large labor input. The situation has not changed much during the last 30 years, irrespective of the introduction of labor saving and efficiency improvement strategies such as mechanization, modular buildings, computer-based monitoring, and expert management systems. The increase in labor-cost led to the closure of many laboratories in developed countries and shifted the production base to developing countries.

COMMERCIAL MICROPROPAGATION TECHNOLOGY

From a commercial perspective, the application of micropropagation may be best organized into three important areas in the development and marketing of an improved product: product development, product enhancement, and marketability of the product.

Product Development

There are several ways by which micropropagation can shorten product development time and speed the release of improved varieties. These are

Rapid multiplication—production of a large number of plants from a limited stock in a relatively short time.

Product uniformity—since a large portion of production cycle take place under artificial conditions, production with a high degree of uniformity can be achieved.

High volume—allows for the production of large number of plants in a relatively small space.

Product Enhancement

Improved phenotype—for some species micropropagation can effectively enhance the quality and desirable characteristics of a plant and thereby provide a product with enhanced value. For example, micropropagated *Syngonium* shows a greater degree of basal branching, which is often cited as a desirable characteristic appreciated by commercial growers.

Disease free plants—micropropagation provides the means of eliminating pathogens, especially virus. In general, the aseptic environment of the tissue culture process results in the production of cleaner and healthier plants.

Marketability of the Product

Among the benefits associated with commercial micropropagation are those allowing for ease of product flow and marketing.

Product diversity—the micropropagation system allows for rapid production of a diverse range of plant species and type of propagules, such as plants fully established in soil, unrooted shoots or micro cuttings, and cultured clumps of shoots, for the grower.

Movement of product—the potential to produce material certified free of particular pathogens allows easy exchange of plant material without being subjected to quarantine procedures. An increasing quantity of bare root plants (free of soil) are being shipped in vitro. Plant tissue culture thus allows the utilization of offshore production to capitalize on lower labor costs and expanded markets.

Non-seasonal production—since plants are produced in an artificial, controlled environment, production can be carried out year round, even 24 hours a day. Thus, once micropropagation requirements for a given species are defined, production cycles can be scheduled to meet peak demands.

LIMITATIONS OF MICROPROPAGATION

Although numerous benefits and advantages are associated with micropropagation, there are three major limitations: product line, customer acceptance, and high product cost.

Product Line

Currently, the choice of crops to be produced by micropropagation is limited to the species for which acceptable micropropagation protocols have been defined.^[3,6,7,10] Further, the product line is determined by the market demand. Although there are numerous reports in literature of micropropagation systems for a wide range of plant species, they are not often amenable to commercial levels of production. Most of this additional development work is conducted by commercial micropropagation companies as part of their in-house research programs.

Customer Acceptance

Product quality—the ability to deliver a product with consistently high quality is of prime importance and directly impacts customer acceptance. To ensure a high level of quality, it is very important to direct particular effort towards quality control, including rouging of off-types, grading by size, and product trials if possible.

Product delivery—the ability to schedule crops accurately and deliver a defined quantity of product consistently are important factors in customer acceptance. Currently, micropropagation is best suited to provide a steady stream of plant material rather than adapt to a customer's seasonal requirements. Most commercial labs require a purchase commitment from customer and a notice of at least six months prior to a change in requested quantities. In addition, familiarity of the grower with micropropagation procedures is required for successful operation if the plants are to be established in soil.

High Product Cost

Relatively large capital investment is required to establish a commercial micropropagation laboratory with its associated facilities. For many species, micropropagation is currently not competitive compared with other conventional methods such as cuttings and seeds. Thus, micropropagation is profitable only when there is an associated advantage over conventional methods.

PRODUCTION TECHNOLOGY

Micropropagation technology generally follows standard tissue culture protocols.^[5,6,9,10,12] For example, a small piece of plant to be multiplied (explant) is isolated from the healthy plant and surface sterilized. The sources of explant material will vary depending on the species, but shoot tips, leaf, stem, and lateral buds have been successfully used. The sterilized explant is rinsed with sterile water and placed in sterile closed containers with specific nutrient media. The explant may produce proliferating shoots or may undergo callus or embryogenic growth in the incubation stage. Media constituents and its combinations mainly determine the nature of growth. Proliferating cultures are transferred periodically to fresh medium to obtain desired number of plants. These plants are rooted individually or in clumps, acclimatized in green or shade houses, packed and shipped to the customers. Although the plants can be multiplied by several techniques, the methods most commonly utilized by commercial micropropagation companies include enhanced axillary shoot branching, adventitious shoot production, and somatic embryogenesis. Depending on the species, a well-defined, species-specific protocol of plant regeneration will be used for plant production.

The adoption of Murashige's^[13] Stage I, II, III & IV production scheme greatly simplifies daily operation, accounting, and product cost analysis of a commercial production facility, and allows for greater care in communication with customers and other laboratories.

PRODUCTION FACILITY

The ultimate success of a commercial micropropagation business is largely influenced by the design, location, and cost of the facility. Commercial tissue culture facilities usually require specialized areas and equipment for culture media preparations, sterilization, and storage of nutrient media, aseptic manipulation of plant material, incubation and maintenance of cultures under controlled conditions of temperature, light and humidity, acclimatization in greenhouse, and packing and shipping.

The laboratories can be classified by the product type offered; the range is from Stage II (culture in vessels) through Stage III (bare root plantlets) to finished Stage IV liners. The product type largely reflects whether or not the

company is equipped with acclimatization and greenhouse facilities. Other potentially available services may include disease indexing and research capability to serve both in-house and external contract requirements.

Competition: Responses to Shade by Neighbors

Carlos L. Ballaré

Universidad de Buenos Aires, Buenos Aires, Argentina

INTRODUCTION

In dense plant populations, neighbors are a central determinant of the growth and performance of each individual plant. Neighbors compete for light and soil resources and influence the interactions between plants and their consumers. Not surprisingly, plant species that often occur in dense canopies have evolved exquisite sensing mechanisms to detect the proximity of neighboring plants. Some of these mechanisms are based on the detection of changes in the light environment. This detection is accomplished by means of dedicated photoreceptors, which constantly monitor the light climate and relay molecular signals to mechanisms that control plant physiology and morphogenesis. Most field crops are grown at high density, in order to maximize yield per unit area. Therefore, variations in the way in which individual crop plants “read” their light environment can have important consequences on the growth rate and yield of the whole canopy. In this article I briefly describe light-sensing mechanisms used by plants to detect neighbor proximity and discuss the ecological and agricultural significance of the responses elicited by these photoreceptors. For a comprehensive review, the reader is referred to Refs. 1 and 2.

FORAGING FOR LIGHT

Plants acclimate to shading by other plants with plastic morphological and physiological adjustments. These adjustments often include changes in the stoichiometry and organization of the photosynthetic apparatus and large changes in shoot morphology and biomass allocation patterns. A typical morphological response to shading is the production of thinner leaves, which has the overall effect of increasing photosynthetic area per unit of carbon invested in leaf production. Other responses vary among taxa and species habitats. Typical responses among dicots from open habitats, such as grasslands and arable land, include increased internode and petiole elongation, production of more erect leaves, reduced branching, and acceleration of flowering. Grasses often respond to shading with reduced tillering, increased sheath length, and increased tiller angles. All these morphological changes

tend to improve the access of the younger leaves to the upper canopy strata, increasing light exposure. In patchy canopies, where the light environment is also heterogeneous over the horizontal dimension, plants actively project leaf area into canopy gaps. This projection is the result of phototropic bending of the shoots and differential branching and growth responses. The combination of morphological and physiological adjustments that plants generate as they grow in a heterogeneous canopy matrix, which results in concentration of photosynthetic power in well-illuminated spots, is often referred to as “shade-avoidance” or “foraging for light.”^[1,3] Interestingly, plants of open habitats are able to detect their neighbors remotely, using changes in the spectral composition of reflected sunlight, and forage for light when growth and morphological development are still not limited by severe shading.^[2]

HOW DO PLANTS READ THE LIGHT ENVIRONMENT?

Plants detect changes in their light environment using specific photoreceptors. In *Arabidopsis thaliana*, three families of informational photoreceptors have been identified: phytochromes (Phy), cryptochromes (Cry), and phototropins (Phot).^[4–6] Phy receptors are maximally sensitive to the red (R, 600–700 nm) and far-red (FR, 700–800 nm) regions of the solar spectrum. There are five Phy receptors in *Arabidopsis* (PhyA–E), which are encoded by a family of five divergent genes (*PHYA–E*). All Phy receptors have the same chromophore, a linear tetrapyrrole. Phy receptors play a central role in regulating nearly all aspects of plant morphogenesis, including seed germination, de-etiolation, stem elongation, leaf morphology and orientation, tropisms, flowering, and organ senescence.^[3] Cry receptors^[5] are specialized sensors of blue light (B, 400–500 nm) and UV-A radiation ($\lambda_{\text{max}} = 370 \text{ nm}$). There are two Cry receptors characterized in *Arabidopsis* (*cry1* and *cry2*). These are encoded by *CRY1* and *CRY2*, respectively, and they both use flavin as chromophore. Cry proteins bear similarities to microbial photolyases but have no photolyase (DNA repair) activity. These receptors play a role in controlling hypocotyl elongation in seedlings and also in the entertainment of the

circadian clock. Finally, two Phot receptors (Phot1 and Phot2) have been found in *Arabidopsis*.^[6] These are also specialized B light receptors that use flavin chromophores and control phototropic responses at several levels, from whole organs and organelles to stomatal opening.

HOW DO PLANTS USE SPECIFIC PHOTORECEPTORS TO FORAGE FOR LIGHT AND RESPOND TO SHADING?

Chlorophyll molecules in photosynthetic organs absorb strongly in the B and R regions of the light spectrum. In contrast, the absorption in the green and FR regions is much lower, and most photons in these wavebands are either transmitted or reflected. Therefore, the proximity of neighboring plants not only reduces the total amount of light energy available for photosynthesis but also has a profound influence on the spectral composition of radiation.^[1-3] Of particular importance, given the spectral characteristics of plant photoreceptors, are the depletion of B light, which can be sensed by Phot and Cry receptors, and the reduction in R-to-FR ratio (R:FR), which is detected by members of the Phy family.

For the purpose of illustration, two general, simplified scenarios will be considered. The first scenario is that of a seedling that emerges under an established leaf canopy and has to deal with a light environment already depleted in photosynthetic light availability (e.g., under a forest canopy). The second scenario is that encountered by seedlings that emerge from bare soil, with no overtopping neighbors but surrounded by other seedlings of similar age and size (e.g., weed and crop seedlings emerging after seed bed preparation in arable land, or cohorts of regenerating seedlings emerging in a clear-cut). The mechanisms whereby plants sense and respond to deep overhead shading (first scenario) have been difficult to disentangle, because multiple environmental factors are affected under the shade of a dense canopy.^[2] Physiological experiments and experiments with mutants suggest that changes in R:FR, perceived by PhyB, are important. However, other factors of the radiation environment, such as reduced overall fluence rate, reduced ultraviolet radiation, and other microenvironmental changes (reduced wind speed and increased humidity), are likely to play a role in controlling plant morphogenesis under natural shade. Mutants deficient in PhyB sometimes show strong responses to shading, confirming the involvement of other sensing mechanisms.

Foraging for light in populations of plants that are approximately even-height (second scenario) often involves perception of FR radiation reflected by neighboring plants (Fig. 1). Back-reflection of FR photons by

neighboring leaves lowers the R:FR ratio in the light that impinges laterally on plant shoots, signaling the proximity of potential competitors before there is significant shading among neighbors.^[1,2,7] Most plants from open habitats use the drop in lateral R:FR as an early warning signal of oncoming competition and respond with a rapid increase in stem (or petiole) elongation, production of more erect leaves (particularly rosette plants), and reduced branching. Studies with photoreceptor mutants show that PhyB plays a key role in the early detection of potential competitors.^[2] In even-height plant populations, the proximity of neighboring plants can also reduce the light fluence rate received by the stems well before there is a significant

Fig. 1 Reflected FR radiation is an early signal of competition. In even-height canopies, such as those shown on the right-hand side panels (cohorts of soybean seedlings and *Datura ferox*), stem elongation responses to crowding occur well before neighboring plants cause a significant reduction in the availability of light for photosynthesis (upper graph). Early responses such as these are triggered by changes in the spectral composition of the light that impinges laterally on the shoots, which is rapidly enriched in FR as neighboring plants grow and the leaf area index of the canopy increases (lower graph and diagram). (For a review, see Refs. 1 and 2.) (View this art in color at www.dekker.com.)

depletion in light availability at leaf level. This reduction in fluence rate promotes stem elongation, and both B light receptors and the phytochromes are involved in the perception of fluence-rate signals.^[2] The generation of rapid elongation responses to early signals of competition increases the likelihood of individual plant survival in a system where access to the light resource rapidly becomes limiting as the plants grow and occupy canopy space.^[1,8]

In patchy canopies, reflected FR is also a directional signal. Plants project leaf area away from potential competitors using negative phototropic responses driven by reflected FR and controlled by PhyB. In addition, plants located at or near the edge of a canopy gap are exposed to intense B light gradients, as B levels are very low within the canopy and high in the gap area. Since plants are positively phototropic to B light (via phot1 and phot2 receptors), these gradients also serve as a directional signal that attracts new shoots to canopy gaps, complementing the negative phototropic responses to FR.^[2]

ECOLOGICAL SIGNIFICANCE

As indicated in the foregoing, and as supported by experiments, foraging for light in response to proximity signals perceived by dedicated photoreceptors is essential for plant survival in rapidly growing canopies.^[1,8] Photomorphogenic signaling among neighbors also has important implications for the functioning of the canopy as a whole.^[1,2] It has been shown that in monocultures of mutants with impaired R:FR sensitivity, size-structuring (i.e., the development of size differences among neighbors) is much more pronounced than in populations of photomorphogenically competent plants.^[9,10] This is because photomorphogenically normal plants respond to early signals of shading with adaptive morphological changes that improve light interception, and the intensity of this response tends to be greater in small (more shaded) plants than in large plants (at least as long as growth is not severely limited by lack of resources).^[9] This morphological adjustment, which is absent in R:FR-blind mutants, attenuates the suppressing effect that large plants have on small (more shaded) plants and thereby retards the development of size hierarchies within the population.

CONCLUSION

Individual crop plants change their shape and allocation patterns to improve light capture in the canopy. What are the implications for crop yield? Can the light-foraging pattern be controlled and improved to increase crop productivity? Researchers have begun to answer these

questions using a variety of experimental approaches, which in most cases have involved manipulations of the light environment and morphogenic sensitivity using model plants such as *Arabidopsis* and tobacco. Two basic hypotheses have been developed and partially tested.^[1] The first hypothesis is that light foraging and shade-avoidance responses, while essential for individual plant survival in the wild, are deleterious to crop yield. The reasoning behind this idea is that height growth responses utilize assimilates that crop plants could otherwise invest in the generation of leaf area or in the development of reproductive structures and harvestable organs. The second hypothesis conveys exactly the opposite idea, i.e., that foraging for light, driven by photomorphogenic mechanisms, is essential to ensure optimal deployment and redistribution of the crop photosynthetic capacity during canopy development and to buffer the crop population against the development of size inequalities. Therefore, eliminating plant sensitivity to light signals of neighbor proximity would have negative impacts on crop yield. Clearly, these hypotheses have very different practical implications for breeding programs that attempt to increase crop yield by manipulation of light sensitivity. Experimental evidence has accumulated in favor of both hypotheses, suggesting that the impacts of altering photomorphogenic behavior on crop growth and yield may vary with crop species, developmental phase, and overall agronomic scenario.^[1] Physiological experiments have shown that directed overexpression of plant photoreceptor genes can be used to molecularly mask specific plant organs to proximity photosignals without altering the light sensitivity of other plant parts. This strategy could be used to target specific plant organs or processes in biotechnological programs aimed at manipulating selected morphogenic responses in cultivated plants.^[11] Alternatively, targeted alterations of crop plant photomorphogenesis could be obtained by directing the bioengineering efforts to signaling components that couple the photoreceptors with the molecular controls of a particular physiological function.

Control of Plant Virus Diseases

Jitender S. Yadav
Roger N. Beachy
Claude M. Fauquet

Donald Danforth Plant Science Center, St. Louis, Missouri, U.S.A.

INTRODUCTION

Plant viruses cause significant agricultural losses worldwide, particularly in tropical and subtropical ecosystems. Although viruses are simple biological entities, with DNA or RNA encoding genetic information that is required for their multiplication in host cells, the mechanisms by which viruses invade cells and subvert sub-cellular machinery,^[1] and how plants defend themselves from viral infection are in general poorly understood. As a result, viruses continue to be a major threat to farmers and reduce both the quantity and the quality of crops. For example, viruses of the genus *Tospovirus* in the family Bunyviridae cause crop losses, which accounts for a loss of more than one billion dollars per year;^[2] viruses of the genus *Begomovirus* in the family Geminiviridae are devastating and cause loss of millions of tons of food annually.^[3] This entry will focus on recent advances made in natural and engineered resistance and their applicability for controlling plant viral diseases.

GENETIC RESISTANCE TO PLANT VIRUSES

Genetic resistance remains the preferred method to protect crop plants from viruses. For more than a century it has been known that plant resistance to disease can be genetically inherited, and plant breeding has been used to develop disease resistant crops, when genes for resistance have been identified. The successes of conventional breeding generally rely on dominant monogenic or polygenic resistance genes.^[4] Monogenic resistance is usually limited to precise host–pathogen relationships and relies on allele-specific genetic interactions between a host resistance (R) gene and a pathogen avirulence (Avr) gene.^[5] The strong defense response that results from this type of incompatible plant–virus interaction is frequently accompanied by localized hypersensitive cell death, termed as the “hypersensitive response” (HR).^[5]

Our knowledge of molecular events that underlie gene-to-gene interactions and progress in molecular biology has led so far to the identification of over

220 virus R genes.^[6] A majority of the studies of disease resistance involve plants in the *Solanaceae*, *Cucurbitaceae*, and *Leguminosae* families and several from the *Poaceae*. More than 80% of the R genes isolated till date show monogenic inheritance and 50% are dominant; in contrast, most of the genes that control bacterial and fungal pathogens are dominant.^[6] In the absence of specific host–pathogen interactions, virus infections may be limited by basal or innate defense responses; however, this topic is not discussed here.

Dominant Resistance

Dominant resistance against plant viruses is often associated with HR,^[5] although the molecular processes that trigger the HR are not well understood. On the basis of predicted protein structural domains, currently known dominant R genes are grouped into eight classes.^[7] The largest class is characterized by a centrally located nucleotide binding site (NBS) and C-terminal leucine-rich repeats (LRR) of different lengths. R genes can be further divided on the basis of N-terminal domains, which consist of either a coil domain or a Toll-interleukin 1 homology region domain.^[8] Among the dominant plant virus R genes, 10 genes have been isolated and sequenced (Table 1). Interestingly, all reported dominant R genes that provide resistance to plant viruses fall in the NBS-LRR class. Resistance imparted by dominant Sw-5 gene to tomato spotted wilt virus (TSWV) has been introgressed in tomato (*Solanum esculentum*) from *S. peruvianum* and provides a broad spectrum and stable resistance against TSWV.^[9]

Recessive Resistance

Along with dominant R genes, studies on plant resistance to viruses have led to the identification of several recessive R genes that are used to protect crops^[10] against begomoviruses, cucomoviruses, luteoviruses, potyviruses, and tobamoviruses. Recessive R genes mostly work at the single cell level or they affect cell-to-cell movement.^[6] Absence of recessive R genes or mutation in them makes

(From Ref.^[6].)

hosts nonpermissive for infection and is called passive resistance.^[4] This “loss of susceptibility,” conferred by such mutations, has been demonstrated for several viruses, but a limited number of host factors have thus far been identified.^[10] Studies on recessive genes to date have focused largely on viruses in the *Potyviridae* family. Mutations in *Arabidopsis* and a host of other viruses such as the beet curly top virus (BCTV), cucumber mosaic virus (CMV), tobacco etch virus (TEV), tobacco mosaic virus (TMV), tomato golden mosaic virus (TGMV), and others have led to the identification of many recessive R genes, some of which are listed in Table 1. The translation initiation factor *eIF4E* has been identified as a recessive resistance factor in pepper (*pvr1/2*), lettuce (*mol*), and pea (*sbm1*),^[6] and has been implicated in barley as candidate for *rym4/5*. *eIF4E* and its isoform *eIF (iso) 4E* confer resistance against the potyviruses TEV, potato virus Y, and pepper mottle virus (PepMoV) infection in *Arabidopsis* and pepper (Table 1). Mechanisms of resistance to potyviruses, conferred by mutations in *eIF4E*, are not clear but mutations in *eIF4* are located around the cap-binding pocket of the protein and they interfere with virus encoded

replicase protein and result in the inhibition of viral accumulation and movement in plants.^[6]

Other examples of virus resistance have been identified but mechanisms of action of R genes remain undetermined.^[11] Although natural virus resistance genes have been used extensively to develop crop plants that have resistance to viruses, the transfer of resistance characters from a wild plant species or a nonadapted variety to a useful crop is a lengthy and difficult process. In many instances, important agronomic and organoleptic qualities of crop plants are lost during the process of plant breeding; in other cases, sources of resistance to specific genes were not found.

ENGINEERED RESISTANCE TO PLANT VIRUSES

Improvement in transgenic technologies, along with a better understanding of the infection mechanisms of viruses, has revolutionized methods for developing virus-resistant transgenic plants (VRTP). The concept of pathogen-derived resistance (PDR) was first

demonstrated in the lab of R. Beachy, where resistance to TMV was demonstrated in tobacco plants, which expressed a transgene that encoded the capsid protein (CP) of the pathogen.^[12] This discovery led to a wider search for viral genes that can be used as a source of resistance to protect crop plants that had inadequate natural-resistance genes or genes that were difficult to work with. Since 1986, the PDR approach has been adopted as a tool to protect crops from viruses and has led to the development of VRTP for commercial

application in potato, squash, and papaya, while many other crops have been authorized for field tests (Table 2).

Pathogen-derived resistance is classified as either protein or RNA mediated, based on the mechanism of resistance. The presence of significant amounts of viral proteins can interfere with the infection by some viruses, but not all. In some cases, it is difficult to distinguish between RNA and protein-mediated resistance.^[13] Unambiguous examples of protein-mediated virus resistance have been demonstrated by expression of viral

(From <http://www.nbiap.vt.edu>)

CPs; furthermore, examples of protein dependent pathogen-derived resistance that is caused by the expression of viral movement proteins (MP) or replicases (Pol or Rep) have also been described.^[13] In some cases, resistance is based on the expression of the full-length functional proteins, while in others the expression of the entire protein leads to incomplete resistance or even to enhanced susceptibility. In contrast, expression of a dysfunctional protein can lead to strong resistance.^[13] Despite the numerous successes of protein-mediated resistance, the molecular basis of protein-mediated virus resistance is not well understood, except in the case of CP-mediated resistance to TMV where CP regulates the uncoating of TMV and specific aspects of virus replication.^[14] The studies on CP from TMV suggest that virus proteins with a regulatory role in replication can be the basis for PDR.

Studies on PDR led unexpectedly to the development of the post-transcriptional gene silencing (PTGS) concept, also referred to as RNA interference or gene silencing. Lindbo et al.^[15] first demonstrated RNA-mediated resistance against TEV in a small number of transgenic plants that contained a gene encoding CP of TEV; this phenomenon was later linked to PTGS, a process that leads to the degradation of viral RNAs. Since that time, RNA silencing or PTGS has been revealed to be a mechanism that is involved in resistance to virus, as well as in cell development.^[16,17] Those RNAs that are homologous to the viral sequences

produced by the transgene are specifically degraded, including viral RNAs that are produced during replication. Resistance based on PTGS is usually very strong and can result in complete immunity. However, as protection is based on high sequence identity of the silencing RNA, resistance is generally narrow and restricted only to the virus from which the transgene was derived or to very closely related isolates, as in the case of tobamoviruses, TEV, alfalfa mosaic virus (AMV), PVY, and CMV^[18] (Table 3). ssDNA geminiviruses seem to be an exception to this rule, at least in the case of cassava geminiviruses, which demonstrated protection against viruses belonging to different species.^[19] Nevertheless, there was a high degree of sequence conservation in the gene targeted for silencing.

The gene silencing mechanism involves the cleavage of double-stranded (ds) RNA molecules into short (21–26 nucleotides) RNAs, known as siRNAs.^[16] To enhance the production of dsRNAs, and thereby triggering the PTGS, plant transformation gene constructs that encode intron-containing RNAs with a hairpin structure have been shown to induce PTGS with very high efficiency.^[20] The major drawback of using siRNA as a resistance strategy is the high level of sequence specificity that is required for degrading the target RNA. Viruses containing >10% nucleotide that differ from the targeted sequence are usually insensitive to RNA degradation.^[18] Another drawback to the use of siRNA is the apparent size of the transgene required

Table 3 List of transgenic plants where RNA interference has been used to develop virus resistant plants

for efficient silencing; while earlier studies indicated that more than 300 base pairs are required to trigger efficient RNA silencing, Parizotto et al.^[21] recently demonstrated that 123 base pair pre-miRNAs can lead to the production of a microRNA of the 21 nucleotides that trigger complete silencing of a transgene.

The major concern for using gene-silencing strategies to control viruses is the fact that many (perhaps all) viruses encode one or more PTGS suppressors.^[17] Therefore, infection by a nontargeted virus may break the targeted resistance, as was observed in the case where transgenic plants that were resistant to potato virus A (PVA) became susceptible to PVA after infection by PVY^[22] (Table 3). Practical applications of PTGS are very appealing, but information on 1) how interaction with different viruses affects endurance of engineered resistance; 2) the prevalence of different species of viruses in an area; and 3) the silencing of PTGS suppressors will be required in designing better PTGS-based strategies to efficiently control plant viruses.

CONCLUSIONS

In the last 20 years, significant progress has been made in the study of plant viruses, in terms of understanding their structure, movement in and between plants, and interactions with their hosts. This has been supplemented with a wealth of information generated by genomic studies and the description of more than 220 virus resistant genes. The PDR has been the most productive in terms of field tests and commercial development and deployment of VRTP. It is clear that the discovery of gene-silencing mechanisms will have a profound impact both on the understanding of the plant-virus interactions and on the control of plant viruses. Further exploitation of this wealth of knowledge is essential to improve the efficiency and the durability of each disease resistance strategy, and to develop additional strategies to cope with the emergence of resistance-breaking viruses.

Crop Domestication in Africa

Rémy S. Pasquet

IRD-ICIFE, Nairobi, Kenya

INTRODUCTION

Several plants, including sorghum, were domesticated in Africa. These indigenous plants provided an adequate base for the development of sedentary agriculture. Furthermore, the highly developed cultures of Nok, Ife, and Benin, as well as the Sudanic kingdoms, were supported by an indigenous African agriculture.

TIMING OF PLANT DOMESTICATION

Plant domesticates appeared in Egypt around 5000 B.C., but these belonged to the Southwest Asia complex, coming from the Levant where agriculture was established by 6000 B.C., without any southern influence. Among the preserved plant materials found in ancient Egyptian tombs, there is not a single African crop.^[1,2] Strikingly, in Africa south of the Sahara, archaeological and linguistic data show that the domestication of animals preceded cereal agriculture by two to four millennia. Cattle were present in Sahara by 5000 B.C., while the earliest dates for crop domesticates are around 1000 B.C. Collection and maybe cultivation of wild grasses was important for early pastoralists, long before plant domestication.^[2,3]

THE NORTHERN SAVANNAS

Vavilov^[4] identified the Ethiopian highlands as a center of plant domestication, and Harlan^[5] considered an area covering all of sub-Saharan Africa north of the equator as a noncenter of plant domestication. Most African crops are savanna species, including the ones cultivated in forest areas. Savannas south of the equator appear not to have been involved in crop domestication. Agriculture spread there with the move of Bantu-speaking farmers. This southward move is well dated archaeologically and started during the first millennium B.C.^[6] However, northern savannas are a complex area, from which three language phyla originated. These three phyla are assumed to have originated in the same ecological zone and adjacent to one another: Niger-Congo around the bend of the Niger, Nilo-Saharan east of Lake Chad, and Afro-Asiatic around the upper Nile.^[3] Therefore, following Ehret,^[7] it should

be possible to consider five domestication centers, all part of Harlan's^[5] noncenter.

MANDE CENTER

Several species are definitely West African, and they all can be linked with Mande language speakers. The African rice, *Oryza glaberrima*, is cultivated from Senegal to Chad. The progenitor is an annual, autogamous grass, *Oryza breviligulata*, adapted to savanna water holes that fill up during the rains, from Senegal to Central Africa. There is also a complex of wild, weedy, and domesticated forms. Highest genetic diversity is found in the inland Niger delta on the one hand, in Guinea and southern Senegal on the other hand.^[1,3] Two small-seeded millets also belong to that center. As a domesticate, *Brachiaria deflexa* is only known from Guinea, while wild *B. deflexa* is widespread all over northern Africa. Fonio (*Digitaria exilis*) extends from Cape Verde to Nigeria and is more important in the western part of that area, when considering both the number of varieties and the acreage. The wild progenitor could be *Digitaria longiflora*, a widely distributed species. The present distribution and archaeological data from Mauritania suggest that these millets were the first cultivated cereals, progressively replaced by rice and pearl millet.^[1,3]

Although the evidence is less clear, pearl millet (*Pennisetum glaucum*), the most important African cereal after sorghum, seems to be of West African origin also. Pearl millet is an allogamous plant cultivated from Senegal to India and southern Africa. The wild forms occur discontinuously in the Sahel and subdesert zone from the Atlantic to the Red Sea, with large hybrid swarms between wild and domesticated types. Regarding the domesticated forms, from a nucleus including late-maturing West African, East African, and Indian cultivars, authors separate early-maturing West African cultivars on the one hand and cultivars from southern Africa on the other hand, an organization reminiscent of that of sorghum and cowpea.^[8] The cereal reached India early, like sorghum and finger millet, which would suggest an East African origin.^[3] However, it is the first cereal to appear in West African archaeological sites, where it predates sorghum: from 1500 B.C. in Mauritania

to 800 B.C. in the Lake Chad area, while sorghum does not appear before 800 A.D. in the latter area.^[2]

BENUE-CONGO CENTER

Yams are the main staple crop in an area from eastern Ivory Coast to Cameroon, and yam names are well correlated with the Kwa and Benue-Congo languages.^[1] There are several species, but the main ones belong to the *Dioscorea cayenensis*–*Dioscorea rotundata* complex. Nevertheless, yams do not seem to be true domesticates in Africa. Yam “domestication” involves vegetative propagation under cultivation conditions adapted for wild material, with wild forms that have been cultivated very recently growing together with older cultivated forms. When the wild *Dioscorea praehensilis* is cultivated, the *D. cayenensis* phenotype is obtained after a few generations, i.e., the amount of fiber in the tuber declines markedly as the starch content increases, there is a drop in the number of thorns, and the number of cataphylls (scale-like modified leaf) borne on the main stem decreases spectacularly. The polyploid complex should be of hybrid origin (*D. cayenensis sensu stricto* and *D. praehensilis*–*Dioscorea abyssinica*, with other minor species), and there is gene flow between wild and cultivated forms.^[8] Two pulses, *Macrotyloma geocarpum* and *Sphenostylis stenocarpa*, belong to that center. *M. geocarpum* is cultivated from Burkina Faso to Nigeria, and its wild progenitor is not really known. Its vocabulary could suggest a link with Gur language groups. *S. stenocarpa* is cultivated from Burkina Faso to Cameroon (mainly for its seeds) and further south in Zaire (mainly for its tuber). Bambara groundnut (*Vigna subterranea*) could also belong to that area. This pulse is widely cultivated in most of Africa, but its wild progenitor is restricted to savannas from Nigeria to Sudan. Its vocabulary suggests a link with Adamawa-Ubangi and Benue-Congo languages. Surprisingly, all the plants from this center are “subterranean.”

EAST CENTRAL CENTER

Sorghum (*Sorghum bicolor*) is widely cultivated all over Africa, although it was recently superseded by maize in some areas. Wild-race verticilliflorum is the primary progenitor candidate and is extremely abundant in the eastern half of Africa, from Chad and Sudan to southern Africa. Domesticated sorghums are classified into five races. Race Bicolor, the most primitive race, includes sorghums cultivated for their sweet stems, for beer brewing, and for dye. Race Guinea is primarily West African and is adapted to high rainfall conditions. Race

Caudatum is grown in the area from Lake Chad to Ethiopia. Race Kafir is found in southern Africa, and race Durra has its main center of cultivation in India. Race Bicolor was disseminated everywhere, and all the other races evolved from race Bicolor, each in its own geographic area.^[3,8] Archaeological data suggest that sorghum was domesticated in the eastern Sahara, where pearl millet is not reported. These earliest finds have been dated to slightly before 1000 B.C. The reliability of claims for domesticated sorghum at earlier sites in Africa, Arabia, and India cannot be substantiated at present,^[2] though sorghum, along with finger millet, was brought to India at an early time.^[3] Like sorghum, cowpea (*Vigna unguiculata*) is cultivated almost everywhere in Africa. In addition to seed production, cowpea is used as fodder and was an important fiber plant. Organization of the domesticated genepool is reminiscent of sorghum. From a nucleus of primitive cultivars (cv.-gr. Biflora), cv.-gr. Melanophthalmus with thin seed testa was developed in West Africa, while photoperiod-independent cv.-gr. Unguiculata and cv.-gr. Sesquipedalis (the yard-long bean) were developed in southern Africa and Asia, respectively. The wild progenitor is a weed encountered all over African savannas, and introgressions between wild and domesticated types are widespread though not frequent. Vocabulary suggests a link with Chadic and Nilo-Saharan speakers.^[8]

EAST CENTER

Finger millet (*Eleusine coracana*) is a small-seeded cereal cultivated from Ethiopia to Cameroon and in southern Africa and India. In the wild, it is a widespread tropical weed, especially abundant in the highlands of East Africa, where there is a crop-weed complex. The crop was introduced early on in India.^[3] Noog (*Guizotia abyssinica*) is an oilseed and a major crop in Ethiopia only, where the complete range of wild, weedy, and domesticated races is found in great abundance.^[1,3] Tef (*Eragrostis tef*) is grown on a very large scale in Ethiopia, but almost nowhere else. The wild progenitor is *Eragrostis pilosa*, a common and widely distributed grass. There is no crop-weed complex since both wild and domesticated races are cleistogamous.^[3]

ENSETE CENTER

Ensete (*Ensete ventricosum*) is widespread as a wild bananalike tree, from Ethiopia to Cameroon and southern Africa. As a starchy crop, it is cultivated only in the Omotic language area of Ethiopia, and like yam, it is

not really a true domesticate. However, it has been hypothesized that the distribution of wild ensete and that of the banana-based cultures of central and eastern Africa, whose traditional life focused on the cultivation of banana, are clearly very ancient. This might suggest that the East Asian domesticate (*Musa acuminata*) could be a replacement for an older, similar crop such as ensete.^[6,7]

CONCLUSION

Plant domestication in Africa was a late event, which took place during the second millennium B.C. or later. All plants were domesticated within the savanna area, which stretches from the Atlantic to the Red Sea. Due to the ethnic and linguistic diversity of Africa, it is possible to identify five domestication centers within this area.

Crop Domestication in China

Tracey L.-D. Lu

Chinese University of Hong Kong, Hong Kong, China

INTRODUCTION

Since J.G. Andersson discovered a piece of rice husk on a Neolithic potsherd at the Yangshao village in the Yellow River Valley in 1927, the origin of agriculture in China has been a topic of scholarly interest.^[1] N. Vavilov and Y. Ding also investigated this issue in the 1920s and the 1930s.^[1] Today, archaeological discoveries from the 1970s, as well as agronomic and genetic studies, have provided information for our understanding of the domestication of several crops and plants in China, but the questions on how, why, and precisely where and when agriculture occurred in this area still remain.

EVIDENCE FOR CROP DOMESTICATION IN CHINA

Breakthrough archaeological evidence for crop domestication in China was first found in the 1970s.^[1] In the Hemudu assemblage in the lower Yangzi River Valley, dated between 7000 and 5300 years ago, rice (*Oryza sativa*) grains and straws were discovered. Remains of foxtail and broomcorn millets (*Setaria sativa* and *Panicum miliaceum*, respectively) were found in the Cishan and Peiligang assemblages in the middle Yellow River Valley, both dated to 7800 years ago (Fig. 1).^[1]

Additional archaeological remains were found in the Yellow and the Yangzi River Valleys from the late 1980s to the 1990s, among them the Jiahu assemblage located between the Yellow and the Yangzi River Valleys, and the Xianrendong, Yuchanyan, Pengtoushan and Bashidang assemblages in the Yangzi River Valley (Fig. 1).^[1] These discoveries and multi-disciplinary analyses of the new data have profoundly enriched our knowledge on the origin of rice farming in China. An initial isotopic analysis on human remains found in Xianrendong suggests that wild rice was gathered and consumed as food by the Xianrendong occupants by 12,000 years ago, probably even earlier.^[2] Phytolith analysis further suggests that the Xianrendong occupants might have started rice cultivation between 10,000 and 9000 years ago.^[2] Meanwhile, rice husks found in the Yuchanyan cave suggest that rice might have also been gathered at the boundary area

between the Yangzi River Valley and South China at the beginning of the Holocene.^[1] The rice husk and grains found in Jiahu, Pengtoushan, and Bashidang, associated with house remains, burials, tools, pottery, and even musical instruments (in Jiahu) illustrate that rice was grown in the Huai River Valley and the middle Yangzi River Valley by sedentary and affluent farmers as early as 9000 to 8500 years ago.^[1]

In addition, Chinese cabbage (*Brassica pekinensis*) seeds were found in Banpo in the middle Yellow River valley, dated to around 6800 years ago (Fig. 1).^[3] Remains of domesticated soybean (*Glycine max*) and peach (*Prunus persica*) were recently discovered in Zaojiaoshu, the middle Yellow River Valley, dated to 3900 to 3600 years ago (Fig. 1).^[4] However, no archaeobotanic remains of tea in prehistoric China have been reported so far.

THE PROCESS OF CROP DOMESTICATION

Crop domestication is a process of manipulating wild plants in such a way that selection under cultivation leads to new plant types that meet human beings' needs. In China's context, the major subjects of this process are the annual green foxtail (*S. viridis*) and the perennial wild rice (*O. rufipogon* Griff.). The wild progenitor of broomcorn millet (*P. miliaceum*) has not been identified to date. Based on plant observations and measurements, it is clear that there are salient differences between green foxtail and wild rice and their domesticated counterparts (Table 1).^[1]

Genetic study of green foxtail is insufficient at the moment. For rice, however, recent genetic research indicates that many phenotypes of the perennial wild rice, such as seed shattering and longer growth cycle, are controlled by several genes, many of them being dominant.^[5,6] In other words, the majority of genes controlling the human-favored phenotypes such as tough rachis, shorter growth cycle, and lower degree of dormancy, etc., are recessive. Humans have made the recessive genes dominant in the domesticated plants through cultivation by consciously and unconsciously selecting plants containing certain recessive genotypes. Archaeological data in China today are still insufficient to fully illustrate this human interference process, but some clues are apparent.

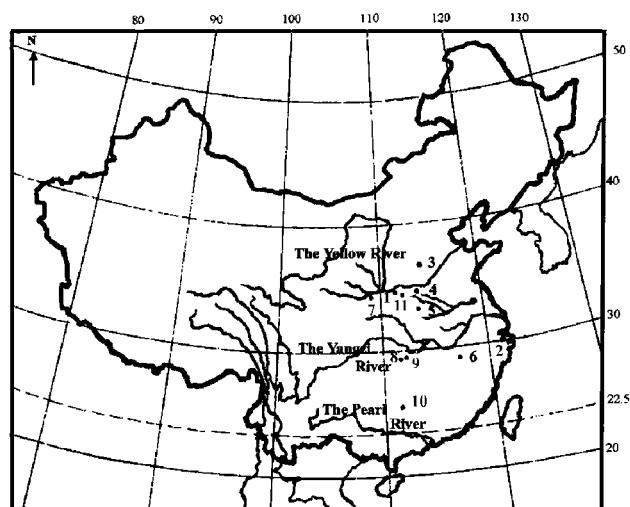

Fig. 1 Archaeological sites mentioned in the text. 1. Yangshao 2. Hemudu 3. Cishan 4. Peiligang 5. Jiahu 6. Xianrendong 7. Banpo 8. Pengtoushan 9. Bashidang 10. Yuchanyan 11. Zaojiaoshu.

As mentioned above, rice gathering might have begun by 10,000 b.p. in the Yangzi River Valley, followed by cultivation at around 9000 years ago. The rice remains found in Jiahu and Bashidang have been identified as a transitional type between wild and domesticated rice, characterized by smaller grains compared to that of current domesticated rice, but displaying various traits of both the *japonica* and *indica* subspecies.^[7] As the quantities of rice grains found in these sites are substantial, they represent the early stage of rice domestication by intensive cultivation.

Compared to rice domestication, data on the domestication process of millets are very limited. Although an initial use-wear analysis indicates that wild grasses might have been harvested in the middle Yellow River Valley before 13,000 years ago,^[8] there is no solid evidence for wild millet gathering to date. Because millets do not seem to produce diagnostic phytolith cells,^[9] the effectiveness of phytolith analysis for millet farming is significantly

hindered. This further affects the study of the origin of millet farming, as seeds are not always well preserved in prehistoric deposits. In order to collect data from different aspects, a green foxtail cultivation experiment has been carried out in the Yellow River Valley since 1999.^[10] The initial result of this experiment, plus ethnographic data from Taiwan indigenous foxtail millet cultivators^[11] and Chinese historic documents, suggests that millets might have been domesticated by rotational cultivation and by consciously selecting plants with larger seeds and fewer panicles.^[10,11]

The result of the green foxtail cultivation experiment also indicates that the return of initial millet cultivation is very low; therefore, the early farmers could not have purely relied on farming for their survival.^[10] A wild rice cultivation experiment conducted by the author in South China since 2000 also suggests a very low output for wild rice farming. Therefore, the process of crop domestication in China might have been a gradual one, and the early farmers might have remained foragers until the output of farming increased.

Archaeological data to date seem to indicate that domesticated cabbage, soybean, peach, etc., occurred well after the domestication of millets and rice in the Yellow and the Yangzi River Valleys. This may suggest that the development of horticulture and the domestication of other plants occurred after farming based on millet and rice became major subsistence strategies in the above regions.

CONCLUSION

Crop domestication in China occurred at the beginning of the Holocene in temperate zones, when the climate began to warm up after the last glacial episode. Current research indicates that wild rice was gathered and consumed as food by 10,000 years ago in the Yangzi River Valley, followed by rice cultivation in the same region by 9000 years ago.^[1] This process from gathering to cultivation is

Table 1 Some major differences between wild and domesticated foxtail millet and rice

Criteria	Wild millets and rice	Domesticated millets and rice
Tillers per plant	More tillers	Fewer tillers
Seed shattering	At a very high rate	Very low rate
Panicle diameter	Usually small	Comparatively bigger
Flowering and ripening	Heterochronous—last for more than one month	Simultaneous
Seeds per panicle	Much fewer seeds	More seeds
Size of seeds	Small	Big
Growth cycle	Longer	Shorter

(From Refs. 1 and 10.)

similar to that in other domestication centers of the world. On the other hand, the process of millet domestication in the Yellow River Valley is much less clear, although it is certain that millets were intensively grown in that region by 7800 years ago.

Archaeological discoveries made in recent years have shed more light on the issue of plant domestication in China, but many questions still remain. First, are the Yellow and the Yangzi Valleys two independent centers for plant domestication, or just one center? Second, what is the impetus to the transition from foraging to farming in China? Third, who are the early millet farmers in the Yellow River Valley, and precisely when did millet cultivation begin in that area? Last, but not the least, what is the taxonomic link between the cultivar groups of domesticated rice (*japonica*, *indica*, and *javanica*)? Which one was domesticated first? Were they the result of separate domestications or of a single domestication followed by divergence under cultivation? Was the *japonica* subspecies domesticated in China and the *indica* domesticated in India? At present archaeologists, agronomists, and geneticists are debating this issue, and no consensus has been reached. All of these questions await further study.

Crop Domestication in Mesoamerica

A. Delgado-Salinas

J. Caballero

A. Casas

UNAM, Morelia, Michoacán, Mexico

INTRODUCTION

Mesoamerica is the cultural area that extends from northern Mexico (except for the northwestern states) south to Costa Rica. This region has been the origin of numerous domesticated plants, many of which are important sources of food and other needs for human populations all over the world. With a vast biodiversity established in arid, temperate, and tropical ecosystems, Mesoamerican human populations diversified into a broad array of cultural groups that have explored, experimented, and modified through selection a great number of plant resources. Mesoamerican peoples have depended on the continued output of food, fiber, medicine, and other essentials derived from wild, weedy, and domesticated plants. Their agricultural landscape has been characterized since early days by irregular patterns of multiple cropping agroecosystems, home gardens, and nearby human-modified vegetation areas (transformed habitats that hold mixed stands of prominent species that provide families with food security and nutritional balance).

ARCHAEOBOTANICAL EVIDENCE

Archaeological research in Mesoamerica has been conducted in regions of Mexico and Central America and provides a glimpse of some of the considerable diversity of both wild and domesticated plants throughout human history. In the highland sites of Mexico (Oaxaca, Tamaulipas, and Tehuacán), changes in major and minor crops, as well as wild and manipulated plants, are represented through different chronological ages. Evidence shows plants imported over great distances or in different stages of domestication. The archaeobotanical record from the highland sites includes macrobotanical remains of maize (*Zea mays*), wild and domesticated beans (*Phaseolus acutifolius*, *Phaseolus coccineus*, *Phaseolus vulgaris*), squash and gourds (*Cucurbita argyrosperma*, *Cucurbita moschata*, *Cucurbita pepo*, and *Lagenaria siceraria*), chili peppers (*Capsicum annum*), husk tomato (*Physalis* sp.), foxtail grass (*Setaria* sp.), chenopods

and amaranths (*Chenopodium* sp.; *Amaranthus cruentus*, *Amaranthus hypochondriacus*), chayote (*Sechium edule*), cotton (*Gossypium* sp.), avocado (*Persea americana*), zapote blanco (*Casimiroa edulis*), zapote negro (*Diospyros digyna*), and guajes (*Leucaena esculenta* and *Leucaena leucocephala*).^[1,2] Evidence from lowland sites (Tabasco, Mexico, Guatemala, El Salvador, Honduras, Costa Rica, and Panama) represents later stages in the archaeobotanical record and partially documents the innovative work of early agriculturalists that locally domesticated cotton (*Gossypium hirsutum*), jícama (*Pachyrhizus erosus*), chayotes (*Sechium edule*), arrowhead (*Maranta arundinacea*), and other crops, in addition to vegetatively propagated vanilla (*Vanilla planifolia*) and henequén (*Agave fourcroydes*). Remains from ca. 6000 b.p. also document the occurrence of maize (pollen), beans, squash, chili peppers, sunflowers, avocado, plums (*Spondias* sp.), and palms (such as fruits of *Acrocomia* sp.).^[1,3]

Recently, age dating of some of these plant remains has been modified by the use of accelerator mass spectrometry (AMS), which has provided new and unexpected information on the history of domesticated plants. Archaeological remains from Guilá Naquitz cave in Oaxaca, México, indicate that ancient populations of domesticated squash (*C. pepo*) are represented as far back as 10,000 years b.p.^[2] Surprisingly, what had been considered the earliest beans records, from Tehuacán, Mexico, have recently been dated as later than thought, at 2300 years b.p.^[4] Furthermore, a domesticated sunflower seed (*Helianthus annuus*) dated ca. 4000 years b.p. has been discovered in Tabasco, Mexico.^[3] This controversial discovery challenges the hypothesis that sunflower domestication originated in eastern United States. In addition, chemical evidence based on chromatography and mass spectrometry of Mayan ceramic vessels from northern Belize has moved back the earliest recorded use of chocolate (*Theobroma cacao*) as a beverage to as early as 2600 b.p.^[5] (Table 1). Some plants gradually faded from the archaeological record (such as *Canavalia* and *Helianthus* in Mexico, and *Setaria*), possibly because of ecological changes or different agronomic practices. The latter explanation was suggested for *Setaria*, which was replaced by maize.^[6]

Table 1 Species diversity and earliest remains of major domesticates and sunflower in Mesoamerica

Genera	No. of species W/D	Archaeological site region	Earliest remains (b.p.)	Plant remains
<i>Capsicum</i>	30/5	Highlands	7,000	seed
<i>Cucurbita</i>	15/5	Highlands	10,000*	seed
<i>Helianthus</i>	70/2	Lowlands	4,000*	seed/achene
<i>Phaseolus</i>	50/5	Highlands	2,285*	pod
<i>Zea</i>	4/1	Lowlands	6,000	pollen

Species diversity (Wild and Domesticated) was obtained from Ref. 12 and for maize from Ref. 8. Remains ages were estimated by indirect radiocarbon method^[1,3] and by Accelerator Mass Spectrometry (AMS, 1:4, 8, 15)* and are given in years before present (b.p.).

SYSTEMATICS AND MOLECULAR EVIDENCE

Within the last 20 years, molecular systematists and geneticists, based on morphological and molecular evidence, have shed light on the systematics, genetic structure, and evolution of several crops.^[7] These studies have assessed genetic variation and determined relationships between wild and domesticated species. Research has also determined centers of origin for some species, such as maize.^[8] Gene pools in centers of genetic diversity have been studied for various species (e.g., *P. vulgaris*).^[9] Also, indirect and direct estimates of gene flow between cultivars and wild counterparts have been obtained for several crops.^[10]

Understanding the phylogeny and genomic evolution of crops has also made possible (albeit not without some problems of calibration) the calculation of rates of evolution of crop lineages.

SINGLE AND MULTIPLE DOMESTICATION EVENTS

Early Mesoamerican agriculturalists, and those from other regions, have converged in their selection of the same widespread genera and, consequently, have often domesticated multiple congeneric species. For example, separate domestications have been proposed for different species of *Gossypium* in both Old and New Worlds.^[11] Also, among others, different species of *Amaranthus*, *Annona*, *Chenopodium*, and *Pachyrhizus* were domesticated in both the northern and southern hemispheres of the New World.^[12] In addition, throughout their distributional ranges, some species have been domesticated more than once. Morphological and molecular evidence has confirmed independent domestication events in *C. moschata*, *Phaseolus lunatus*, and *P. vulgaris* in both Mesoamerican and Andean regions.^[9,13] *C. pepo* was domesticated in both southern Mexico and eastern United States.^[14] Often these vicarious domestications have accentuated popula-

tion differences within species, such as in *P. vulgaris*, where Mesoamerican and South American gene pools are molecularly distinguishable.^[9] However, many species have been domesticated only once in their history. A single domestication of maize is proposed from southern Mexico ca. 9000 years ago.^[8] The wild progenitor of tomato (*Solanum lycopersicum* var. *cerasiforme*) was apparently domesticated once, in Mesoamerica, even though the genus is highly diversified in South America. Molecular evidence has shown that the domestication region of cocoa (*Theobroma cacao*) was in fact the Amazon basin, and not in southern Mesoamerica as was earlier thought.^[15]

IN SITU DOMESTICATION BY SELECTIVE TOLERANCE

Manipulation of plant resources by local peoples has influenced plant evolution in various ways and continues to operate in Mesoamerica. At present, indigenous peoples in Mesoamerica utilize more than 6000 plant species for food, medicine, and a great variety of other purposes. Management of plant resources involves different forms of manipulation, which increase the availability of plants in space and time and provide a glimpse of different stages of domestication. Most plant species are harvested from the natural vegetation, but some plant resources, mainly trees and other perennials, are selectively spared when cutting down the forest to establish maize fields or settlements. In some cases, plant individuals or their populations are protected by controlling or eliminating their competitors and predators. The conscious dispersal of sexual and vegetative propagules of plants is another way in which selection may be imposed. Cultivation of wild plants in home gardens and croplands is also a common practice that maximizes reproduction and productivity of plant resources. Many species are managed simultaneously in two or more ways in different regions, and even within a single region or locality, by the same people. Studies on morphological variation of some

species of central Mexico show that selective tolerance and other forms of plant management constitute active processes of in situ domestication. It is known that when gathering plants in the wild, people frequently harvest only those individuals that they recognize as more desirable, because they have better flavor, texture, color, shape, disease or insect resistance, etc. For example, the Mixtec and the Nahuatl of central Mexico recognize differences in the quality of edible fruits such as guayaba (*Psidium guajava*), guamuchil (*Pithecellobium dulce*), nance (*Byrsonima crassifolia*), and ciruela (*Spondias purpurea*). The recognition of variation in wild plants by indigenous peoples may be the first step in the process of conscious selection of the most desired phenotype. In situ domestication by selective tolerance seems to be a common and current process in Mesoamerica. Selective tolerance has been described for *Leucaena esculenta* ssp. *esculenta*, *Opuntia* spp, and several species of columnar cacti such as *Stenocereus stellatus*, *Escontria chiotilla*, *Polaskia chichipe*, and *Polaskia chende*. In all these cases, selection has favored phenotypes with larger, more flavorful seeds, although they are more susceptible to predation, in the case of *L. esculenta*, and fruits that are larger, sweeter, thinner skinned, and less spiny, in the case of cacti. In the case of *P. chichipe*, selection has also favored individuals that self-pollinate and germinate more rapidly. This form of management allows local people to modify the genetic structure of a population by increasing the frequency of the most desired phenotypes while eliminating those that are not desirable. At least 37 other wild species have been reported as selectively tolerated and sometimes promoted by local people. This number could be much higher given the relatively scant attention that ethnobotanists have paid to the study of this kind of plant management. Moreover, in situ domestication has favored the maintenance of vital coevolutionary processes of long-term ecological associations between crop plants and their wild pathogens and symbionts.

CONCLUSIONS

Since most plants subject to in situ domestication are common elements of the landscape of the indigenous regions of Mesoamerica, the crops, pasturelands, and fallow fields of the region can be seen as complex agrosilvicultural systems. All elements of these systems, including the apparently wild plants, have a role in the local economy and are the result of some degree of selection and manipulation by local people. Cutting down the natural vegetation for agricultural purposes involves a significant loss of biodiversity; conversely, domestication processes add an important amount of human-created biodiversity to nature.

The important ecological and evolutionary role that skilled indigenous Mesoamerican peoples have played and continue to play is undeniable. Their activities result in the creation, maintenance, and enhancement of plant genetic resources, which results in worldwide contributions to food support and other human needs.

C

Crop Domestication in Prehistoric Eastern North America

David L. Asch

John P. Hart

New York State Museum, Albany, New York, U.S.A.

INTRODUCTION

At European Contact, eastern North American Indian agriculture featured the New World cosmopolitan “three sisters:” maize, beans, and squash. Maize and beans had diffused from the tropics as domesticates, as did some squashes. The dominance of this triad in temperate eastern North America was recent. Maize became an important crop only about 1000 years ago, and beans entered the region at 850 b.p. But before maize became preeminent—as early as 3500 b.p.—there was an “Eastern Agricultural Complex” (EAC), which consisted of several indigenous crops. EAC was largely an indigeneous development; its origins can be traced back at least 7300 years.

EARLIEST AGRICULTURE

Eastern North American agriculture (Tables 1 and 2) began with the growing of yellow-flowered gourd and bottle gourd cucurbits whose hard-shelled fruits presumably had toxic, bitter flesh. These plants have edible seeds, and the fruits were useful as containers, fishnet floats, and rattles. By c. 7300 b.p., the first was present in a habitation-site midden in Illinois (Koster) and the second with human burials in Florida (Windover) (see Fig. 1 for site locations).^[1–4]

A yellow-flowered gourd subspecies presently grows spontaneously and persistently in naturally disturbed floodplains from east Texas to the Ozarks.^[3,4] In Florida, seeds of yellow-flowered gourd are found in Late Pleistocene sediments predating human presence.^[4] Seeds and fruit rinds from Middle Holocene archaeological sites located far north and east of these regions (Table 2) imply that humans, carrying the plant from site to site, were responsible for a major range extension.^[5,11] Although self-seeding would have occurred, occasional planting and care probably were essential for long-term persistence in parts of the archaeological range where today yellow-flowered gourd is evanescent without planting.^[3] Separate domestication of a second subspecies occurred in Mexico.^[4]

The geographic range of bottle gourd before it entered into a mutualistic relationship with humans is undeter-

mined, but the species probably originated in tropical Africa. It has been recovered at Mesoamerican and Andean archaeological sites of about the same age as in Florida, or older.^[1,3] Unless the fruit was transported by ocean currents to Florida, it arrived there by human hands. Its presence in southeast Missouri at c. 5000 b.p.^[2] was surely due to human transport. Bottle gourd persists spontaneously in areas of human disturbance, but long-term survival requires occasional planting or care.^[3]

Marshelder was the first species to be cultivated (i.e., planted) primarily for food in eastern North America. At Napoleon Hollow, Illinois, the mean size of its achenes at 4000 b.p. is larger than in modern wild populations, implying domesticatory selection.^[2] Marshelder may have been cultivated earlier at nearby Koster where it is the most common seed from a 5700–4900 b.p. occupation, but those achenes are indistinguishable from wild plants. Giant ragweed is the second most common seed in that deposit. At Marble Bluff, Arkansas, giant ragweed achenes were preserved in a 2850-b.p. cache with seeds of known crops.^[10] This species is much less frequent in later prehistoric seed assemblages. Although evidence is lacking for range extension or morphological changes, the temporal pattern of its archaeological occurrence suggests that it was an early crop that was later abandoned.

EASTERN AGRICULTURAL COMPLEX

Over the millennia, several annual species grown primarily for their edible seeds were added to the agricultural ensemble (Table 2). By 2000 b.p., six were cultivated in the Midwest: oily-seeded marshelder and sunflower, and starchy-seeded goosefoot, knotweed, maygrass, and little barley.^[1,5] Biological domestication of marshelder, sunflower, and probably knotweed is attested by gradually increasing achene size.^[2,3,13] Goosefoot domestication is evinced by occurrence of two seed forms that have a testa thinner than in wild plants, perhaps resulting from unconscious selection.^[1,8] It is likely that thin-testa seeds germinated promptly when sown, which in an optimal garden-bed environment would give the seedlings an advantage in competition for light and nutrients.^[11] Morphological changes in maygrass and little barley are

Species	Common name	Family	How propagated	Major uses ^a
<i>Amaranthus hypochondriacus</i> L.	Grain amaranth	Amaranthaceae	Annual from seed	Edible seed
<i>Ambrosia trifida</i> L. ^b	Giant ragweed	Asteraceae	Annual from seed	Edible seed
<i>Chenopodium berlandieri</i> Moq.	Goosefoot	Chenopodiaceae	Annual from seed	Edible seed
<i>Cucurbita argyrosperma</i> Huber	Cushaw squash	Cucurbitaceae	Annual from seed	Fruit with edible flesh
<i>Cucurbita pepo</i> subsp. <i>ovifera</i> (L.) Decker	Yellow-flowered gourd; squashes: crookneck, scallop-forms, and other forms	Cucurbitaceae	Annual from seed	Fruits: hard-shelled forms for containers, rattles; some forms with edible flesh; edible seed
<i>Cucurbita pepo</i> L. subsp. <i>pepo</i>	Pumpkin	Cucurbitaceae	Annual from seed	Fruit with edible flesh; edible seed
<i>Echinochloa muricata</i> (P. Beauv.) Fernald ^b	Barnyard grass	Poaceae	Annual from seed	Edible seed
<i>Helianthus annuus</i> L.	Common sunflower	Asteraceae	Annual from seed	Edible seed
<i>Helianthus tuberosus</i> L. ^c	Jerusalem artichoke	Asteraceae	Herbaceous perennial from tubers	Edible tubers
<i>Hordeum pusillum</i> Nutt.	Little barley	Poaceae	Annual from seed	Edible seed
<i>Ilex vomitoria</i> Ait.	Yaupon holly, cassine	Aquifoliaceae	Perennial shrub, transplanted	Leaves and twigs brewed to make ceremonial/ medicinal "black drink"
<i>Iva annua</i> L.	Marshelder, sumpweed	Asteraceae	Annual from seed	Edible seed
<i>Lagenaria siceraria</i> (Molina) Standl.	Bottle gourd	Cucurbitaceae	Annual from seed	Fruits for containers, rattles; edible seed
<i>Nicotiana quadrivalvis</i> Pursh	Tobacco	Solanaceae	Annual from seed	Leaves smoked for ceremonial or medicinal purposes
<i>Nicotiana rustica</i> L.	Tobacco	Solanaceae	Annual from seed	Leaves smoked for ceremonial or medicinal purposes
<i>Passiflora incarnata</i> L. ^c	Maypops	Passifloraceae	Herbaceous perennial vine from seed or root division	Sweet, slightly acid, edible fruit
<i>Phalaris caroliniana</i> Walt.	Maygrass	Poaceae	Annual from seed	Edible seed
<i>Phaseolus vulgaris</i> L.	Common bean	Fabaceae	Annual from seed	Edible pods (green) and seed
<i>Polygonum erectum</i> L.	Erect knotweed	Polygonaceae	Annual from seed	Edible seed
<i>Zea mays</i> L.	Maize, corn	Poaceae	Annual from seed	Edible seed

^aThe term "seed" is employed in a common-language sense.

^bProbably planted.

^cSpontaneous in fields; probably planted as well.

(From Refs. 1–11, which include citations of primary literature.)

absent or less convincingly substantiated, but cultivation can be inferred from archaeological occurrences at locations beyond the extended modern ranges of these weedy species.^[6]

For the cucurbit species, there is unambiguous evidence of larger seed and fruit size and thicker fruit rind, with a diversification of forms that increased overall

technological utility. At an undetermined time, a yellow-flowered gourd was selected whose fruit had nonbitter edible flesh, which thus can be called a squash.^[1,3]

Of the six seed crops, four mature in late summer/autumn, two in late spring. Immature squash could be a summer vegetable. Effective harvests of marshelder, maygrass, little barley, and perhaps other species would

require planting in dense stands. Sunflower and cucurbit plants could be individually tended.

Generally in eastern North America, plant materials decay rapidly and are preserved at archaeological sites only when carbonized, making it difficult to determine dietary importance of EAC crops. Critical evidence on diet comes from a few caves and rockshelters (mostly in the Ozarks and Kentucky) where desiccating environments have preserved uncarbonized perishables.^[10,14] Indians mining mirabilite in Salts Cave, Kentucky at 2500 b.p. deposited feces that are preserved intact. The fecal bulk is mostly seed remains. In a sample of 100 paleofeces, Yarnell^[14] identified EAC seeds in 98 specimens, with a mean of 3 EAC species per specimen. Starchy and oily seeds co-occurred in most feces. Twenty percent contained both spring- and fall-harvested crops, an indication of seed storage for out-of-season use. On the cave floor were thick-shelled gourds fashioned into containers.

For several millennia, eastern North American agriculture developed in near-total isolation from other agricultural centers. However, tobacco, an exotic, ap-

peared 1800 years ago during EAC ascendancy.^[3] The earliest macrobotanical record of maize is 2100 b.p., but maize was uncommon for centuries thereafter.^[5,8,9] Possibly there were other extraregional contacts before the late prehistoric period. Little barley and maygrass are indigenous in both the southwestern and southeastern United States, and they occur archaeologically in the southwest.^[6] Domesticated common sunflower has been reported at a prehistoric site in Mexico,^[15] and domesticated *Chenopodium berlandieri* occurs today in Mexico (as subsp. *nuttalliae* H.D. Wilson & Heiser).

LATE PREHISTORIC AND HISTORIC AGRICULTURE

Introductions of domesticated plants from beyond eastern North America continued in late prehistoric times—including common bean, a squash domesticated from the Mexican lineage of yellow-flowered gourd, a second squash species, and a grain amaranth.^[5,8] Several

Fig. 1 Archaeological sites listed in Table 2 and mentioned in the text.

domesticates accompanying Europeans in the early Contact period (e.g., watermelon and peaches) were assimilated rapidly.^[3]

After maize became the dietary staple around 1000 b.p., EAC crops continued to be grown for a few centuries, at least in the Midwestern core area. Ultimately, the maize-beans-squash triad supplanted EAC crops, except for sunflower. Cultivars of several indigenous species that had evolved during millennia of domestication were lost.^[1,5]

Some species grown before European Contact have probably not been recognized on account of their low archaeological visibility or difficulty of distinguishing them from wild plants. For instance, Europeans recorded that Southeastern Indians transplanted the yaupon holly shrub from the seacoast to interior villages. This assured a convenient supply of the caffeine-containing leaves and twigs from which was brewed the “black drink” used

in social/ceremonial contexts.^[3] A survey of historic documents from Contact to 1940 found that Indians of Eastern North America grew over 20 “specialty plants”—i.e., species having nonfood uses or eaten for reasons other than their caloric contribution.^[3,8] These were mostly non-weedy perennials, in contrast to the EAC crop progenitors, which were weedy annuals. The specialty plants were seldom grown in fields with annual plants and sometimes were replanted in the habitat where they were collected; Indian plant husbandry included activities that do not resemble agriculture from a European perspective.

PLANT HUSBANDRY

Husbandry or management of ecosystems may have altered availability of so-called wild foods.^[5] Historic

records document Indian planting of wild rice (*Zizania* spp.) to establish it in northern lakes where it was absent.^[3] In the Northeast, groundnut (*Apios americana* Medik.) occurs exclusively as a sterile triploid that reproduces from the tubers (which were an important Indian food); Indians possibly established groundnut in that part of its range.^[5] Finally, effective large-scale hickorynut (*Carya* spp.) harvesting, which dates to as early as 7500 b.p.^[2,5] would have been possible only with access to the concentrated masts that open-grown trees can produce. Intentional burning, selective girdling of trees, and opening the forests for agriculture likely contributed to this resource's availability.

Crop Domestication in Southeast Asia

Victor Paz

University of the Philippines, Diliman, Quezon City, Philippines

INTRODUCTION

The time depth for the origin of Southeast Asian agriculture is not well established. The nature of the early agriculture, though, is clear—it is based on the domestication of root crops and the cultivation of tubers. The characteristics of early agriculture in the region are also tightly intertwined with the practice of arboriculture. Southeast Asia may be geographically divided into two main parts: Mainland and Island. The extent of the Mainland is within the land area of present-day Myanmar, Thailand, Cambodia, Laos, Vietnam, and the Malay Peninsula. Island Southeast Asia is within the bounds of the Philippines, Malaysia, Brunei, and Indonesia. The present nature of agriculture in Southeast Asia may be characterized as dominated by cereal cultivation. This was not the case, however, at the origin of a way of life that depended on the cultivation and domestication of plants. Cereals, such as rice (*Oryza sativa* L.), are the main crop of current agriculture in Southeast Asia.

ORIGINS OF CEREAL AGRICULTURE

With the absence of any well-founded evidence for the earliest cereal agriculture and the lack of any early evidence for early domestication of field-working animals in the region, it is not likely that agriculture based on rice or millet (*Echinochloa frumentacea* Link or *Setaria italica* (L.) P. Beauv.) started out in Southeast Asia earlier than in East Asia, where a whole suite of evidence supports the presence of cereal agriculture not later than 8000 before present (b.p.).^[1–3] The question of the origin of agriculture can best be addressed by evidence of human utilization of plants and the presence of cultivars at an established time depth. In both cases, the antiquity of the evidence depends on the nature of the archaeological data.

From well-determined archaeobotanical remains, the beginning of rice and millet cultivation in Mainland Southeast Asia may be roughly placed around 5000 to 3000 b.p., and in Island Southeast Asia at 4000 to 3850 b.p.^[4,5] On the other hand, there is a clear picture of tubers and nut utilization in the region as far back as the late Pleistocene and early Holocene, based on plant remains coming from several sites in Island and Mainland

Southeast Asia, e.g., Niah West Mouth Cave in Sarawak, Ulu Leang in Sulawesi, and Spirit Cave and Banyan Valley Cave in Thailand (Fig. 1).^[5,6] There is also substantial evidence of root/tuber consumption and the exploitation of tree products continuing all throughout the later epochs of the region's archaeological record.^[6,7]

NONCEREAL PLANT UTILIZATION

The accumulated current evidence from the archaeology of the region, which is still growing, shows the existence in deep history of a people–plant relationship that may be described as tuber-based agriculture coupled with arboriculture. In this type of relationship, humans depended mainly on the exploitation of food resources coming from the forest, which involved the utilization of a substantial number of plants that eventually led to the cultivation of a considerable number of species and the local domestication of some of these plants. It may also be argued that the start of tuber-based agriculture in Southeast Asia coincided with the development of the greater yam *Dioscorea alata* L. from its two known wild progenitors—*D. hamiltonii* Hook f. and *D. persimilis* Prain and Burkill^[8,9]—somewhere in northern Mainland Southeast Asia. As a cultivar, *D. alata* is definitely the consequence of a practice that involved the cultivation of several nondomesticated vegetative plants for generations.

NATIVE AND INTRODUCED PLANT UTILIZATION

The time depth for the dominance of forest plant utilization perhaps began as soon as the appearance of modern humans in the region, with the number of species cultivated increasing through time—even during and after the introduction of cereal crops and other root crops. Although we talk of local plants cultivated or domesticated, it is significant to note that introduced plants were also integrated into the system in later times, as reflected best by the integration into the system of *Ipomoea batatas* (L.) Lam. and *Manihot esculenta* Crantz, both coming from South America.^[10]

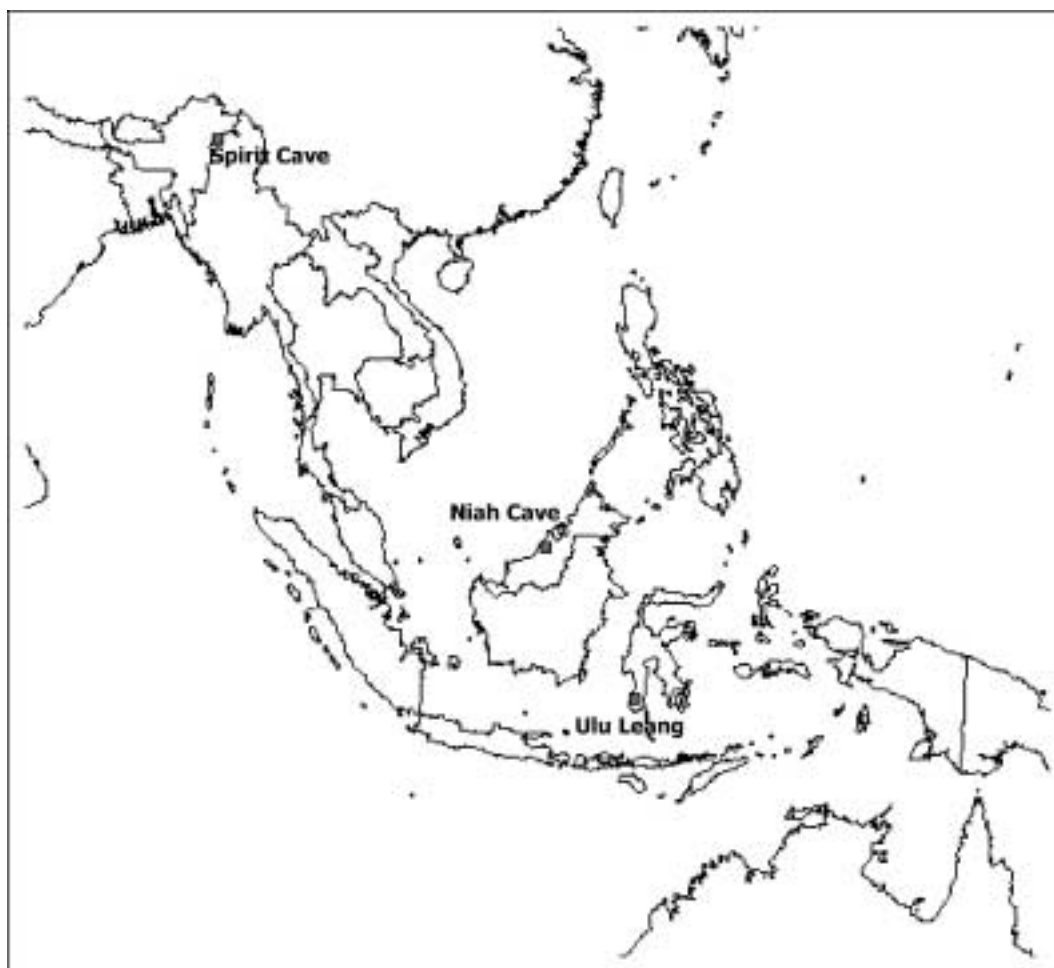

Fig. 1 Locations of plant remains from the late Pleistocene and early Holocene. (View this art in color at www.dekker.com.)

There is a strong possibility that the beginnings of an agricultural way of life in the region revolved around the cultivation of a variety of yams and the pantropical domesticate *Colocasia esculenta* Schott (taro), together with other cultivated “wild” species of *Dioscorea* and *Alocasia*. The diet was further supported by *Musa* spp. (plantains) and nut-bearing trees such as *Canarium* spp., mostly cultivated in their natural habitats inside the forest or at the fringes of settlements. The exploitation of cultivated and a few wild tuber-yielding plants inside the forest corresponded to an arboricultural relationship of people with the rest of the forest’s plant population.

CONCLUSION

The foregoing description briefly illustrates the nature of the origin of agriculture in Southeast Asia. Tuber-based agriculture and arboriculture may perhaps be the main reasons why early introduction of cereal agriculture had a

slower and more fragmented acceptance. Future archaeobotanical work coupled with more palynological sequences from the late Pleistocene to later periods will further improve our knowledge of the nature and time depth of Southeast Asian agriculture.

Crop Domestication in the American Tropics: Phytolith Analyses

Dolores R. Piperno

Smithsonian Tropical Research Institute, Balboa, Republic of Panama

INTRODUCTION

The lowland American tropical forest was one of the world's primary centers of agricultural origins. Many important seed, root, and tree crops—including manioc (*Manihot esculenta* Crantz) and sweet potato (*Ipomoea batata* L.), at least two species of squashes (*Cucurbita argyrosperma* Huber and *Cucurbita moschata* Duchesne), and perhaps maize (*Zea mays* L.)—were brought under cultivation and domesticated within its floristically diverse borders. The inimical conditions for plant preservation in these humid forests severely hampered the study of their agricultural history. Since 1980, archaeobotanists have developed a technique, phytolith analysis, that provides tangible evidence of early Neotropical plant cultivation and crop dispersals, as well as of the crop production systems that supported nascent agriculture. This article summarizes the results and ramifications of some of these efforts.

PHYTOLITH ANALYSIS

Phytoliths are microscopic bodies of silica ($\text{SiO}_2 \cdot n\text{H}_2\text{O}$) that form in growing plants and are released into the environment after a plant has died and decayed. Phytoliths (literally, plant stones) resist processes that cause the decomposition of other plant materials, and are thus preserved over long periods of time.^[1] Formerly thought to be waste products secreted by plants, scientists now identify a number of different roles phytoliths play in plants. Among the most important may be their role in deterring herbivory and pathogenic fungi.

For example, studies of phytolith and lignin formation in wild and domesticated species of *Zea* and *Cucurbita* indicate that phytolith formation is genetically determined, and that the same loci that govern lignin deposition also regulate the production of phytoliths.^[2,3] The genetic loci involved are teosinte glume architecture (*tga1*) in *Zea* and hard rind (*Hr*) in *Cucurbita*, which, as its name implies, makes the fruit exterior hard. Lignin's role in plant defense is unquestioned; fortifying seed bracts or

fleshy fruit rinds with two hard and undigestible substances appears to be a better strategy for some plants than using just one. Because silicification sites in many other plants are likely to cause maximal discomfort to overreager herbivores (e.g., leaf hairs, seed and leaf epidermes),^[1,3,4] more demonstrations of genetic control over phytolith formation are expected.

CROP PLANT IDENTIFICATION THROUGH PHYTOLITH STUDY

Numerous gymnosperms, monocotyledons, and dicotyledons heavily silicify their vegetative, reproductive, and underground organs, and produce phytoliths of taxonomic utility at levels varying from the family to the species.^[1,4] Phytolith morphology is diagnostic in part because phytoliths are often silicified casts of the cells and plant tissues in which they form. Hence, phytoliths reflect the gross morphology of these structures, obviously useful in plant identification.^[1,3–5] This aspect becomes particularly important for studying plant domestication when, as has been demonstrated for *Zea* and *Cucurbita*, the genetic loci that control phytolith formation in glumes, cupules, and fruit rinds also accounted for significant phenotypic changes, and thus in their phytoliths during the domestication process.^[2,3]

Crop plants that were either originally domesticated or heavily used in the Neotropical forest and that produced diagnostic phytoliths upon multiple independent investigations of different regional flora include maize,^[1,5,6] squashes and gourds of *Cucurbita* spp. and bottle gourd (*Lagenaria siceraria* L.),^[1,3,5,7,8] and arrowroot (*Maranta arundinacea*).^[4,5] Phytoliths from the rachis, seed glumes, and leaves of Balsas teosinte (*Z. mays* ssp. *parviglumis*) differ from those of its domesticated product, maize^[1,2,6,9] (Fig. 1a,b). Phytoliths from some species of squashes (e.g., *Cucurbita maxima* ssp. *andreana*; *Cucurbita maxima*, *Cucurbita moschata*) appear to differ on a morphological basis (Fig. 2a–d), and phytolith size also differentiates many domesticated from wild taxa.^[3,8]

Fig. 1 (a) A group of articulated phytoliths from a fruitcase (lower glume and rachis segment) of Balsas teosinte. (b) Phytoliths from a cob (cupule and glumes) of maize, Race Maiz Ancho. The following differences can be observed: In teosinte, there are many more long-cell phytoliths, some of which are unique, and the spherical short-cell phytoliths (called rondels by phytolith researchers) are more highly decorated than in maize, where undecorated types of rondels dominate the phytolith assemblage. These differences are caused by the locus *tga1*, which regulates which cells become silicified in these structures of wild and domesticated *Zea*. The significant contrasts in ornamentation between wild and domesticated *Zea* phytoliths largely result from the differing degrees of lignification in these taxa, also primarily controlled by *tga1*.

PHYTOLITHS AND NEOTROPICAL CROP PLANT EVOLUTION

The phytolith record from the Neotropical forest, where systematic studies addressing a broad range of economic plant taxa have been carried out longer than in other regions of the world,^[4,5] reveals considerable new data on plant use. This section summarizes some of this evidence, with special attention to earlier parts of the archaeological record and two important genera, *Cucurbita* and *Zea*, for which information garnered from previous studies of inadequately preserved macroplant fossils is particularly slim.

Squashes and Gourds of *Cucurbita* spp.

The high oil and protein content of *Cucurbita* spp. seeds made them favorite resources of human populations in the New World. In the lowland tropics, as in highland Mexico (Delgado-Salinas et al., this volume), the genus appears to have been cultivated at an early date. Phytolith analysis of an important preceramic cultural tradition on the coast of Ecuador, called Las Vegas, indicates that a wild species of *Cucurbita* was exploited by 10,000 b.p., and that varieties of squashes and gourds having phytoliths with sizes characteristic of modern, domesticated plants developed between 10,000 and 9500 b.p.^[8,10,11] The particular species involved was probably the only free-growing *Cucurbita* known from Ecuador, *C. ecuadorensis*.

Cucurbita phytoliths the size of modern domesticated species also left records dating to about 8000 b.p. in the Colombian Amazon,^[11] where no wild species are distributed today. In Panama, phytoliths identifiable on a morphological basis as *C. moschata* (Fig. 2b) occur in contexts that predate 7000 b.p., perhaps by 1000 years (Piperno, unpublished information). Phytoliths from bottle gourd are also present at all of these sites, supporting evidence from highland areas that this plant was dispersed and well used at an early date in the Americas.

Phytoliths and the Origins and Dispersals of Maize

Mexico is the undisputed cradle of origin for maize, but the timing and routes of maize domestication are under active debate. Some investigators,^[12,13] relying on the existing macrofossil evidence from a few sites in the dry Mexican highlands, adhere to a mid-Holocene time frame for maize's beginnings (ca. 5500 to 5000 b.p.). Others^[11,14] estimate that domestication by ca. 7000 b.p. is more accurate, given the existing microfossil evidence

Fig. 2 a–e. Phytoliths from the fruit rinds of various species of *Cucurbita* and bottle gourd. They are formed in specialized spaces at the interface of the hypodermis and upper mesocarp of the rind, and thus acquire the characteristics of these cell arrangements, which are diagnostic of *Cucurbita* and *Lagenaria* and can be species-specific in *Cucurbita*. (a) *Cucurbita moschata*; (b) *C. moschata*; (c) *C. maxima* ssp. *andreana*; (d) *C. maxima*; (e) *Lagenaria siceraria*. (Published with permission from the Proceedings of the National Academy of Sciences.)

from south of Mexico (discussed later). Because the earliest known maize macrofossils date to 5400 b.p. at Guilß Naquitz Cave and are already domesticated, and because no prior evidence for the exploitation of a wild or domesticated *Zea* exists from this site or others located in the dry Mexican highlands,^[15] the record is clearly incomplete. Recent pollen evidence indicating that maize spread to the Gulf Coast lowlands of Mexico by ca. 6200 b.p., where it was likely grown under slash-and-burn methods of cultivation, helps to fill this gap.^[14]

Regardless of their chronological stripes, many investigators, relying on the molecular evidence obtained from modern maize and its closest living wild relatives, looked to the tropical deciduous forest of the Central Balsas River Valley in southwestern Mexico as a likely region for maize's origins.^[4,12,14,16] A recent molecular analysis indicates that the oldest surviving maize races are from the Mexican highlands, although the lower-elevation Central Balsas populations of parviglumis teosinte are still identified as being genetically closest to maize.^[17] Whether these findings reflect a different distribution of Balsas teosinte during the early Holocene than seen today, an inadequate representation of prehistoric lowland maize diversity in extant Mexican maize, or simply the nearly total lack of archaeological information from sites in the Balsas River Valley, requires further archaeological and paleoecological research in the Balsas and other lowland regions and more excavations in the highlands.

Of greatest concern is that microfossils of maize—be they pollen or phytoliths—are routinely recovered from archaeological and paleoecological contexts in southern Central America and northern South America that date from ca. 7000 to 5000 b.p.^[11] A middle-Holocene time frame for maize domestication does not seem to account for these findings. At the Aguadulce Rock Shelter, Panama, where discrete assemblages of phytoliths from maize cupules and chaff are stratified in deep, securely dated, late preceramic sediments (7000 to 6000 b.p.), residues from plant grinding stones from the same contexts also yield starch grains from maize kernels and maize chaff/cupule phytoliths^[11,18] (Piperno and Holst, this volume). Future work in Mexico will reveal the age of *Zea* as a domesticated taxon, but newer research to the south increasingly indicates it was dispersed into the tropical lowlands of Central America and northern South America at an earlier date than once believed. It may have been a valued plant in the ceremonial life of social communities, and consumed as a fermented beverage.

Phytoliths and the Prehistory of Slash-and-Burn Cultivation

Indigenous agriculture in the tropical forest today often involves the practice of swidden, or slash-and-burn, cultivation by people whose settlements are small and

impermanent clusters of houses exercising social and political autonomy. Swidden cultivation is land-extensive; that is, one to two hectares of land are typically required to feed a single family, meaning that large areas of terrain are abandoned after a few years of use. Therefore, although early human settlements may be hard to identify archaeologically, past agricultural practices in the forest should leave identifiable signatures in paleoecological records, where a regional portrait of vegetational change reflecting forest clearing, burning, and plant succession may be obtained through pollen and charcoal studies.^[14]

Phytolith analysis of lake sediment cores provides comparable signals of these activities.^[19] When phytolith, pollen, and charcoal studies are carried out in tandem, more refined pictures of past agricultural practices can be obtained because each technique has strengths that redress the other's shortcomings in terms of the production and taxonomic specificity of major, indicator arboreal and herbaceous taxa.^[19] Such multiproxy evidence for the beginnings of slash-and-burn cultivation in the Neotropics has been obtained from lake sediments in Panama and Ecuador, dating to 7000 b.p. and ca. 5300 b.p., respectively.^[11] In these sequences, phytoliths and pollen from cultivars, including maize, are embedded within large phytolith and pollen populations of early successional herbaceous and arboreal species, and numerous micro- and macrofragments of charcoal. In Panama, the paleoecological data originate from the same region and time periods providing the archaeological phytolith and starch grain evidence noted in the foregoing. Other paleoecological findings wherein phytolith studies are not yet incorporated are similar, with agricultural systems containing maize and other cultivars (e.g., manioc and tree crops) being evidenced on the Gulf Coast of Mexico at 6200 b.p.,^[14] and in the Cauca Valley, Colombia, and the Colombian Amazon by 5200 and 4700 b.p., respectively.^[11]

It thus appears that techniques of swidden cultivation have considerable antiquity in the American tropics. Combined archaeobotanical and paleoecological data indicate that earlier (ca. 9000 to 7000 b.p.) food production seems to have been a more simple and inexpensive kind of horticulture, perhaps practiced largely in house gardens, which did not involve significant field preparation and the progressive removal of primary forest trees from large areas.^[11]

CONCLUSION

Phytolith studies provide empirical data relating to the early use and spread of some important crop plants in the American tropics. The results, especially when combined with those from palynology and starch grain analysis (see [Piperno and Holst](#), this volume), indicate that the lowland Neotropical forest was an early and important center of

plant husbandry in the Americas. Although Neotropical plant husbandry has been typically viewed as root and tree crop based, some seed crops (e.g., *Cucurbita*) were incorporated into early cultivation practices. We can expect continued accumulation of information, as new sites are excavated or existing sediments and other cultural materials are analyzed using phytolith techniques.

Crop Domestication in the American Tropics: Starch Grain Analyses

Dolores R. Piperno

Irene Holst

Smithsonian Tropical Research Institute, Balboa, Republic of Panama

INTRODUCTION

A cardinal attribute of New World agriculture is the large number of plants that were taken under cultivation and domesticated for their starch-rich underground organs.^[1,2] The lowland tropical forest contributed several of these, including manioc (*Manihot esculenta* Crantz), sweet potato (*Ipomoea batatas* (L.) Lam.), yams (*Dioscorea trifida* L.f.), yautia (*Xanthosoma sagittifolium* (L.) Schott & Endl.), arrowroot (*Maranta arundinacea* L.), and lirén (*Calathea allouia* (Aubl.) Lindl.).^[1–3] However, research bearing on when and where they were originally domesticated and dispersed out of their cradles of origin has been hampered by a paucity of data. In all but the most arid climates, soft, starchy plant structures are not preserved in archaeobotanical records, and most root crops similarly contribute sparse pollen records and few or otherwise unidentifiable phytoliths.^[4]

Starch grain studies can help us to elucidate these problems. This paper discusses some present applications and future directions of starch grain analysis in tropical archaeology. It describes how starch analysis may document not only past root crop cultivation, but also the early use and spread of important seed plants such as maize (*Zea mays* L.) and beans (*Phaseolus* spp.).

STARCH GRAINS: THEIR PROPERTIES AND ARCHAEOLOGICAL IDENTIFICATION

Starch grains, which are found in large quantities in most higher plants, are the major form in which plants store their carbohydrates, or energy.^[5,6] Starch grain molecules are primarily composed of amylose and amylopectin. They can be found in all organs of a higher plant, including roots, rhizomes, tubers, leaves, fruits, and flowers. However, only subterranean organs and seeds commonly possess what is called reserve starch, which is differentiated from another type of starch called chloroplast or transitory starch. The latter is principally formed in leaves and other vegetative structures and can also be found in pollen.^[5,6] An important difference between chloroplast

and reserve starch relevant to archaeological research is that reserve starches are produced in a highly diverse array of forms that may be genus- and even species-specific, while transitory granules are mostly of the same type and of limited use in identification. Also, transitory starch, as its name suggests, is formed during the day and utilized at night, while reserve starch is stored and utilized later in the cycle of the plant. Therefore, it is the reserve starch, formed in tiny organelles called amyloplasts, that is most useful for archaeobotanical enquiry. Because reserve starch grains are quite different in morphology from transitory starches, one can also identify the source of many reserve starches as seeds or underground plant organs.

There is a large amount of literature on starch grain properties and morphology that researchers interested in archaeological applications can refer to.^[5–8] Any number of atlases and keys of starch grains exist, among the most extensive of which are Reichert's^[5] and Seidemann's,^[9] which contain descriptions and photographs of starches from hundreds of economically important tropical and other plants. A dedicated starch journal, *Die Stärke*, also exists, in which starch grains of various taxa are routinely described and illustrated. It is widely acknowledged by botanists that the morphology of starch granules can be specific to, and diagnostic of, an individual genus or species. The morphological features that allow for identification can be observed with a compound light microscope and include granule shape and size, form and position (centric or eccentric) of the hilum (the botanical center of the granule), presence and types of fissures (natural cracks on the grains at the hila) and lamellae (growth bands), and number and characteristics of pressure facets.^[5,10] Studies undertaken in the authors' laboratory of over four hundred species of crop and other plants of economic importance indicate that starch grains from maize, *Phaseolus* and *Canavalia* beans, manioc, sweet potato, yams, arrowroot, yautia, yam beans (*Pachyrrhizus* spp.), peanuts (*Arachis hypogaea* L.), squashes (*Cucurbita* spp.), and palms possess the same morphological attributes noted by previous investigations and are distinguishable from each other and those of different genera in this reference collection (Fig. 1a–h).

Fig. 1 Starch grains from various crop plants of the Neotropics showing how they are differentiable on the basis of overall shape and characteristics of the hila, fissures, pressure facets, and lamellae. **a** manioc roots; **b** sweet potato roots; **c** maize kernel, Race Jala; **d** maize kernel, Race Harinoso de Ocho (eight-rowed flour corn); **e** yam (*D. trifida*); **f** arrowroot root (*M. arudinacea*); **g** lirén root (*Calathea allouia*); **h** common bean (*Phaseolus vulgaris*). Also notice that starch grains from hard and soft endosperm maize varieties can be distinguished (**c** and **d**) because the manner in which they congregate at formation creates differences in their starch populations (rough, angled, and irregular in hard endosperm vs. circular, smooth, and without fissures in soft endosperm).

The large corpus of literature on starch grain morphology was mainly compiled by researchers focused on the purely botanical aspects and commercial uses of starches. Less attention was understandably given to how grain size and morphology in domesticated crops might differ from those in closely related wild species. This will become an area of intense interest for paleoethnobotanists, as they seek to explore the potential of starch grain studies in investigating the earliest histories of some important roots and tubers. Studies carried out recently, for example, by the authors and others indicate that starch grains from bitter and sweet forms of manioc sampled from Central and South America can be distinguished from those of its wild ancestor, *M. flabellifolia* (Pohl) Ciferri^[11] and other

wild species of *Manihot* occurring in southern central America on the basis of both morphology and size.^[10,12,13] More work of this kind will eventually determine which other domesticated species might be identifiable in their cradles of origin.

ARCHAEOLOGICAL RECOVERY AND APPLICATIONS

As with phytolith studies, starch analysis is predicated on the notion that when the macro-structures of tubers decay, some of the starch grains they contain will survive in a largely unaltered state and be retrievable for study. The properties of starch grains and their sensitivity to degradation under various conditions, which largely determine their capacity for long-term survival, are fairly well understood and can be summarized as follows: Starches are highly sensitive to heat, strong acids and bases, and oxidizing compounds. Many grains start to gelatinize, whereby they melt and lose their diagnostic properties, at temperatures of between 40 and 50°C. These factors probably mean that they may often be more poorly preserved in some contexts associated with ancient human settlements (e.g., leached and acidic soils, alkaline shell middens, locations near the heat of hearths) than are either phytoliths or pollen grains. Similarly, starches may not commonly remain as identifiable residues in archaeological ceramics (unless the pots had a storage function), although this question is in need of study.

The number of archaeological starch grain studies carried out to date in the humid Neotropics is limited, but results have been rewarding. Starch grains from a variety of plants survive well on the used facets of plant grinding stones, where the superficial cracks and crevices on the stones apparently afford them long-term protection from the various processes that degrade them. In contrast, and not surprisingly, associated archaeological sediments examined thus far from the tropical forest contain almost no starch. For example, the authors isolated starch grains from early Holocene-aged (ca. 10,000–9000 b.p.) grinding stones from the Upper Cauca Valley, Colombia.^[3] A variety of taxa were represented, including *Maranta* spp. and unidentified legumes and grasses. Grinding stones from late preceramic (7000–5000 b.p.) and early ceramic archaeological contexts (ca. 5000–3000 b.p.) in Central Pacific Panama yielded starch grains from a variety of plants, including manioc, maize, arrowroot, yams, and legumes.^[10,12] This study also indicated that (a probably sweet form of) manioc was domesticated and then spread into southern Central America from southern Amazonia, its area of origin,^[11] by ca. 7000 b.p. to 6000 b.p., and it supported previously obtained archaeological and paleoecological phytolith and pollen data for an early

development of agriculture in central Panama using both root and seed crops.^[13]

Another recent archaeological starch grain study involves analyses of small, longitudinal chips of stone, called “grater chips”, retrieved from archaeological sites in the Middle Orinoco Basin dated to between A.D. 430 and 720.^[13,14] On the basis of an ethnographic analogy, these quartz flakes were thought to have been used for processing bitter forms of manioc. The starch studies, however, resulted in the recovery of hundreds of starch grains, none of them from manioc. With the use of a large reference sample of plants from the region and published starch grain atlases, starches from maize, yams, palms, and *Calathea* spp were identified, showing a more diverse assemblage of plants than was expected on the artifacts based on inferences derived from ethnographic analogies.^[13,14] The absence of manioc starches also raises new questions concerning the antiquity of bitter manioc-based economies in this region of South America. Finally, maize-like starch grains have been found in Mayan teeth calculi,^[15] where they were the most abundant starch remains present. Possible manioc grains were also present on the teeth. Food residue of various types found in tooth calculi, while not commonly studied at present, have considerable potential for the elucidation of dietary trends in the Neotropics.

CONCLUSIONS

Starch grain research in the humid tropics is in its beginning stages, but the considerable potential is obvious. Armed with good modern reference collections, archaeobotanists can begin addressing a number of important questions concerning agricultural history in the lowland Neotropics. With the considerable amount of basic information already available on starch grain morphology, researchers should be able to fairly expeditiously move into questions concerning the discrimination of starches from crop plants and their closest living wild relatives. Archaeological specimens from newly excavated cultural occupations or well-curated artifacts and sediments retrieved from previous research may form the basis for starch grain analysis.

Crop Domestication in the Andes and Lowland South America

Barbara Pickersgill

Department of Agricultural Botany, School of Plant Sciences, The University of Reading, Reading, Berkshire, U.K.

INTRODUCTION

South America is a continent of contrasts. In the west, the north–south chain of the Andes rises abruptly from one of the driest deserts in the world. In the east, the Andes fall equally abruptly to the Amazon Basin. The distinction between highlands and lowlands is reflected in both crops and cultures. The Andean region is the source of potato, common and lima beans, one species of cotton, and tobacco, *inter alia*. Cultigens of the lowlands include cassava, sweet potato, peanut, and pineapple. There is controversy about whether South American crops were domesticated independently of domestication in Mesoamerica,^[1] whether the concept of plant cultivation arose independently in the Andes and Amazonia,^[2] whether there were discrete centers of domestication or whether the whole continent was a noncenter,^[3] and whether the same crop was domesticated more than once within South America.

Resolving these controversies requires a two-pronged attack: study of living plants and study of archeobotanical remains. Recently, advances have been made on both fronts. The DNA polymorphisms in living plants may allow the wild progenitor(s) and also the location(s) that gave rise to a given cultigen to be identified. Pollen and phytoliths can be recovered from archeological contexts in humid as well as dry soils, and may be identifiable to genus or even species, as may starch grains recovered from use surfaces of stone tools. None of these techniques is free from controversy but, employed critically, they promise to advance considerably our understanding of plant domestication in South America.

GEOGRAPHICAL BACKGROUND

South America was originally part of Gondwanaland, whereas Mesoamerica was part of Laurasia. The two continents became connected by a land bridge about three million years ago, coincidental with the major uplift of the Andes.^[4] Prior to this, the Amazon drained into the Pacific. Subsequently, it formed a gigantic lake over what is now the Amazon Basin,

before cutting a new exit to the Atlantic. Much of this Basin is extremely low-lying. Winds from the Atlantic retain considerable moisture until they reach the Andes. The tributaries of the Amazon have large catchments and also drain areas of high rainfall; so these tributaries and the Amazon itself flood seasonally and spectacularly. Only short-season crops (e.g., some types of peanut and maize) can be grown on the productive floodplain soils. Long-season crops (e.g., cassava) are grown on the less fertile interfluvial soils.

Conditions west of the Andes are dramatically different. The cold northward-flowing Humboldt Current causes air from the Pacific to shed much of its moisture before it reaches land; so the coastal plain of Peru and Chile is an extremely dry desert. The western slopes of the mountains are likewise dry. Numerous rivers drain these slopes. Many do not flow year-round because of their short courses and limited rainfall in their catchments. However, as they cross the coastal plain, they produce locally higher water tables, making possible some specialized forms of agriculture.

DIVERSITY OF CROPS DOMESTICATED

Table 1 lists the major crops domesticated in South America. It omits crops of mainly local importance (such as the highland grain crop quinoa, the complex of highland root crops oca, ullucu, and añu, and the lowland root crops arrowroot, lleren, and achira), crops that have lost their previous importance, such as bottle gourd and calabash gourd, and species such as Brazil nut, which were neither cultivated nor domesticated, but exploited and, by analogy with present-day Amerindian practice, probably enhanced in frequency by deliberate planting along trails, etc.

In both highlands and lowlands, domesticates included all components of a balanced diet: sources of calories and carbohydrates (potato in the highlands; cassava in Amazonia), protein-rich legume seeds (common and lima bean in the Andes; peanut in Amazonia), and seeds or fruits rich in oil (peanut, various species of squash, avocado, etc.). Chili peppers added spice; cotton provided fiber for clothing, fishing, and

Table 1 Major crops domesticated in South America, their probable place of domestication and earliest archeobotanical occurrence

Crop	Place of domestication		Earliest archaeological record		
	Location	Evidence	Site	Date ^a	Evidence
Root crops					
White potato <i>Solanum tuberosum</i> ssp. <i>andigena</i>	Lake Titicaca region of Peru and Bolivia	Distribution of wild and cultivated relatives	Ancón-Chillón, central coast of Peru	c. 4500 bp	Tubers (not identified to ssp.)

^bThese dates were obtained from associated wood charcoal. Direct accelerator mass spectrometry dates on a sample of crop specimens were essentially modern.

cordage; ritual or recreational needs were satisfied by tobacco, coca (source of cocaine), and various hallucinogens. Although not domesticated by the Amerindians, rubber and quinine also originated in South America.

SIMILARITIES BETWEEN ANDEAN AND MESOAMERICAN CROPS

Domesticates common to the Andes and Mesoamerica include *Phaseolus* and *Canavalia* beans, squash, cotton, chili pepper, amaranth, *Chenopodium*, avocado, and bottle gourd. In most cases, different species were domesticated in each region. Common bean and lima bean are exceptions, but on molecular, morphological, and biosystematic evidence both were domesticated independently in Meso- and South America from wide-ranging wild ancestors. Avocado also occurs early in both Meso- and South America, and may have been domesticated independently in each continent.

In all these genera, a wild taxon apparently migrated from one continent to the other by natural long-distance dispersal, and the geographically isolated populations then differentiated into distinct species or infraspecific variants. Similarities in the wild plant resources available in the dry highlands of Mexico and the Andes, rather than extensive contacts between their prehistoric inhabitants, led to the striking parallels in the crops of the two areas.

However, man must have spread maize from Mesoamerica to South America, possibly at least 6700 years ago (evidence from phytoliths) and certainly by 4000–2600 years ago (macroscopic remains).^[3] *Cucurbita moschata* also occurs from 6900 bp in Mexico and 5000 bp in Peru. It is unknown in the wild, seems to be close to a group of Mesoamerican wild species, but is thought, on rather weak evidence (Table 1), to have been domesticated in South America. Maize, beans, and squash form the so-called Holy Trinity of New World agriculture, but if maize and *C. moschata* spread as a complex, one would expect to find evidence of maize in South American sites producing early remains of *C. moschata*, and this does not occur.

Cacao (*Theobroma cacao*), the source of chocolate, originated in South America but was an important domesticate in Mesoamerica. Molecular data show that the “ancient Criollo” cacao of Mesoamerica is more similar to wild cacao from eastern Ecuador than to any other cultivated or wild cacao.^[7] Man may be implicated in the spread of cacao from South America to Mesoamerica, but it is not yet clear whether this involved the spread, in cultivation, of a species that had already been domesticated in South America, or the dispersal and enhancement of an exploited, but

not yet domesticated, species, as already outlined for Brazil nut in Amazonia.

DOMESTICATION WITHIN SOUTH AMERICA

The Andean region has long been considered a center in which agriculture originated, preceding and possibly stimulating the development of agriculture east of the Andes. An alternative view^[2] is that agriculture in the humid lowlands developed independently, possibly very early. There are few reliably dated archeobotanical specimens from the highlands, so the antiquity of highland agriculture is not yet securely established, though highland cultigens are present on the desert coast by about 5000 bp (Table 1). In Amazonia, there is evidence of forest clearance from 10,000 bp onwards, together with phytoliths identified as those of bottle gourd, domesticated squash (on the basis of size), and the root crop lleren (*Calathea allouia*).^[2] Carbonized remains of palm and other fruits were recovered from some of these sites, although there were no macroremains of gourd or squash. This, together with the ease with which microscopic objects such as phytoliths could become displaced in the archeological sequence, suggests that the relative ages of highland and lowland agriculture are still unclear.

The Andean region and Amazonia are both large areas, and it has been suggested that within each there may be several localized foci of plant domestication (Table 1).^[8] In the Andes, these foci are the highlands of southern Peru and Bolivia (potato and the highland root crop complex, *Chenopodium quinoa*, common bean, *Cucurbita ficifolia*, and others), northwest Peru and Ecuador, possibly extending to Colombia (lima bean, cotton, and *Cucurbita ecuadorensis*), and Chile (*Fragaria chiloensis*, *Bromus mango*, and possibly *Solanum tuberosum* ssp. *tuberosum*). In Amazonia, major centers have been suggested in northwest Amazonia (*Xanthosoma*, *Cucurbita moschata*, pineapple, avocado, cacao, and *Capsicum chinense*) and the southern rim of the Amazon basin, extending to lowland Bolivia and Argentina (cassava, peanut, *Cucurbita maxima*, and tobacco, and possibly *Canavalia plagioperma* and *Capsicum baccatum*). In addition, four minor centers of crop diversity (though not necessarily domestication) and five regions of diversity have been suggested.^[8] These multiple foci fit with the concept of South America as a noncenter of domestication.^[3]

MULTIPLE DOMESTICATIONS OF SOUTH AMERICAN CULTIGENS

Molecular data have recently been used to argue for multiple domestications of some South American

species. In common and lima beans, differences in seed storage proteins suggest that these were perhaps domesticated independently in Colombia as well as further south in the Andean region.^[9] In tetraploid *S. tuberosum*, cytoplasmic differences and one feature of chloroplast DNA (but not others) may indicate that ssp. *andigena* was domesticated in the Peruvian-Bolivian highlands and ssp. *tuberosum* in Chile.^[10] However, in both beans and potatoes, hybridization of introduced domesticates with local wild taxa could explain these differences. In cotton, archeological specimens from coastal Peru show an increase through time in seed size and fiber diameter, strongly suggesting local domestication. But morphological differences between western Andean and Amazonian cottons may argue for a second center of domestication in Bolivia,^[11] in or near the southern Amazonian center of domestication.

On the other hand, molecular data clearly demonstrate that cassava was domesticated in a single locality,^[12] although previously it was a favorite candidate for multiple domestications.

Both the Andes and lowland South America thus seem likely to differ radically from Southwest Asia, not only because they may be noncenters rather than centers of domestication, but also because wide-ranging species may have entered cultivation several times, not just once.

CONCLUSIONS

Table 1 clearly demonstrates how much has still to be learned about where, when, and from what many of the major crops of South America were domesticated. Although new tools are now available for investigating these questions, they have yet to be applied to a sufficient number of the South American cultigens for a clear picture to emerge of the number of centers of domestication, the relative antiquity of each, and hence their independence from one another.

Crop Domestication: Fate of Genetic Diversity

Gideon Ladizinsky

Hebrew University, Rehovot, Israel

INTRODUCTION

Nearly all crop plants originated directly from wild ancestors, some of which are still thriving in natural habitats. Populations of wild progenitors of crop plants, and of other wild plant species, usually exhibit various degrees of diversity in morphological and physiological traits as well as in molecular markers. Crop plants usually possess only part of the genetic diversity of their progenitors, but are characterized by traits that never occurred in their wild parents. As crop plants and their wild progenitors are still capable of free gene exchange, what were the processes and forces that caused such a shift in genetic diversity between the two? As is shown in this article, human selection (unconscious and deliberate) and the adaptive value of domesticated characters under this selection played a key role in that shift in genetic diversity.

THE SHAPE OF GENETIC VARIATION IN CROP PLANTS AND THEIR WILD PARENTS

Crop plants and their wild parents differ from each other in a few key characters known as the domestication syndrome. These sharp differences are the main reason that in classical taxonomy the two are still treated as separate species.

Variation in natural populations of wild progenitors is believed to be regulated mainly by natural selection. Yet, the adaptive value of variation in molecular markers is often questioned and has even been regarded as neutral. Evidence of the adaptive nature of molecular variation is not prevalent, as consistent differences in allozyme and microsatellites pattern between wild wheat plants occurring across narrow boundaries of basalt and terra-rossa soil types^[1] indicate that these differences are of adaptive nature.

Whereas populations of wild progenitors have perpetuated themselves for millennia in their natural habitats, crop plants cannot survive without human care. This is because of the loss of several traits that are vital for survival in nature but are selected against in cultivated fields. In most seed crops the loss of the seed dispersal mechanism marks the transition from wild to domesticat-

ed state. Wild barley, *Hordeum spontaneum*, disperses its seeds shortly after maturity when the spike axis (rachis) disintegrates into individual dispersal units. Each unit contains at the bottom a segment of the spike axis, a single seed of the central spikelet ending in a long awn, accompanied by two sterile lateral spikelets. This arrowhead structure ensures quick burial of wild barley seeds in the ground. In domesticated barley the spike axis remains intact after maturity and occasionally even upon threshing (Fig. 1). Tough spike axis is controlled by each of two recessive genes. Hence, the transition from wild to domesticated state in barley is due to a single mutation. Other components of the domestication syndrome in barley and in other crops that are unique to domesticated forms are also the result of mutation in a single gene or in a small number of genes.^[2]

HOW MUCH VARIATION OF THE WILD PROGENITOR IS POSSESSED BY THE CROP?

Barley and many other grain crops are selfers and any individual plant is homozygous for most of its genes. Because the transition from wild to domesticated state in barley and many other crops is due to mutation in a single gene, the entire crop could theoretically have evolved from a single wild plant. If this is true, one would expect that of each polymorphic locus of the wild progenitor, only one or two alleles would be included in the crop. This must also be true for vegetatively propagated crops.

Comparison of DNA variation attempted between domesticated forms and their wild ancestor of many crops has shown that numerous (but not all) alleles of the wild progenitor's polymorphic loci are present in the crop plant. Molecular markers are suitable for such comparisons because, since the beginning of domestication, they have not been subjected to human selection, at least not directly. The results of these comparisons have two main implications for the nature of variation in crop plants: 1) domesticated products have undergone considerable genetic bottleneck; and 2) there must have been circumstances by which more than one allele of the wild progenitor's polymorphic loci could have been introduced into the crop plant.

Fig. 1 Wild and domesticated barley, natural size. At right, dispersal unit of wild barley; at left, postthreshing intact spike axis of two-row domesticated barley.

DOMESTICATION AS A FOUNDER EFFECT

Founder effect is a situation wherein a few individuals, possessing a portion of the variation of their mother polymorphic population, establish a new population in isolation from the mother population, and therefore are much more monomorphic.^[3]

Whenever sufficient evidence is available on the geographic distribution of the wild ancestor of the crop, the geographic distribution of the crop's wild genetic stock, and the locations where the crop was firstly domesticated, it

becomes obvious that only a few wild populations could have given rise to the crop. For example, the lentil's wild progenitor, ssp. *orientalis*, is native to the Middle East and Central Asia. All the tested domesticated lentils are interfertile, possess the same chromosomal architecture, and are almost monomorphic for their cytoplasmic genome (cpDNA). All the tested ssp. *orientalis* populations from Israel and Lebanon differ from the cultigen by a single chromosomal rearrangement. Other populations from Turkey differ from the cultigen by other chromosomal aberrations, and others are cross-incompatible with the cultigen. Sub sp. *orientalis* accessions from Central Asia possess the chromosomal architecture of the cultigen but differ in their cpDNA. Only populations from northern Syria and southern Turkey match the chromosomal architecture of the cultigen or share its cytoplasmic genome and crossability potential. Again, hidden traits that could not be selected for or against by humans and that are polymorphic in the wild progenitor but monomorphic in the cultigen, can be utilized for determining the wild genetic stock of the cultigen.^[4] It is safe to say that domesticated lentil evolved from wild populations in a rather restricted area of the wild lentil's distribution range; consequently, genetic variation of other populations was excluded upon domestication. Concomitance between domestication and founder effect is not unique to lentil. Of the three chromosomal types of wild pepper *Capsicum annum* var. *minimum*,^[5] only one is present in the cultigen. Of several phaseoline seed protein types of wild bean, only one is present in the domesticated bean.^[6] Similarly, sunflower is monomorphic for several enzymes and cpDNA, and is identical to one of the wild sunflower subsets.^[7] Alleles of enzymic genes occurring in wild soybean,^[8] barley,^[9] and radish^[10] are missing in their domesticated counterparts. These examples and many others indicate a severe bottleneck situation during domestication as a result of founder effect.

POSSIBLE SOURCES OF PARALLEL VARIATION IN THE CROP AND ITS WILD FORM

Crop plants differ from their wild ancestors by a set of characters favored by humans and better adapted to their agricultural technology, but negatively selected in the wild. In other words, they are the outcome of changes in selection pressure exerted by humans. Traits not involved in that adaptation have been affected by natural selection and in the wild. As indicated in the foregoing, some of the molecular alleles of the wild progenitor are missing in the cultigen, although a great many of them are present. With the notion that crops derive from a single mutant plant, it is assumed that the parallel variation of molecular genes in

crops and in their wild ancestors is due to postdomestication mutations in the crops, or to gene flow between the crops and their wild form.

It is highly improbable that postdomestication mutation in the crop has created similar allelic frequency of molecular genes in the crop and its wild ancestor, particularly in the relatively short time since domestication began (see Kaplan contribution). Gene flow between the two is also an inadequate explanation, even when they grow side-by-side. When hybridization between the two takes place, the wild plant is usually the pistil parent because the amount of pollen released by the crop is far greater than that produced by the wild form (see Papa and Gepts contribution). Gene flow from the crop to its wild form can be detected by the aid of the crop's traits that never occurred in the wild. Such a character in barley is six-row spike, which resulted from a mutation changing the two lateral sterile spikelets at each spike node into fertile ones. Hybrids between six-rowed barley and *H. spontaneum* have brittle six-rowed spikes known as Agriocriton. Small populations of the Agriocriton type may occur at edges of fields and along roadsides, and some persist for many years. Similarly in maize, gene flow from the cultigen to its wild form, teosinte, created a seed dormancy-free teosinte type that became a serious weed in parts of Mexico.^[11] Hybridization wherein the crop plant is the pistil parent must occur as well, particularly in cross-pollinating plants and garden crops, where gene flow from the wild parent is prevented by weeding out such hybrids or hybrid derivatives.^[11]

Similar allelic frequency of molecular genes in the crop and its wild form cannot be accounted for by gene flow at the transitional period when farmers grew mixtures of domesticated and wild forms.^[12]

The conclusion from all these is that many crop plants have evolved not from a single mutant plant but from several independent mutants, each of which contributed to the crop the same or different alleles of molecular genes. The number of domesticated mutants that gave rise to the barley crop has been estimated to be about 100.^[13] This number could allow the introduction of esterase alleles into the cultigen, occurring at the rate of 0.01 in wild barley.

CONCLUSION

Founder effect and bottleneck situations during the first stages of domestication have caused only part of the genetic variation of the crop's wild progenitor to be present in the domesticated forms. Domestication occurred in a restricted area of the distribution range of the crop's wild progenitor, and was involved in a relatively small number of individuals. Parallel variation in the crop and its wild form is due mainly to the number of the crop's founder

mutants, and only negligibly to postdomestication gene flow. Under domestication, crop plants have acquired new traits that are negatively selected in the wild and have never been recorded in the wild form. Many of these traits are monogenic and highly adapted to agriculture practices and technology. Their establishment could occur automatically or with the aid of active human selection.

Because only part of the wild form's genetic variation is present in the crop, the wild form remains a valuable source of economically important traits for crop improvement. Most notable is pest and disease resistance, but stress-tolerant food quality and other traits may be demanded in the future.

Crop Domestication: Founder Crops

Daniel Zohary

Hebrew University of Jerusalem, Jerusalem, Israel

INTRODUCTION

At present, the questions of when and where plant domestication started and how agricultural systems evolved are only partly answered. This entry tries to sketch what is already known on 1) the nuclear areas where plant domestication was independently initiated in several parts of the world and 2) the founder crops that, in each of these core areas, triggered the shift from hunting and gathering to food production. The survey focuses on the origin and subsequent development of the region of Mediterranean agriculture (Southwest Asia, the Mediterranean basin, and temperate Europe). This is the most extensively explored agricultural system. It is also the region in which the earliest, definite evidence on plant domestication has been discovered to date.

KINDS OF EVIDENCE FOR ELUCIDATING THE BEGINNING OF AGRICULTURE

The study of the origin of domesticated plants is an interdisciplinary venture based on information obtained from numerous fields. However, the modern synthesis^[1–3] leans heavily on two principal sources: 1) the archaeological evidence obtained from examining plant remains uncovered in archaeological excavations and 2) the botanical and genetic evidence extracted from the living plants. Archaeology supplies the fossil evidence and a radiocarbon ¹⁴C timetable for the reconstruction of the history of farming. The study of the living plants identifies (by genetic tests) the wild ancestry of the crops, and uses the geographic distribution ranges of the wild progenitors to define the general areas in which domestication could have taken place. In addition, comparisons between the wild forms and their domestic counterparts reveal the changes that the crops underwent under domestication. Molecular surveys of the genetic polymorphism found in the crops and in their wild counterparts provide clues as to how and, more specifically, where these plants could have been domesticated.

In both disciplines, considerable information has already been assembled.^[1,2,4] However, this evidence is very uneven. A few parts of the world (southwest Asia, Europe, Meso- and North America) have been extensively

studied—both archaeologically and botanically. In these territories, critical information on the start of agriculture is already available, permitting a relatively safe evaluation. The archaeological exploration of several other large landmasses (East Asia, the Indian subcontinent, South America) is much scarcer. Yet the finds do provide some clues about the early history of farming in these territories. In still other large parts of the world (Africa south of the Sahara, most of the tropical belts of America and Asia), the archaeological evidence is still deplorably insufficient. (Yet, in tropical crops analyses of starch grains and phytoliths might soon change this picture.) All together, the information on the beginning and early expansion of agriculture is strongly skewed. At present, what can be reliably evaluated is not the full global picture, but only the relatively better-explored regions.

FOUNDER CROPS AND NUCLEAR AREAS

In spite of the large lacunae that still exist in the archaeobotanical information, the combined evidence from the excavations and from the living plants clearly shows that farming was independently initiated in several parts of the world. In each such separated, relatively small nuclear area, or cradle of agriculture, indigenous wild plants were taken into cultivation. They evolved into the first crops (the founder crops) that initiated food production in these core areas. Consequently the growing of these cultigens triggered the development of distinct, agricultural systems—each with its characteristic and largely unique crops. To date, the following five nuclear areas (Table 1) have been widely accepted by crop plant evolutionists and archaeologists:^[2,4] 1) The Fertile Crescent belt in the Near East; 2) The valleys of the Yangtze River and of the Yellow River in China; 3) Southwest Mexico; 4) The Central Andes; 5) and the eastern United States. Additional nuclear areas have been proposed by various authors (for example, the Sahel belt and the Ethiopian highlands in Africa; and the Papuan highlands in New Guinea). However, in the view of the present author, the archaeo-botanical evidence essential for backing these claims is, as yet, far from being sufficient.

It is also worth mentioning that not in every traditional agricultural system was farming started *de novo* by

Table 1 The five commonly accepted “nuclear areas” of the world (1–5), two examples of suspected ones (6?–7?), and the main founder crops that were uncovered in each of them^a

Nuclear area	Characteristic founder crops	Earliest definite signs of farming	Resulting agricultural system
1 The Fertile Crescent belt in the Near East	Emmer wheat, einkorn wheat, barley, pea, lentil, flax	9500 ¹⁴ C yrs b.p. (=10,500 cal yrs b.p.)	S.W. Asia, the Mediterranean basin, and temperate Europe
2 Valleys of the Yangze River and the Yellow River	Asian rice, foxtail millet	8500 ¹⁴ C yrs b.p. (=9500 cal yrs b.p.)	East Asian farming
3 Southwest Mexico	Maize, squash, common bean	4700 ¹⁴ C yrs b.p. (=5300 cal yrs b.p.)	Mesoamerican farming
4 Central Andes	Potato, quinoa, common bean	4500 ¹⁴ C yrs b.p. (=5100 cal yrs b.p.)	High altitude farming in the Andes
5 Eastern United States	Goosefoot, sunflower, squash	4500 ¹⁴ C yrs b.p. (=5100 cal yrs b.p.)	Died out
6? The Sahel belt and/or the Ethiopian highlands in Africa	Sorghum, pearl millet, cow pea, African rice	Sites containing early contexts were not uncovered yet	The savanna belt south of the Sahara
7? New Guinea highlands	Bananas, sugar cane, taro	6100 ¹⁴ C yrs b.p. (=7000 cal yrs b.p.)	Tropical S.E. Asian farming

^aAlso listed are the ages before present (b.p.) of the earliest definite signs of farming in each core area (both radiocarbon ¹⁴C age and calibrated, calendar age). For more information about ¹⁴C age calibration consult Ref. 5, particularly the “Calibration Table for Radiocarbon Ages” on p. 253.

isolated, independent domestication of native founder crops. The available archaeo-botanical information clearly indicates that in some parts of the world, agriculture was initiated by the arrival, from outside, of fully domestic alien crops, while domestication of a rich variety of indigenous plants came only later. The Indian subcontinent seems to be a relatively well-documented example for this kind of development. There, food production seems to have been started by the arrival (from the West) of the Near Eastern package of crops.^[1] Indigenous cultigens appeared in this landmass only later.

THE RISE AND SPREAD OF MEDITERRANEAN AGRICULTURE

In terms of the amount of information assembled on the origin of domesticated plants, the traditional region of Mediterranean agriculture (comprising Southwest Asia, the Mediterranean basin, and temperate Europe) is the best studied one. Its wild flora (including the identification of the ancestors of domesticated plants) is well recorded. Moreover, plant remains that have been expertly identified and radiocarbon dated are now available from hundreds of Neolithic and Bronze Age sites scattered all over this vast region. The earliest, definite signs of agriculture in this region were found in the Fertile Crescent belt of the Near East.^[1,2,4] Here, a string of early Neolithic farming villages appeared at the second half of the 10th millennium before present (b.p.) uncalibrated radiocarbon ¹⁴C time (=second half of the 11th

millennium b.p. calibrated time). (For further information on calibration of radiocarbon ¹⁴C ages consult.^[5]) Moreover, this colonization intensified in the next thousand years. Remains retrieved from these Pre-Pottery Neolithic B early sites show that eight plants growing wild in the Fertile Crescent, namely emmer-type hard wheat, einkorn wheat, barley, pea, lentil, chickpea, bitter vetch, and flax had already entered domestication.^[1] Common (and most revealing) are the remains of the wheat and barley. In contexts starting from 9500 ¹⁴C yrs b.p. (=10,500 cal yrs b.p.) onward, forms with nonshattering ears appear. This is a reliable indicator of domestication. It shows that there and then these cereals were already grown as crops. By 8500–8000 ¹⁴C yrs b.p. (=9500–8800 cal yrs b.p.) convincing signs of sheep, goat, cattle, and swine domestication appear, as well, and the Near Eastern Neolithic food production “package” was formed.

Once this package was assembled, and the early Neolithic farming villages were established, this new technology started to expand,^[1] and it did so explosively. By 8000 ¹⁴C yrs b.p. (=8800 cal yrs b.p.) this type of agriculture reached Greece. By 7000 ¹⁴C yrs b.p. (=7800 cal yrs b.p.) it had already established itself in southern Italy, Serbia, the Caucasus, and Turkmenistan. Less than 800–1000 years later, grain agriculture (as well as the rearing of sheep, goat, and cattle) was already widely practiced in the loess soil belt of temperate Europe—from the Ukraine to northern France. More or less at this time, this new technology spread to the western parts of the Mediterranean basin, and to the Nile Valley, reaching also the Indus basin. All over these vast territories, agriculture

was started by the introduction of the same Near Eastern founder crops. Additional Mediterranean plants, some native to other parts of this huge agriculture region, were incorporated only later. Most of the alien crops, domesticated outside the Mediterranean system, appeared much later.

Some three thousand years after the start of Neolithic grain agriculture, fruit tree cultivation (based on the invention of vegetative propagation) appeared in this region.^[1] As with grain crops, the earliest convincing signs of fruit crop horticulture were found in the Near East. Here, the native olive, fig, grape vine, and date palm have been introduced into cultivation at Chalcolithic times, some 5500 ¹⁴C yrs b.p. (=6300 cal yrs b.p.). Fruit growing, too, spread quickly. By the Early Bronze Age around 5000 ¹⁴C yrs b.p. (=5700 cal yrs b.p.), olive, grape vine, and fig were already principal elements of food production in the Levant countries. Their cultivation was soon extended to the Aegean belt. Date palm groves flourished in Mesopotamia and the warm fringes of the Near East. In Egypt, date cultivation seems to have started somewhat later. Remains of its fruits appear in masses from the Middle Kingdom times onward. More or less at this time the cultivation of this palm extended eastward and reached the Indus Plain.

From the Bronze Age onward there are also sound indications of cultivation of vegetables.^[1] Melon, watermelon, onion, garlic, leek, and lettuce were apparently the first vegetable crops grown in Egypt and Mesopotamia. Definite signs of their cultivation appear by 4500–3500 ¹⁴C yrs b.p. (=5100–3800 cal yrs b.p.). By 2800–2000 cal yrs b.p. the list of Mediterranean and Southwest Asian vegetable crops had grown considerably, and beet, turnip, cabbage, radish, carrot, parsnip, celery, parsley, and asparagus had also entered cultivation. More or less at the same time (about 2400–2000 cal yrs b.p.), a second group of native fruit trees (those in which cultivation depends on grafting) were also added. Most conspicuous among them are the apple, pear, plum, cherry and carob trees. Contrary to the earlier crops that were almost all introduced into cultivation in the Near East, many of the vegetables and the later fruit trees were probably picked up not in the Near Eastern nuclear area but in other parts of the Mediterranean system of agriculture. Thus, starting in the early Neolithic and ending in classic times, an impressive assemblage of native crops were domesticated, and they diffused all over Southwest Asia, the Mediterranean basin, and temperate Europe. Most of them remained economically important until today.

MODE AND PLACE OF DOMESTICATION

Recently, the comparison of the amount of genetic polymorphism present in domesticated crops with that

found in their wild progenitors provided effective tools for answering the following questions: 1) What was the mode of domestication of these founder crops? Were their wild progenitors introduced into cultivation only once, and in a single locality (and therefore had a single or monophyletic origin), or, alternatively, were they taken into cultivation several times and in different places (and therefore had a multiple or polyphyletic origin)? 2) Where (within the geographic distribution range of each of the wild progenitors) could domestication have taken place?

For elucidating the mode of domestication, one tries to assess what part of the genetic polymorphism found in the wild progenitor is also present in the crop.^[6] In cases of a single event, only a limited fraction of the total genetic variation present in the wild progenitor should be expected to enter the domesticated gene pool. In contrast, when multiple domestications occur, a much larger fraction of wild genetic variation has a chance to enter the domestic gene pool. Indicative of this is also the nature of the genes controlling key domestication traits (i.e., traits that were automatically and immediately selected for once the wild progenitor was introduced into cultivation). If in all cultivars of the crop a given domestication trait is found to be governed by the same major gene (or the same combination of genes), this uniformity suggests a single origin. In contrast, when in different cultivars (within the crop) such a domestication trait is governed by different nonallelic mutations, one should suspect multiple domestications. Comparisons have already been made in the following Near East founder crops: einkorn wheat, emmer wheat, barley, lentil, and pea.^[6–8] In all five founder crops, the available data suggest a monophyletic origin or, at most, very few domestication events.

For pinpointing the place of domestication, it is essential to test representative samples of the wild progenitor obtained from throughout its geographic range and to compare these samples with equally representative sampling of the domestic gene pool. The location where the progenitor's populations are genuinely wild and exhibit the closest genetic similarity to the crop should be suspected to be the place of domestication of the cultivar. In some of the Near Eastern founder crops (particularly in the wheats) extensive comparisons have already been carried out.^[7,8] Thus the place of domestication of cultivated einkorn wheat has been pinpointed to a small area in Southeast Turkey. Also in Mesoamerica, maize was similarly surveyed.^[2,6] Here populations of teosinte (the wild progenitor of domestic maize) showing full genetic similarity with the crop were found to be confined to a small territory in Southwest Mexico. In contrast, another basic crop of the New World, namely the common bean, apparently had a polyphyletic origin.^[10] The available evidence convincingly shows that different wild forms of this bean were taken independently into cultivation, both in Meso- and in South America.

CONCLUSION

As previously noted, our knowledge of where, when, and how agriculture evolved is still fragmented and skewed. Yet the available evidence fully supports the notion that farming was independently initiated in several nuclear areas. In each such cradle of agriculture, indigenous, wild plants were taken into cultivation. Some evolved as successful founder crops, initiated farming, and later frequently triggered the development of a distinct agriculture system. Equally impressive is the fact that many of the earliest crops retained their central role in food production all through the history of agriculture. This is the case with wheat, barley, pea, and lentil, i.e., the main founder crops in the Near East, rice in China, maize and beans in Mesoamerica, and (probably) bananas and taro in New Guinea. All seem to have founded agriculture; all are economically leading crops even today.

Crop Domestication: Role of Unconscious Selection

Daniel Zohary

Hebrew University of Jerusalem, Jerusalem, Israel

INTRODUCTION

The following two types of selection are associated with domestication. They operate (and complement each other) when wild plants are introduced into cultivation: 1) conscious selection applied deliberately by the growers for traits of interest to them; 2) unconscious or automatic selection brought about by the fact that the plants concerned were picked from their original wild habitats and placed in a new (and frequently very different) human-made environment. This shift in the ecology led automatically to drastic changes in selection pressures. In response to the introduction of the plants into the anthropogenic environment, numerous adaptations vital for survival in the wild environment lost their fitness and broke down. New traits were automatically selected to fit the new conditions, resulting in the build-up of characteristic domestication syndromes—each fitting the specific agricultural conditions provided by the domesticators.

It is now widely accepted that unconscious and conscious selection are closely intertwined and played an important role in shaping many of the domestication traits that characterize crops and distinguish them from their wild ancestors. This article outlines the role of unconscious selection in crop plant evolution. It evaluates some of the principal changes in the environment that these wild plants were exposed to, once taken from their natural habitats and transferred into cultivation. It traces some of the main changes in selection pressures that could have been caused by this shift in ecology, and it points out some of the morphological, physiological, and chromosomal developments expected to have evolved in response to these environmental changes.

MAINTENANCE PRACTICES AND THEIR IMPACT

Two main practices are used by the cultivator to grow plants: 1) planting of seed and 2) vegetative or clonal propagation. The choice between these two agronomic methods is also the choice between two contrasting patterns of selection and evolution under domestication.

With very few exceptions (of apomictic crops), seed planting can be equated with sexual reproduction. Cultivated plants maintained by seed (the bulk of grain crops, numerous vegetable and truck crops) undergo a recombination-and-selection cycle every sowing. In other words, such crops have been subjected, under domestication, to hundreds (or even thousands) of cycles of selection.^{1,2} They have been continually molded either as 1) clusters of inbred lines (in predominantly self-pollinated crops) or as 2) distinct cultivated races (in cross-pollinated plants). In numerous sexually reproducing crops, the results of such repeated selection are indeed impressive. Under domestication, these crops diverged considerably from their wild progenitors. At present, they are distinguished from them by complex syndromes of morphological, developmental, physiological, and biochemical traits.

In contrast, vegetatively propagated crops (most of the fruit crops and the tuber crops, some of the vegetables) have had an entirely different history of selection. Cultivars in these crops are not true genetic races, but just clonal replications of exceptional individuals, excelling in fruit or tuber qualities, which as a rule are also highly heterozygous. They were originally picked up from variable, panmictic, wild populations, and later also selected from among segregating progeny produced by the cultivars. In terms of selection, domestication of clonally propagated crops is largely a single step operation. With the exception of rare somatic mutations, selection is completed once a given clone is picked up. In traditional horticulture, the turnover of clones has been quite low, and appreciated genotypes were frequently maintained for long periods. Thus, clonal crops underwent, under domestication, only few recombination-and-selection cycles. In sharp contrast with sexually reproducing grain crops, their cultivars do not represent true breeding races, but only clones that, as a rule, segregate widely when progeny tested. Significantly, the large majority of such segregating progeny are economically worthless. Moreover, they often regress towards the mean found in wild populations, showing striking resemblance to the wild forms.

Seed and pollen fertility (including stable behavior of chromosomes in meiosis) are additional traits in which one finds wide differences between seed-planted crops and clonally propagated ones. In sexually reproducing populations, fertility is automatically safeguarded each generation by stabilizing selection. Mutations affecting fertility are promptly weeded out. As a rule, sexually

reproducing cultivars are generally fully fertile. In contrast, the shift from sexual reproduction (in the wild) to vegetative propagation (under domestication) brings about drastic relaxation of the stabilizing selection that safeguards fertility.^[1,2] Under such maintenance practice, sterile or semi-sterile clones are tolerated, including unbalanced chromosomal situations such as triploid, pentaploid, and aneuploid clones. Indeed, intracrop chromosomal polymorphism is quite common among clonally propagated crops. Besides, it should be pointed out that in clonally propagating crops, fertility is affected not only by the maintenance practice, but also by the choice of the desired parts (see next section).

THE PURPOSE FOR WHICH THE PLANT IS GROWN

Some cultivated plants are grown for their vegetative parts (roots, tubers, leaves, stems, etc.). In others, the reproductive parts (inflorescences, flowers, fruits, seeds) are used. The choice of the desired parts introduces automatically contrasting selection pressures, particularly in traits associated with the reproductive biology of the crops.^[2]

As already noted, when crops are grown for their seeds, they are protected (like their wild relatives) by stabilizing selection, which safeguards their fertility. Grain crops have the most rigid protection of this kind. Yields in these sexually reproducing crops depend decisively on normal chromosome behavior in meiosis and on streamlined development of flowers, fruits, and seed. Deviants are promptly weeded out and the reproductive system is kept in balance. It is no wonder that among cultivated plants, grain crops are the most conservative in this regard. In spite of the fact that many of the grain crops have already produced hundreds (or even thousands) of generations under domestication, they show very little intracrop chromosome divergence or chromosome instability. With very few exceptions (such as the formation of hexaploid bread wheat), chromosome sets in grain crops are identical with those found in their wild progenitors, and wild and tamed forms are fully interfertile.

In contrast with the sexually reproducing grain crops, considerable reduction of pollen and seed fertility (as well as chromosome stability) is tolerated by the bulk of the vegetatively propagated crops grown for their fruits. Since in these crops the target of the grower is the fruit, the reproductive parts of the crop (inflorescences, flowers, fruits) are unconsciously kept intact. Yet, in fruit crop culture, the following conflict has to be resolved: The growers consciously select clones producing fleshy, tasty fruits. They are also equally attracted to seedless fruits or to fruits with reduced number of pips or stones. However, in most plants, the development of fruits commences only

after fertilization and initiation of seed development. Several solutions for curtailing seed set without harming fruit formation evolved automatically in fruit trees.^[2,3] Most conspicuous among them are mutations conferring parthenocarpy, that is, induction of fruit development without fertilization and without seed set (e.g., in bananas, common fig, and some pear cultivars).

Crops maintained by vegetative propagation and grown for their vegetative parts exhibit the most drastic disruption of their flowering and fruiting system, and the most bizarre chromosomal situations. In contrast to the fruit trees, conscious selection in these crops focuses on the increase of vegetative output. Because these crops are clonally propagated, this pressure is rarely counterbalanced by stabilizing selection to retain the reproductive organs. Root and tuber crops are outstanding examples of such evolution. Cultivated clones of cassava, yams, taro, sweet potato, or garlic frequently show drastic reduction of the amount of flowering. Some rarely produce any flowers. When rare flowers do appear they are frequently abnormal and sterile. Many of these crops are also exceptionally chromosomally variable, and frequently contain several ploidy levels and/or aneuploid number of chromosomes. Thus, in the yams, *Dioscorea alata* is known to contain all ploidy levels between $3x$ and $8x$, where as in *D. esculenta* $4x$, $6x$, $9x$ and, $10x$ cultivars are reported.^[4] Sugarcane confronts us with an even more complex chromosome picture.^[5] Cultivated clones in this crop are all highly polyploid, and frequently also aneuploid. Modern cultivars contain $2n = 100$ to $2n = 125$ chromosomes. Older cultivars vary from $2n = 80$ to $2n = 124$.

THE IMPACT OF SOWING AND REAPING

Traditional grain agriculture is based on sowing the seeds of the crop in a tilled field, harvesting the mature plants, and threshing out the grains. The introduction of grain triggers into the system of tilling, sowing, and reaping triggers automatic selection towards the following changes,^[1,2,6,7] setting them apart from their wild progenitors:

First, there is an automatic selection for retaining the mature seed on the mother plant, i.e., for the breakdown of the wild mode of seed dispersal. Most conspicuous is the shift from shattering spikes or panicles in the wild cereals to the nonshattering condition in their domesticated counterparts, or the parallel evolution of nondehiscent pods in the cultivated legumes. The loss of the wild-type devices for seed dissemination is one of the most conspicuous outcomes of the introduction of grain plants into cultivation. It is also the most reliable indicator of domestication in grain crop remains retrieved from archaeological excavations.^[3] Moreover, both theoretical considerations and experimental evidence suggest that at

least in the wheats and in barley, the establishment of nonshattering mutants under the system of sowing and reaping could have been a fast process. It could have been accomplished in the course of only several scores of generations.^[8]

A second major outcome of introducing wild grain plants into a regime of tilling, sowing, and reaping is the breakdown of the wild-type inhibition of germination. Wild plants are adapted to spread the germination of their seed over time. A common, vital adaptation (especially in annuals) is spreading the germination of the seed yield over several years.^[3,6,9] Again, under a regime of cultivation, such germination inhibition is automatically selected against. Most grain crops have lost their wild-type regulation of germination. Practically all seed produced by their cultivars germinate immediately and synchronously upon imbibition.

Numerous other traits seem to have been automatically selected for once grain plants were introduced into the regime of tilling, sowing, and reaping.^[6,9] Some are noted here for illustration. Under such practice, dense and uniform stands are frequently established in the tilled fields, and plants with erect habit will be favored. In response to the way the crops are harvested, synchronous ripening will be selected for. Because the seeds are stored (and protected) in granaries, thinner shells will evolve. Since seeds are sown deeper in the ground under tilling compared to the situation in the wild environment, increase in seed size would be expected. Since tilling enhances soil fertility, there is unconscious selection for increasing the number of fertile flowers in the inflorescences.

FRUIT TREE CULTIVATION AND ITS CONSEQUENCES

Most fruit trees under domestication are derived from cross-pollinated wild progenitors in which this pollination system is safeguarded either by self-incompatibility or by dioecy (male and female flowers borne on different individuals). Because of this background, the shift from sexual reproduction (in the wild) to the planting of vegetatively propagated clones, introduced serious limitations on fruiting.^[10] Planting a single self-incompatible clone, or alternatively a female clone (or clones), would not bring about fruit set. Several horticultural inventions to assure fruit set were made by the growers (e.g., mixed planting of several genotypes in self-incompatible fruit crops, adding male individuals or practicing artificial pollination in dioecious crops). They were accompanied by unconscious selection for several types of mutations that resolved the restrictions set by self-incompatibility and/or sex determination.

In several self-incompatible crops (peach, apricot, sour cherry, as well as in several varieties of almond or olive), mutations appeared that caused the breakdown of self-

incompatibility. In several originally dioecious species (such as grape vine and the carob), changes from dioecy to hermaphroditism evolved and rendered cross-pollination unnecessary. Finally, as previously mentioned, in numerous self-incompatible and dioecious fruit crops, pollination has been dispensed altogether by incorporation of mutations conferring parthenocarpy (fruit development without pollination and without seed development).

CONCLUSION

The present survey illustrates how conscious selection and unconscious selection have operated closely and complemented each other in crop plant evolution. Several innovative decisions made by the ancient farmers such as 1) in what ways to reproduce or propagate the crops, 2) how to raise and harvest them, and 3) which parts of the plants would be of use, were critical. They automatically set the chosen plants on different and contrasting courses of evolution under domestication.

Crop Improvement: Broadening the Genetic Base for

Toby Hodgkin

International Plant Genetic Resource Institute, Rome, Italy

INTRODUCTION

Crop improvement occurs through selection operating on genetic variability and depends on the continuing availability and use, by plant breeders, of sufficient desirable genetic variation. The difficulty in many plant breeding programs is to determine what constitutes “sufficient desirable genetic variation.” Too much variation can become unmanageable, while too little will result in a failure to obtain any significant advances from selection.

In crops, the amount of variability available for selection is limited by comparison with their wild relatives. The process of domestication has usually involved a dramatic reduction in the genetic diversity of the crop gene pool. This limitation in the amount of diversity within the crop has often been followed by further losses of genetic diversity in specific areas or materials—as crops were taken to new geographic areas, as the types desired by farmers became more narrowly determined, as selection to deal with specific disease outbreaks was required, or as plant breeders tended to restrict the materials they used to meet increasingly rigorous standards of performance and uniformity.

In its widest sense, base broadening includes increasing the amount of genetic variation used in cultivar selection programs and increasing the genetic diversity present in production systems (through increasing the range of diversity available to farmers and increasing the numbers of crops or cultivars grown in production systems). In this article, various ways of determining the need for base broadening will be illustrated and some methods for increasing the amounts of diversity in plant breeding programs, will be briefly described. A much fuller treatment of crop improvement issues and aspects of base broadening in production systems has recently been provided by Cooper, Spillane, and Hodgkin.

THE NEED FOR BASE BROADENING

This continuous narrowing of the genetic base of a crop is widely believed to be undesirable and even to have had dramatic consequences on production and human well-being. It has been blamed for the Irish potato famine, caused by late blight, and for the maize southern leaf

blight epidemic. This latter event led to a report by the U.S. Academy of Sciences that recommended broadening the genetic base of major staple crops. Despite this recommendation, there appear to have been few substantial efforts to develop and implement base-broadening programs, and modern cultivar production often continues to depend on recycling the variations present in selected elite materials.

Evidence that there is a need (or, perhaps better, an opportunity) for base broadening in a crop can come from the identification of bottlenecks, from the detection of limited amounts of genetic diversity, or from production characteristics suggesting that variation available for improvement has become limiting.

Bottlenecks

The first, and often the most significant bottleneck in crop plants occurs on domestication. In many crops there are very large amounts of genetic diversity present in the nearest related wild taxa.^[4] Domestication is usually accompanied by substantially reduced gene flow between the crop and related wild taxa, even where they belong to the same primary gene pool. In many crops there are no wild relatives in the primary gene pool, and the barrier to gene flow is virtually complete (e.g., *Triticum aestivum*—bread wheat; *Brassica napus*—oilseed rape; *Cocos nucifera*—coconut). Other crops considered to have a narrow genetic base because of domestication bottlenecks include rice, durum wheat, *Phaseolus* beans, tomato, pigeon pea, and chick pea.

Significant bottlenecks have also occurred when crops have been taken to new production locations. These founder effects result in a set of cultivars drawn from a restricted sample of the total diversity of a crop. A classic example of this has been the introduction of potato in W. Europe. Other examples include maize in W. Africa, soybean in the United States, lentil in S. Asia, and tropical commodity crops such as cocoa, coffee, and rubber.

The development of specific crop types to satisfy particular needs has also resulted in a noticeable reduction in diversity in different types and limited gene flow between them. For example, as the different horticultural *Brassica oleracea* crop types became established (e.g., cabbage, Brussels sprout, cauliflower, kohlrabi, calabrese)

they ceased to be intercrossed, and some of the genetic diversity found in one of the different crops no longer occurs in others. This effect becomes more extreme as selection becomes more intense. Highly specialized crop types such as spring-malting barley may show significant loss of diversity, even when compared with the full range of modern barley cultivars—let alone when compared with local cultivars from the crop's center of origin. The narrow genetic base of U.S. maize is a classic example in this respect.

Genetic Diversity

Studies on the amount and distribution of genetic diversity can provide an important way of quantifying the effect of a known or believed bottleneck. Of course, such studies could also indicate when the effect of an identifiable bottleneck has been limited by subsequent gene flow. However, most of the investigations to date, confirm substantial reductions in the diversity of modern cultivar material, as compared with traditional cultivars or wild relatives. Miller and Tanksley^[4] found that diversity in RFLPs of tomato cultivars was virtually absent compared with traditional cultivars and with other *Lycopersicon* species. Allard^[5] noted that modern California cultivars of barley had half the number of alleles per locus found in M. Eastern traditional cultivars, which themselves had half the number of alleles found in wild *H. spontaneum*. Sonnante et al.^[6] detected a similar pattern in the amounts of diversity found in different *Phaseolus* bean germplasm classes.

In the United States, a number of crops including wheat rice have a narrow genetic base, as indicated by their coefficient of parentage.^[7] Current varieties derive from a very limited number of parents, and over 70% of the diversity found in U.S. soybean is estimated to be derived from just seven parents. In other cases, such as oats in the United States or soybeans in China, the genetic base is much broader, and in China it is estimated that 70% of the genetic diversity found in current soybean cultivars can be attributed to more than 70 parents. Of course, a broad genetic base in plant breeding, obtained through the use of large numbers of parents, may not of itself lead to diversity in production systems. This requires a breeding program that produces large numbers of genetically distinct varieties, as measured by direct genetic diversity studies.

While it has been suggested that the genetic base will continue to erode, this does not seem always to be the case. In the United Kingdom, the amount of diversity present in nationally listed wheat cultivars appears to have remained largely unchanged over the last 70 years, since the 1930s.^[8]

Production Problems

A number of aspects related to production characteristics are considered to indicate that there may be a need for base-broadening actions. The most substantial of these is evidence that a yield plateau has been reached and that little further progress is being made in crop performance. Continued crop failure through vulnerability to specific diseases or pests may also indicate an absence of desired variability in breeding material. In these cases, breeders often tend to look to more exotic material (e.g., wild relatives) to find genes that meet their needs. This may even involve using the tertiary genepool and in vitro culture to obtain desired traits.

Farmers and consumers can themselves provide indicators that base broadening is needed. If there is clear evidence that farmers' cultivar needs are not being met or that the crop is becoming unprofitable for growers who are failing to obtain adequate returns, this may be because necessary characteristics are not present in breeding material.

OPTIONS FOR BROADENING THE BASE

As a result of the international efforts to conserve plant genetic resources, there is available to the plant breeder a very substantial amount of desirable genetic diversity in genebanks throughout the world. There may be problems in accessing the material, and it may be difficult for breeders to know what is the most useful material to include in breeding programs, but for most major crops, obtaining diversity is not the biggest problem.

Often, the plant breeder's preferred approach when producing new cultivars will be introgression of the desired new trait into an elite background, incorporating as little additional genetic material as possible. This is particularly the case when the material with the desired trait belongs to the secondary or tertiary genepool. However, this process does not necessarily result in a significantly broader genetic base for the crop. Indeed, one aim of such a program is usually to limit introgression to the single desired gene, and molecular markers are substantially improving the efficiency of this process. Base-broadening approaches are different, in that they seek to deliberately enhance the amount of variation in the breeding programs. A number of ways to achieve this objective in a more or less systematic way have been described.

Population Management

Populations can be established by crossing a number of genetically different parents, often from different

geographic areas so as to maximize their distinctness. These populations are then commonly established at a number of different locations and allowed to adapt to new conditions with minimum artificial selection. Examples of these include the barley composite cross populations^[5] and the dynamic wheat populations developed in France.^[9]

Incorporation

Simmonds^[10] describes procedures that combined repeated cycles of recombination and mild selection in the target environment on sets of extremely diverse material. The objective is the wide-scale incorporation of genetic variability into existing crop material so as to enhance diversity and provide a basis for the identification of new, useful variation. Incorporation programs have been developed for potato and sugar cane, and in the latter have led to the development of much useful germplasm.

Germplasm Enhancement

A number of procedures have been developed which allow breeders to identify and include new material in breeding programs in a systematic way. These include the Genetic Enhancement of Maize (GEM) program and the Hierarchical Open-Ended (HOPE) system for broadening the breeding base, also in maize. Similar approaches have been developed for maize in France and for sugar beet in Europe.

Traditional and Participatory Breeding

Conscious inclusion of traditional cultivars from a wide genetic base, as in barley at ICARDA^[12] and by CIMMYT in its wheat breeding work,^[12] will materially increase diversity in the breeding program. While there is much that can be done in this way, the base-broadening effect will be rather variable depending on the parents chosen and selection pressure used. The increasing interest in participatory plant breeding is also likely to result in increased variability in production systems and, potentially, a broader base for crop improvement.^[13]

Crop Responses to Elevated Carbon Dioxide

Leon Hartwell Allen, Jr.

USDA, Gainesville, Florida, U.S.A.

P. V. Vara Prasad

University of Florida, Gainesville, Florida, U.S.A.

INTRODUCTION

Atmospheric carbon dioxide (CO₂) concentration has increased from 280 ppm (parts per million, mole fraction basis) in preindustrial times to 370 ppm today. As concentrations of CO₂ and other greenhouse gases rise, global temperature is anticipated to increase.^[1] Elevated CO₂ will improve crop yields due to increased photosynthesis. However, at above-optimum temperatures for reproductive growth processes, the benefits of elevated CO₂ could be overwhelmed by negative effects of high temperature, leading to lower seed yield.

The extent of growth and yield responses of plants to elevated CO₂ depends on the photosynthetic pathway. Crops with C₃ photosynthesis will respond markedly to increasing CO₂ concentrations. Common C₃ crops are small grain cereals (wheat, rice, barley, oat, and rye); grain legumes or pulses (soybean, peanut, various beans and peas); root and tuber crops (potato, cassava, sweet potato, sugar beet, yams); most oil, fruit, nut, vegetable, and fiber crops; and temperate-zone (cool-climate) forage and grassland species. In contrast, plants with C₄ photosynthesis will respond little to rising atmospheric CO₂ because a mechanism to increase the concentration of CO₂ in leaves causes CO₂ saturation of photosynthesis at current ambient concentrations. Common C₄ crops are maize (corn), sugarcane, sorghum, millet, and many tropical and subtropical zone (warm-climate) grass species. This article focuses on responses to elevated CO₂ and increased temperature of C₃ crops. Response patterns are similar, but not the same, across a broad range of species and conditions.^[2]

EFFECTS OF CO₂ AND TEMPERATURE

Photosynthesis and Respiration

Doubling of CO₂ concentration will increase photosynthesis of C₃ crop species by 30–50%.^[2–4] The primary enzyme in leaf photosynthesis of C₃ plants, ribulose 1,5-bisphosphate carboxylase/oxygenase (Rubisco), can bind

to either CO₂ or O₂. An increase in the concentration of CO₂ enables this molecule to better compete with dissolved O₂ for binding sites on the Rubisco protein, thus leading to an increase of photosynthesis of C₃ species. The CO₂ concentrating mechanism of C₄ plants is mediated by the enzyme phosphoenolpyruvate carboxylase (PEPcase). The contrasting effect of CO₂ on photosynthesis of C₃ and C₄ plants is illustrated in Fig. 1. Response curves of photosynthesis versus CO₂ are nonlinear, and little benefit will accrue above 700 ppm.

The hypothesis that elevated CO₂ has a direct, immediate effect in decreasing the respiration rate of plants seems to have little basis. However, the indirect, long-term effect of elevated CO₂ can cause an increase in respiration via an increase in the amount of living biomass. Rice plants grown in CO₂ ranging from 160 to 900 ppm had respiration rates directly proportional to the total nitrogen content (protein content) of the plant.^[5] However, elevated temperatures can increase plant dark respiration rates regardless of CO₂ concentration. Furthermore, elevated temperature decreases solubility of CO₂ relative to O₂ in the cytosol, thereby decreasing photosynthesis, but this solubility effect on photosynthesis is usually offset more in high CO₂ than in ambient CO₂.

Stomatal Conductance, Transpiration, and Water Use

Increasing CO₂ causes partial closure of stomata, the small pores (formed by slits between two flexible guard cells) on leaves that govern photosynthetic CO₂ uptake and transpiration (water vapor loss). Stomatal conductance for water vapor decreases about 40% for a doubling of CO₂. Decreased stomatal conductance decreases transpiration of leaves, but not in direct proportion to the decrease of stomatal conductance because leaf temperature increases by 1–2°C in doubled CO₂ due to decreased evaporational cooling. In turn, vapor pressure of water inside leaves increases and causes a greater leaf-to-air vapor pressure difference, which is the driving force for transpiration. This effect partially offsets decreased stomatal conductance, and thus whole-crop transpiration

Fig. 1 Typical leaf photosynthetic rate responses of C_3 and C_4 plants to CO_2 concentration when measured in non-limiting (high light) conditions.

is maintained only slightly lower (10%) than would exist at ambient CO_2 .^[6]

Although crop transpiration might decrease slightly in elevated CO_2 , water use will increase if temperatures rise. Fig. 2 shows the increase of average daily transpiration of a soybean crop with increasing temperature at two levels of CO_2 . The reduction in water use by doubled CO_2 was about 9% at the mean temperature of 23°C. Crop water use might increase about four-fold over the average daily temperature range of 20–40°C. Therefore, small increases in temperatures would more than offset the water-saving effect of CO_2 via reduced stomatal conductance.^[6]

Shoot and Root Growth

Crops exposed to elevated CO_2 generally grow larger.^[2] Plants such as soybean have a higher percentage of total biomass in stems to support leaves and seed pods. Crops such as rice and wheat produce a larger number of tillers, which leads to greater yield because of the greater number of seed heads per plant. Leaves may be larger or thicker and accumulate more starch, especially for plants like soybean.

Elevated temperatures may either increase or decrease the vegetative biomass production of crops. Vegetative biomass of warm-climate species or cultivars of forages, sugarcane, soybean, and peanut may increase slightly with temperature increases, whereas vegetative biomass of cool-climate cultivars tends to decrease with increasing temperature.

Elevated CO_2 generally increases biomass, volume, and length of roots, as well as increasing biomass allocation to roots (increased root-shoot ratio). Root and tuber crops tend to have a greater yield response to elevated

CO_2 than seed or forage crops. Increased photosynthesis also favors symbiotic nitrogen fixation in legumes. Since legumes can supply nitrogen via symbiotic nitrogen fixation, crop legumes (both seed and forage crops) might respond relatively more to a rise in CO_2 concentration than non-legumes.

Seed Yield and Quality

Seed yields generally increase nonlinearly in response to increasing CO_2 , but this increase is not quite as much as the increase in photosynthesis.^[2] Part of the additional carbon fixed goes into producing more plant vegetative biomass. Increases in seed yields of many C_3 crops range between 20% and 35%,^[3] whereas increases for C_4 crops are only about 10% to 15%. Elevated CO_2 may cause higher carbohydrate and lower nitrogen content of small cereal grains, but no changes tend to occur in grain legumes.^[7] Although wheat and barley showed increases in seed numbers (about +15%) in elevated CO_2 , seed N concentration was even more strongly reduced (about –20%). Under limiting water or nutrient conditions, relative yield responses to elevated CO_2 may increase, although absolute yields will decrease.

Increasing temperature is detrimental to seed production, as illustrated for tropical lowland rice and kidney bean in Fig. 3.^[4,8] The quantitative responses of seed yield reduction to increasing temperature vary among species and crop cultivars, but the pattern is the same. Each crop has an optimum temperature for reproductive growth processes. Seed yields decline about 10% per °C to zero at about 10°C above the optimum temperature. Seed yields decline to zero at about 32°C for a cool-climate cultivar of kidney bean, 36°C for tropical lowland rice, and 40°C for warm-climate cultivars of peanut and soybean. Fig. 3

Fig. 2 Typical average daily whole-crop transpiration of C_3 plants when grown at two levels of CO_2 and across a mean daily temperature range of 20–40°C. (Adapted from Ref. 6.)

Fig. 3 Typical seed yields of rice and kidney bean at two CO₂ concentrations (ambient and double ambient) and across a range of temperatures. (Adapted from Refs. 4 and 8.)

shows that elevated CO₂ does not offset the decline of seed yield with increasing temperature.

Crops are especially sensitive to elevated temperature from a few days before pollen maturation through fertilization of the ovule.^[9] Important processes during this period are viable pollen production, pollen shedding, pollen tube growth, and fertilization. Crops may also be sensitive to temperature during seed-filling processes, the time when the seeds load up with proteins, carbohydrates, oils, and other nutrients.^[7] Soybean and kidney bean seeds increasingly fail to fill properly as temperatures increase and form smaller, shriveled seeds with reduced seed germination capability and nutritional quality than under optimum temperatures.

CONCLUSION

Photosynthesis and growth of C₃ crops are increased when grown at high CO₂; however, the extent of stimulation varies with temperature among species and cultivars. The potential decrease in transpiration caused by partial closure of stomata in elevated CO₂ is largely negated by the energy balance between the crop and environment, which results in similar total water use in similar climatic conditions. Seed yields are increased by elevated CO₂ under optimal temperature. However, at supra-optimal temperature, seed yields are decreased under both ambient and elevated CO₂.^[2,5,8] If increases in temperature accompany increases in CO₂ concentration, seed yields will decrease in regions where temperatures are at or above optimum. Future research should be directed toward identifying high-temperature tolerant cultivars that can produce more seeds under harsh climatic conditions.

Cropping Systems: Irrigated Continuous Rice Systems of Tropical and Subtropical Asia

Achim Dobermann
Kenneth G. Cassman

University of Nebraska, Lincoln, Nebraska, U.S.A.

INTRODUCTION

Irrigated rice is grown in banded, puddled fields with assured irrigation for one or more crops a year on alluvial floodplains, terraces, inland valleys, and deltas in the humid and subhumid subtropics and humid tropics of Asia. Favorable climatic conditions and fertile soils in combination with irrigation allow farmers to grow one to three crops per year in submerged soil. The irrigated rice ecosystem accounts for 55% of the global harvested rice area and 75% of the world's annual rice production.

By 2020, average yields of irrigated rice must rise by about 20 to 25% to meet expected demand. However, growth rates of both yield and total irrigated rice production have slowed down in recent years, raising concerns about the sustainability of intensive irrigated rice systems and future rice supply.

Future yield increases will require germplasm with increased yield potential and substantial improvements in soil and crop management—particularly with regard to nutrient, water, and pest management—to lift average farm yields to about 70% of the yield potential. Technological advances to achieve such improvements must be synergistic with dynamic changes in the socioeconomic and biophysical environment in Asia, where competition for natural and human resources continues to intensify. This article characterizes intensive, irrigated rice systems and discusses the critical current and future challenges to crop improvement and management.

IMPORTANCE, GEOGRAPHICAL DISTRIBUTION, AND PRODUCTION TRENDS

Worldwide, about 79 million hectares (ha) of rice (*Oryza sativa* L.) is grown under irrigated conditions (55% of the global harvested area), accounting for about 75% of the annual rice production. Irrigated rice-based cropping systems include single-crop rice, rice–upland crop double cropping, or continuous monoculture with two to three rice crops per year.^[1] Double- and triple-crop monoculture systems occupy a land area of about 24 million ha in

Asia, allowing 49 million ha of rice to be harvested annually.^[2] These systems account for 40% of the global rice supply and feed about 1.8 billion Asians. Rice accounts for 30 to 80% of the calories consumed in most countries of Asia. The ability to produce a rice surplus on good irrigated land has contributed much to the economic development and political stability in that region.

Continuous rice systems are mostly located on flood plains along major rivers, terraces, inland valleys, and coastal plains in the humid and subhumid subtropics and tropics. Rainfall ranges from 1000 to more than 2000 mm per year. The warm climate and access to water allow farmers to grow two to three short-duration rice crops per year (Fig. 1). Rice is grown in dry seasons with low rainfall and high solar radiation and in humid seasons with lower yield potential due to cloudy conditions and high rainfall. Soils vary widely, but are mostly of relatively high quality. Common soil types include Inceptisols, Alfisols, Entisols, Vertisols, Mollisols, and Ultisols. Irrigated rice is also grown on more marginal soils that have various problems, which may cause mineral nutrition deficiencies or toxicities in some cases.^[3]

Double cropping became common in China about 1000 years ago, and triple cropping probably started in the 14th century.^[4] Intensification since the mid 1960s has involved an increase in the number of crops grown per year and greater yield per crop cycle. Higher yields have resulted from the combination of increased yield potential of modern varieties, improved crop nutrition made possible by fertilizer application, and improved host-plant resistance and pest management.^[5] The current average grain yield of irrigated rice is about 5.3 mega grams per hectare (Mg ha^{-1}) per crop. Growth rates of yield and total irrigated rice production have slowed down, but they vary among countries and regions (Fig. 2). From 1967 to 1984, rice production grew at an annual rate of 3.2%, mainly because of yield increases ($2.5\% \text{ yr}^{-1}$), but declined to $1.5\% \text{ yr}^{-1}$ (production) and $1.2\% \text{ yr}^{-1}$ (yield) during the period from 1984 to 1996. This slowdown is partly due to lower rice prices and the slowdown in demand growth, but concern was also raised about resource degradation. Yield declines were observed in

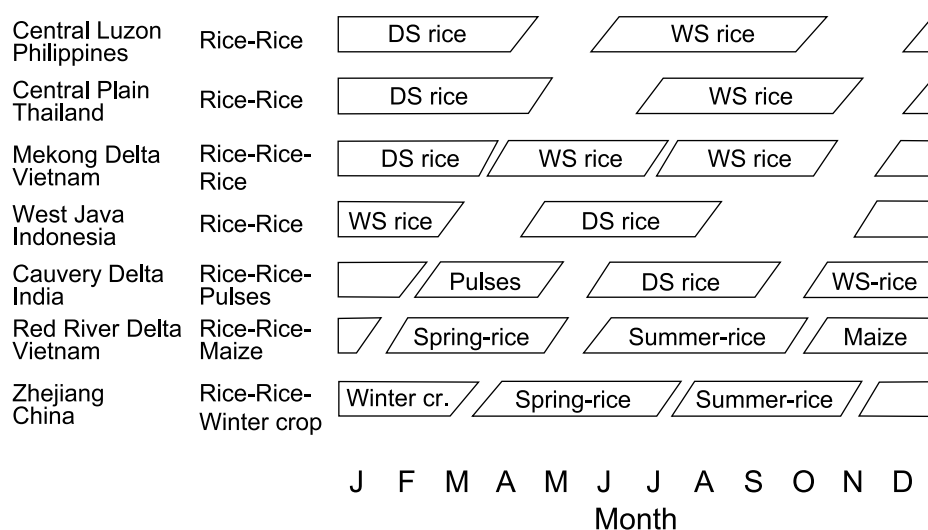

Fig. 1 Cropping systems and the annual cropping calendar in major irrigated rice areas of south, southeast, and east Asia. Each site shown represents a large irrigated area in which intensive rice cropping is the dominant agricultural enterprise. DS = dry season; WS = wet season.

some long-term research experiments, but appear not to be widespread at current production levels.^[6] In some countries and large rice production domains where farmers were early adopters of modern irrigated rice production technologies, yields have stagnated since the mid-1980s (Fig. 2).

SOIL AND CROP MANAGEMENT

Germplasm

Nearly all irrigated rice is produced with modern rice varieties. The release of high-yielding rice varieties such as IR8 (1966), IR20 (1969), IR36 (1976), IR64 (1985), and IR72 (1988) helped fuel the Green Revolution in Asia. The new varieties provided a quantum leap in yield potential compared to the traditional land races they replaced because of shorter stature, lodging resistance, greater harvest index, and responsiveness to nitrogen (N). Due to their short growth duration (95 to 115 days) they became a key factor in the expansion of double- and triple-crop rice systems. Rice hybrids with a 10% increase in yield potential above that of the best inbred varieties presently account for about 18 million ha (50%) of the Chinese rice harvest area. Adoption of hybrids is also beginning to occur in other countries, in a total of about 0.5 million ha.

Breeding programs during the past 30 years have focused on incorporating disease and insect resistances into irrigated rice varieties, which has increased yield

stability under continuous cropping. Although there has been little increase in the yield potential of inbred rice varieties since IR8 was introduced, efforts are in progress to develop a new plant type with a 25% larger yield potential (12 to 12.5 Mg ha⁻¹ in tropical regions) compared to the best inbred indica varieties.^[7] Another key challenge is to combine the traits of high yield with high grain quality. Genetic engineering and molecular breeding techniques have been used to improve host-plant resistance to pests, or, more recently, to improve specific grain-quality traits such as vitamin A or iron content.

Nutrient Management

A rice crop yielding 6 Mg ha⁻¹ takes up about 105 kg N ha⁻¹, 18 kg P ha⁻¹, 100 kg K ha⁻¹, 11 kg S ha⁻¹, and 0.3 kg Zn ha⁻¹.^[3] About 40% of the N, 80–85% of the K, 30–35% of the P, 40–50% of the S, and 60% of the Zn absorbed by rice remains in vegetative plant parts at maturity. For centuries, naturally occurring sedimentation, nutrient inflow by irrigation, organic residues and amendments, biological N₂ fixation, and carbon assimilation by floodwater flora and fauna^[8] maintained soil fertility in the relatively low-yielding traditional irrigated rice systems. With intensification, annual crop nutrient removal has increased and mineral fertilizers have become the primary nutrient source. Nitrogen-fixing green manures are not widely used because their main purpose of providing N has been replaced by fertilizer N. Straw is the major organic material available to most rice farmers,

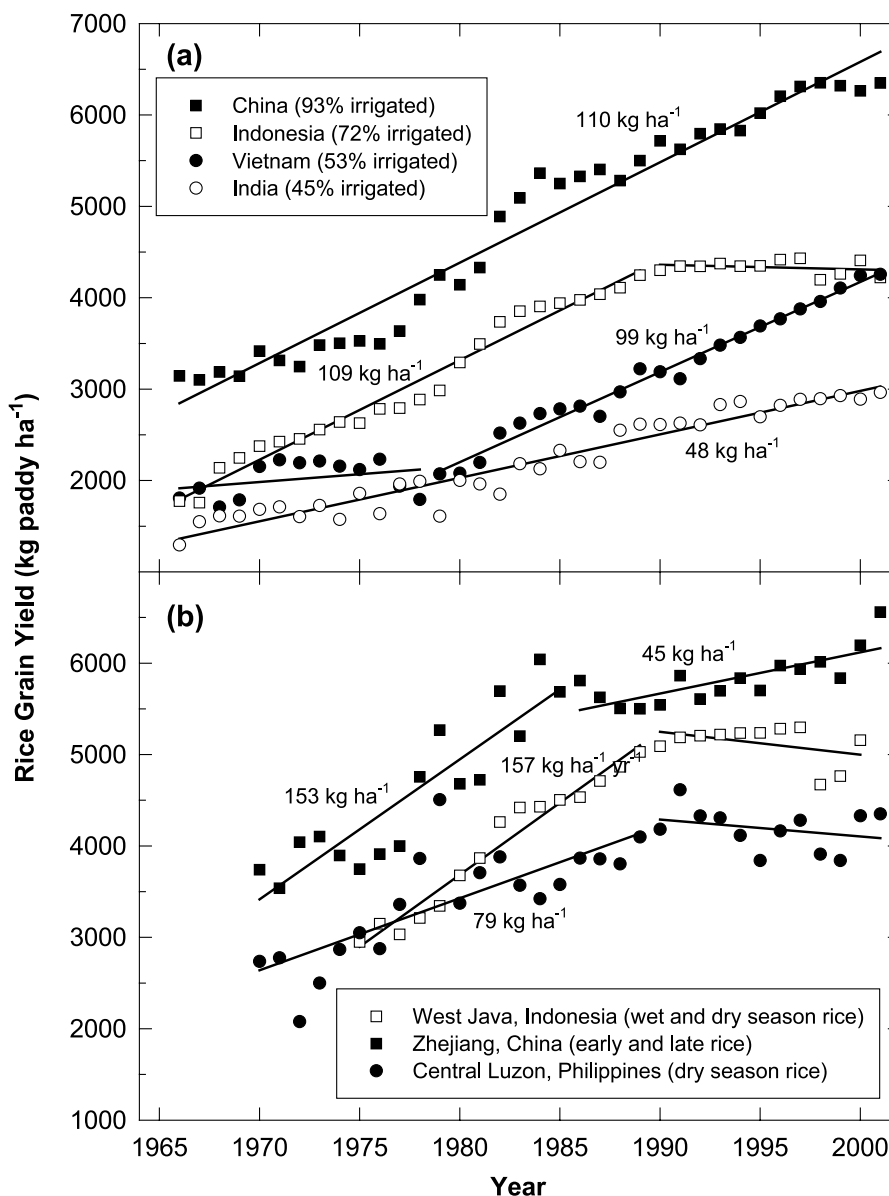

Fig. 2 Trends of national average rice yields in several Asian countries (a) and average irrigated rice yield in three provinces in which farmers were early adopters of modern rice and continuous annual double-crop systems during the late 1960s (b). Annual rates of yield increase (kg ha^{-1} per year, estimated from linear regression) are shown for periods with statistically significant yield changes.

but it is removed from the field, burned in the field, incorporated into the soil, or used as mulch for the following crop.

Fertilizer rates in most irrigated rice farms of Asia typically range from 80 to 140 kg N, 10 to 25 kg P, and 0 to 50 kg K ha^{-1} per crop. Fertilizers are mostly broadcast by hand, and the number of N applications varies from one or two up to five or six in certain regions. Soil testing is not common and most fertilizer recommendations are given as blanket recommendations for larger regions. On

average, only 30% of the applied N is taken up by the crop and only 20% of all farmers achieve uptake efficiencies of more than 50%.^[9] The main reason for the low N-use efficiency is a lack of congruence between nutrient supply and crop demand, resulting in significant nitrogen losses due to denitrification and ammonia volatilization.^[10] Nutrient balance estimates (Table 1) suggest that, at the average farm level, phosphorus (P) applications generally are in balance with crop P removal, although P deficiency occurs in some areas. Due to low fertilizer rates and

Table 1 Estimated average input-output balance of N, P, and K in intensive rice systems of south and southeast Asia with an average yield of 5.2 Mg ha⁻¹

Inputs and outputs	kg ha ⁻¹ crop ⁻¹		
	N	P	K
Inputs

(From Ref. 17.)

significant straw removal, negative potassium (K) input-output balances are common. About 80% of the intensive rice fields in Asia have a negative K balance, but K budgets may vary from -100 to +100 kg K ha⁻¹ per crop.^[11]

Tillage and Crop Establishment

Wet-soil tillage is predominant in irrigated rice systems of Asia.^[12] It involves plowing, puddling, and harrowing passes to create a homogeneous slurry-like surface soil and to reduce water percolation. These operations are accomplished using manual labor, traction animals, and small 2-wheel hand-held tractors. Four-wheel tractors are becoming available in some areas. Puddling helps control weeds and incorporates crop residue and fertilizer. Transplanting 10- to 30-day-old rice seedlings is the predominant crop establishment method, but direct seeding is becoming common in many intensive rice areas. Broadcast seeding of presoaked seed at rates of 100 to 200 kg seed ha⁻¹ is used in irrigated rice areas with high labor cost or insufficient labor availability. Other forms of direct seeding include row seeding or dry seeding of rice.

Water Management

More than 80% of the developed freshwater resources in Asia are used for irrigation purposes and more than 90% of the total irrigation water is used for rice production. Traditionally, irrigated transplanted rice has been grown in a permanent floodwater layer of 5 to 20 cm depth

throughout the whole growing period. Besides supplying water to the plant, the ponded water layer helps suppress weed growth and increases nutrient availability.^[12] Direct-seeded rice is typically grown with a floodwater-free period of two to three weeks after seeding, which is then followed by flooding throughout the remaining growth period.

Increasing competition for water among agriculture, industry, and the rapidly growing urban population will force many rice farmers to use less water and increase their water use efficiency. Water-saving intermittent irrigation techniques have been developed, but they require a high degree of management control at both the farm and irrigation system levels. They are often associated with increased herbicide use and larger N losses. Research is ongoing to understand the complex interactions between water management and other crop management practices.

Pest Management

Hand-weeding is widespread in transplanted rice areas, but is labor-intensive (150 to 200 h ha⁻¹ per crop). In recent years, herbicide use for weed control has become a common practice, particularly in areas with direct seeding. Strong host-plant resistance to major disease and insect pests has been the focus of rice breeding programs during the past 30 years and provides the foundation of integrated pest management.^[13] Modern approaches to crop protection rely on pest management rather than control or eradication. Predatory and parasitic natural enemies contribute to keeping insect pests in check. However, insecticide use ranges from 0.1 to more than 1.0 kg active ingredient ha⁻¹ per crop, and fungicide use ranges from 0 to 0.3 kg active ingredient ha⁻¹. Fungal and bacterial diseases are mostly a problem in high-yielding environments, especially in humid environments. Excessive use of N fertilizer may attract insect pests as well as increase disease incidence, whereas elements such as potassium and silicon improve the resistance to diseases.

SOIL QUALITY AND ENVIRONMENTAL CONCERNS

Several soil characteristics contribute to the unique biophysical sustainability of continuous rice farming systems.^[4] Acidification is a relatively minor problem because the physical chemistry of flooded soil systems causes soil pH to stabilize around 6.5 to 7 after flooding. Nutrients tend to be leached into lowland soils rather than

out of them because of their landscape position. Erosion rarely occurs because fields are well leveled and surrounded by bunds. Phosphorus is maintained in more readily available forms than in aerated, upland soils. Significant input of C and N is derived from biological activity in the soil-floodwater system. Increases in soil C and N content occur over time, even with complete removal of above-ground plant biomass. Recent concerns have mainly centered on a possible decline in soil nutrient availability. In continuously flooded systems, the accumulating N is likely to be stored in organic matter pools that are less plant-available than in well-aerated soils.^[10] Soil K stocks are declining in many intensive rice areas, even on the most fertile lowland rice soils, and K deficiency is becoming more frequent. Constraints such as micronutrient deficiencies, salinization, and iron toxicity are of concern in some irrigated rice areas of Asia.

Gaseous losses of N often exceed 50% of applied fertilizer N, mostly due to ammonia volatilization. Nitrous oxide emissions occur as a result of nitrification–denitrification during periods of alternating soil wetting and drying. In irrigated rice systems with good water control, N₂O emissions are small except when excessively high N fertilizer rates are applied to fertile rice soils. Nitrate leaching losses are usually below 10% of the applied fertilizer N. Irrigated rice monoculture systems in Asia sequester atmospheric CO₂, but they also account for about 2 to 5% of the global methane (CH₄) emissions into the atmosphere.^[14] Methane emission can be managed through a variety of means, including organic and inorganic amendments as well as crop management practices that also affect nutrient dynamics. Misuse of pesticides and other agrochemicals may adversely affect human health and water quality in intensive, irrigated rice areas.^[15]

FUTURE CHALLENGES

Total rice demand will continue to increase at an annual rate of about 1%.^[16] There will be little net increase in rice cropping area or in the amount of irrigated land available for rice production. Therefore, average yields of irrigated rice must reach 6.5 to 7 Mg ha⁻¹ to meet expected demand in 2020. Labor costs will continue to rise faster than the cost of energy and fertilizer, favoring the adoption of mechanized technologies. Competition for water resources will intensify. Where feasible, cropping systems will diversify, but rice monoculture in double- or triple-crop systems will remain the preferred choice in lowlands with heavy clay soils and other constraints to the production of upland crops.

Increases in rice yield potential through germplasm improvement will require substantial research investments. Meanwhile, increased production from irrigated rice systems will come largely from improved crop, soil, water, and pest management that slowly closes the existing gap between average and potential yield levels. Increasing nutrient and water use efficiency, improving seed quality and crop establishment, and reducing crop losses due to pests are the key challenges for fine-tuning soil and crop management. Nutrient management will require a more dynamic, site-specific approach to account for spatial and temporal variability in indigenous nutrient supplies and crop nutrient needs.^[9] New technologies must not conflict with the need to reduce labor and other production costs or the need to contribute to reducing potential environmental impacts from rice production. The application of biotechnology will be crucial for improving grain quality traits—especially those that can improve nutritional status for low-income people who rely on rice as their primary staple—and for maintaining adequate levels of durable pest resistance.

Cropping Systems: Irrigated Rice and Wheat of the Indo-gangetic Plains

David J. Connor

University of Melbourne, Melbourne, Victoria, Australia

INTRODUCTION

Rice and wheat are the world's two most important cereal crops that have evolved in distinct geographic distributions—rice in the tropics and wheat in temperate regions. Suitable thermal conditions for both crops are found during the annual cycle of the Indo-Gangetic Plains (IGP), where 13.5 Mha (85% of cropped area) are now devoted to rice-wheat (R-W) production sequences. There are an additional 9.5 Mha of R-W sequences in south and south-central China, where climatic conditions and access to irrigation also allow double cropping. The expansion was driven by the increasing demand for food and was made possible by the development of short-duration cultivars of both species, and in some places by subsidies and increased use of irrigation, fertilizers, and pesticides. The rice-wheat system is now the most important production system for the food security of south Asian countries. Demand for high-aggregate yield from the R-W system makes it a case study in contemporary agriculture: the search for high-yielding systems that are also sustainable.

The brief treatment presented here concentrates on the IGP and on the main crops of rice and wheat, dealing with productivity and the key management processes related to soil, nutrients, and water. Readers are referred to recent reviews^[1,2] for more detail and to the Web site of the R-W Consortium.^[3]

DISTRIBUTION AND SYSTEM CHARACTERISTICS

The R-W areas of the IGP currently cover 10 Mha in India, 2.2 Mha in Pakistan, and 0.5 Mha each in Bangladesh and Nepal. The origin of the system differs from east to west. In the east, wheat was introduced into rice areas as a winter crop (e.g., in Bangladesh), while in the west rice was introduced as a summer crop after wheat (e.g., in the Punjab and Haryana states of India). There are two broad production systems.^[4] In the west, as in the Indian and Pakistani Punjab, monsoon rice is followed by wheat. Rice is transplanted from late May to July and harvested from September to late November. Wheat is

then grown from October/November to March/April. In the eastern, warmer areas, rice is grown during the summer to early winter, usually from June/July to October/November, and wheat from November/December to March. This allows for the possibility of a third crop, often a legume, after wheat and before rice.^[4] A detailed agroclimatic analysis of the R-W zones of India is available for Ref. 5.

Rice-wheat systems are practiced on soil types ranging from sandy loam to heavy clay. The common requirement is sufficient clay content to hold ponded surface water for rice production, but in some areas of coarse-textured soils on which the system has developed (e.g., the Indian Punjab) soils do not hold water, so rice crops are continuously irrigated. Fertilizer use is variable. Many subsistence farmers (e.g., in Bangladesh) still rely on farm-yard manure combined with small amounts of inorganic fertilizer, while up to 300 kg N/ha are applied to rice and wheat crops combined in the Indian Punjab.^[6] Rice is mostly transplanted by hand, with mechanical transplanters being adopted in some areas (e.g., the Indian and Pakistani Punjab). Much rice is now direct-seeded, but there is no reliable data on its extent in R-W systems. Machinery is increasingly available for sowing and harvesting, and many small-scale farmers in the eastern IGP (e.g., Bangladesh) have access to small machinery powered by two- and four-wheeled tractors.

PRODUCTIVITY AND NUTRIENT BALANCE

The R-W system is highly extractive at the levels of yield that are being sought. That condition is exacerbated by the frequent harvest or burning of straw and by the small amount of organic matter that can be returned as farm-yard manure because of its competing use as fuel for cooking.

The average annual productivity of the R-W system in IGP is small (5 to 7 Mg/ha) by comparison to currently attainable (8 to 10 Mg/ha) and site-potential (12 to 19 Mg/ha) yields.^[6] India is an exception, with current yields of 9 Mg/ha.^[5] Although concern has been expressed about yield stagnation of the system, a recent

analyses of long-term experiments (1983 to 1999) at six locations in the IGP^[7] does not support that conclusion. The analysis reveals that crop performance depends upon nutrient management. When the results were averaged over locations, rice yields exhibited a declining yield only in those treatments that received no fertilizer. Yield trends were positive with recommended fertilizer application, especially where nutrient demand was met by a combination of inorganic fertilizer and organic manure. In wheat, yield declined without fertilizer but remained constant with applied fertilizer. Consideration of nutrient extraction (in harvest) and input by fertilizer explains these results, revealing that greater yields will require greater and more carefully targeted fertilization. There are two parts to this process.

The first is attention to providing adequate and balanced macronutrients needed to sustain the system.^[8] Based on average nutrient concentrations in grain and straw, a yield of 10 Mg/ha equally divided between rice and wheat requires an estimated replacement for continuing productivity of 163, 34, and 47 kg/ha of N, P, and K, respectively, to account for grain harvest. This increases to 243, 45, and 63 kg/ha when stubble is also removed. The second part of the process is to correct micronutrient deficiencies of Zn, Fe, Mn, B, Cu, and Mo that are now identified across the region, depending mostly on soil type but also on previous cropping history.^[9]

The inclusion of legumes is seen by many as the way to supply N to the system. Nutrient balances show, however, that legumes make only small contributions to the N requirement, relative to the high yields required of the system.^[4] Further, legume N is not a free good but is accumulated at cost to land, time, labor, water, fertilizer, and the opportunity cost of other crops. It is not surprising that in terms of N balance alone, few farmers find legumes to be economic at the current price of N fertilizer. There are, however, other reasons for crop diversification: to assist soil, disease, and weed management; to improve human nutrition; and to increase or stabilize economic returns.

PUDDLING AND THE WET-DRY CYCLE

Preparation of land for rice by puddling, followed by inundation until crop maturity, have significant effects on the physical, chemical, and biological status of soils, influencing growing conditions for all crops in the system.^[10,11] Puddling, the repeated tillage of saturated (inundated) soil in preparation for a rice crop, is undertaken because it offers significant advantages to rice production. It softens soil to facilitate transplanting of rice seedlings, promotes root growth, aids weed control,

and reduces water and nutrient losses caused by leaching. As an additional benefit, inundation mobilizes phosphorus and holds nitrogen in the ammonium form. Puddling, however, disperses soil aggregates, destroys soil structure, and in fine-textured soils forms a massive topsoil that sets hard and often cracks widely when dry. When repeated from year to year, puddling may form a compacted layer up to 5 to 10 cm thick at 10 to 40 cm depth. In R-W systems, the destruction of surface soil structure and the formation of hardpan as the compacted layers dry can be serious liabilities to the establishment and performance of wheat and other upland crops grown after rice.^[10,11]

An important question asks if this wet-dry transition, when managed by puddling, is inimical to the high-aggregate productivity of all crops in the system? If so, under what conditions are alternative management systems required?

WEEDS, PESTS, AND DISEASES

The productivity of R-W systems may be significantly reduced by competition from weeds, insects, rodents, termites, and nematodes, as well as diseases.^[4] The wet-dry transition provides a barrier to carryover from crop to crop—for example, by termites, rodents, and some weeds and soil-borne diseases—but significant problems remain. The outstanding weed is phalaris (*Phalaris minor*), which has become widespread in wheat crops. Insect problems include the rice pink stem borer (*Sesamia inferens*) and the shoot fly (*Antherigona oryzae*). Interestingly, both insects originally attacked only rice, but they now infect wheat also and have become a significant general threat. Nematodes are soil-living organisms that feed on root systems, and while some species are specifically associated with either rice or wheat, others (e.g., *Meloidogyne* spp.) are polyphagous, can attack all crops in R-W sequences, and pose a serious threat to the system. There is also a range of soil- and seed-borne diseases that can be transmitted from crop to crop in R-W sequences. Some soil-borne pathogens (e.g., *Fusarium*, *Rhizoctonia*, and *Sclerotinium*) survive the anaerobic conditions during the rice phase and build up in continuous R-W cropping. Leaf blights (*Helminthosporium* spp.) are considered the most pathogenic, and because they can proliferate on crop residues they are set to become a greater problem in developing zero-tillage systems.

DIRECTIONS FOR THE FUTURE

The R-W system of the IGP has developed quickly from both rice- and wheat-based origins, but it is unlikely that

its area can increase significantly. Change will continue to characterize the system as it struggles to intensify productivity within environmental constraints. Productivity relates to the advantages of crop diversification and new management options, while environmental constraints are principally the availability of water and labor and pollution from stubble burning. The challenge can be summarized as the need for greater productivity combined with greater use-efficiencies of water, nutrients, and labor.

Two directions are likely to lead to a marked divergence within the system.^[12] First, improvements will be made to the traditional system by gradually improving nutrient management as cultivars are improved; by mechanization that allows more timely sowing and harvesting; and by residue management techniques to improve soil structure. Second, the present early initiatives to modify production toward raised-bed culture of both rice and wheat will offer an immediate increase in yield and profitability associated with greater use-efficiencies of water, nutrients, and labor, and will be associated with greater opportunities for crop diversification.

Cropping Systems: Rain-Fed Maize-Soybean Rotations of North America

Douglas L. Karlen

USDA—ARS, Ames, Iowa, U.S.A.

INTRODUCTION

A two-year maize-soybean rotation became the dominant land use in the midwestern United States during the last half of the 20th century. This occurred primarily through public and private research and development efforts devoted to the genetic improvement of maize and to making soybean a truly “miracle crop,” but also coincided with major changes in the livestock industry that decreased demand for oats and alfalfa. Herein, soil, plant, weed, and insect management practices used to enhance the maize-soybean rotations are reviewed. Economic, environmental, and social effects associated with the rapid expansion and dominance of maize-soybean rotations are also discussed.

NORTH AMERICAN MAIZE AND SOYBEAN PRODUCTION

North American maize and soybean production totaled approximately 259 and 75 million metric tons respectively, in 1999–2000,^[1] or about 44 and over 50% of global production. Of this total, Mexico and Canada produce approximately 7 and 4%, respectively. In the United States, these two crops were grown on approximately 32 and 30 million hectares (ha), generally in a two-year rotation. Assuming the irrigated proportion was similar to 1998,^[2] rain-fed production accounted for approximately 85 and 93%, respectively.

WHY ARE MAIZE-SOYBEAN ROTATIONS INCREASING?

Table 1 shows that between 1950 and 2000, soybean increased by 500%^[3] while oat and alfalfa declined by 90 and 20%. Domesticated in northeast China around the 11th century B.C., soybeans were first brought to the U.S. in 1804 as ballast in a cargo ship.^[4] United States farmers first grew the crop in 1829, primarily for soy sauce or as “coffee berries” when real coffee was scarce. During the late 1880s, farmers began growing the crop for forage or

green manure. George Washington Carver began studying soybean at the Tuskegee Institute in 1904 and made several discoveries regarding its use for protein and oil.

World War II cut U.S. imports of edible fats and oil by 40%, forcing processors to soybean oil. Then through public and private investment in plant genetics, processing techniques, and new uses (e.g., soybean meal for livestock and poultry) soybean’s popularity quickly increased. The bushy, green plants often grown in rotation with maize flower during the summer and produce 60–80 pods, each holding 2–4 pea-sized beans. Harvested in the fall, each bushel (27.3 kg) of seed yields approximately 22 kg of protein-rich meal and 5 kg of oil. Now grown in more than 30 states, soybean is the second largest cash crop in the United States.

Soybeans contain eight essential amino acids that are not produced naturally in the human body. The oil is used for cooking and numerous food and nonfood products.^[4] Lecithin (a mixture of the diglycerides of stearic, palmitic, and oleic acids linked to the choline ester of phosphoric acid) is extracted from soybean oil and used for products ranging from pharmaceuticals to protective coatings. It is a natural emulsifier and lubricant. Soybean hulls provide a natural source of dietary fiber for bran breads, cereal and snacks. After removing the oil, soybean flakes can be processed into various edible soy protein products or used to produce meal for animal feeds.

Maize is a staple food in Mexico and several other Central and South American countries, but in the United States it is used primarily as the energy source in livestock feed and as a sweetener to replace sugar. World trade is also an important factor with 66% of exported maize originating in the United States.^[5] Each bushel of maize (25.4 kg) provides 14.3 kg of starch or 15 kg of sweetener or 9.45 L of ethanol fuel, plus 6.1 kg of gluten feed (20% protein), 1.2 kg of gluten meal (60% protein), and 0.7 kg of oil. Annual research and development investments of more than \$137 million dollars by private industry focus on improving maize hybrids for farmers.^[6] This investment has helped promote maize-soybean rotations by providing improved plant genetics, better production practices, new uses for maize, and a stable market. Maize genetic improvement has generally focused on yield enhancement and stability under drought and disease stress, while

Table 1 Estimated U.S. maize, soybean, oat, and alfalfa production for 1950 and 2000^a

Crop	1950	2000
Maize	33.55	32.20
Oat	18.24	1.81
Alfalfa	30.42	24.23
Soybean	6.09	30.16

^aIn million hectares. To convert hectares to acres, multiply by 2.47.

production issues have focused on tillage, fertilizer, and water use efficiency.

Industrial uses for maize include a wide array of bio-carbon products including starch, plastics, and ethanol. Research on the extraction of polyol derivatives for ethylene glycol (antifreeze) and propylene glycol (food and health products), development of new commercial manufacturing processes to convert maize fiber into value-added chemical feedstocks, development of a microbe that will simultaneously convert the glucose, xylose and arabinose from maize to ethanol, development of technologies to produce 1,3-propanediol for plastics, and studies on the maize genome are all contributing to the support for maize-soybean rotations.

MANAGEMENT CHALLENGES ASSOCIATED WITH MAIZE-SOYBEAN ROTATIONS

Compared to monoculture maize, a two-year maize-soybean rotation will generally increase yields of both crops by 10% or more.^[7] However, several factors must be managed well if both crops are to achieve their full genetic potential. As shown for soybean (Fig. 1), multiple factors including herbicide injury, nematodes, diseases, and other stresses^[8] interact to reduce potential yield. One advantage of rotation is that some stressors are host-specific (e.g., soybean cyst nematode), but others, such as the northern corn rootworm, are no longer managed by rotation^[9] because of natural selection for extended egg diapause. This adaption allows the insect’s eggs to survive in the soil through two growing seasons. Similarly, some populations of western corn rootworm are no longer managed by the rotation because they have adapted behaviorally with the females ovipositing in soybean fields during the nonmaize phase of the rotation.

Weed control within a maize-soybean rotation is complementary because maize is a C4 grass crop, whereas soybean is a broadleaf C3 crop. As a result, herbicides applied for weed control are rotated from year to year. Furthermore, through development of herbicide-resistant

genetically modified (GMO) crops, weed control is generally not a major production challenge.

Nematodes affecting maize have received less attention than those affecting soybean, but if damaging levels are found, control measures should be used. In infested fields, maize plants may appear to be moisture-stressed, stunted and chlorotic, or exhibit less extreme signs of poor plant growth.^[10] The most important maize nematodes in North America and their type of damage are listed in Table 2.

Nutrient management, row and plant spacing, N rates, winter and early-spring weeds, and insects (e.g., borers, root and ear worms, aphids, beetles, grubs, and maggots) can all affect maize within the rotation. Applying starter fertilizer may increase root proliferation and can promote uniform early-season plant growth and development if soil-test phosphorus (P) and, sometimes, if potassium (K) levels are low. More rapid early-season growth and development through hybrid vigor, fertility, and disease and insect resistance may hasten flowering (i.e., tassel and silk development) by 1 to 3 days. More rapid canopy closure can reduce late-season weed development and perhaps reduce the potential for water stress during pollination and grain-fill. Plant spacing influences light

Fig. 1 Factors affecting soybean yield potential. (View this art in color at www.dekker.com.)

Table 2 Important North American maize nematodes

Common name	Latin name	Frequency and type of damage
Dagger	<i>Xiphinema</i> spp.	Occasional and moderate damage. Severe plant stunting, chlorosis, few fine feeder roots.
Lance	<i>Hoplolaimus</i> spp.	Occasional and moderate damage. Reduces root system, darkened discolored roots, moderate stunting, and chlorosis.
Lesion	<i>Pratylenchus</i> spp.	Very common and moderate damage. Small root system, darkened and discolored roots, moderate stunting.
Root knot	<i>Meloidogyne</i> spp.	Occasional and moderate damage. Swollen roots, moderate stunting, associated with a small root system.
Spiral	<i>Helicotylenchus</i> spp.	Occasional and damaging at high populations. Smaller than normal root system, moderate stunting, chlorosis.
Sting	<i>Belonolaimus</i> spp.	Rare but very damaging. Severe stunting, chlorosis, small and devitalized root system.
Stubby-root	<i>Trichodorus</i> spp.	Rare but very damaging. Stubby lateral roots, coarse roots, excessive upper roots, severe stunting, chlorosis.
Stunt	<i>Tylenchorhynchus</i> spp.	Occasional and damaging at high populations. Smaller than normal root system, moderate stunting, chlorosis.

(Adapted from Ref. 9.)

interception (radiant energy-use efficiency), and by encouraging more efficient photosynthate partitioning, may affect stress tolerance. Poorly spaced or missing maize plants generally decrease yield, whereas an occasional extra plant tends to increase it. The use of variable N rates offers potential economic and environmental benefits, but adoption has been slow because of uncertainty associated with predicting available soil N, especially in tile-drained Midwestern soils.^[11] Several new systemic insecticide seed treatments and genetic engineering technologies (e.g., development of Bt hybrids) are being used to minimize European corn borer and corn rootworm damage, although each of these increases the overall cost of production.

Planting dates and rates, row spacing, fertilization strategies, and genetics are also important for soybean. Recently, earlier planting dates have been used to increase soybean yield potential, but this exposes the crop to stand establishment, disease, and frost risks. Sudden death syndrome (SDS) is one disease that has spread northward throughout the U.S. SDS is caused by a specific strain of a common soil fungus (*Fusarium solani*) that infects the roots and produces a toxin that damages the soybean leaves. The incidence of SDS is often higher if the crop is exposed to cool, moist soils early in the growing season. Management strategies include selecting tolerant varieties, delaying planting, improving drainage, reducing compaction, and reducing crop stress.

Green stem syndrome (GSS) is another disease that has increased dramatically in North America. Plants exhibiting this disease retain green stems, leaves, and petioles late in the season after normal leaf drop. They are also susceptible to leaf and pod distortion, shattering, and seed

coat stains. Multiple factors appear to be contributing to this disease, but due to the similarity of symptoms, GSS is often attributed to virus infection. However, not all plants with GSS are infected with known viruses, and plants may be virus-infected without showing symptoms of GSS. Large increases in bean leaf beetle (*Ceraotoma trifurcata*) and aphid populations are presumably responsible for increased virus infections. The bean leaf beetle is a vector contributing to the spread of the bean pod mottle virus, a disease that can result in multiple symptoms including mottled leaves, stunted plants, reduced top growth and nodule weight, and mottled or stained seeds.

The bean leaf beetle has also been identified as a very important problem for producers of organically grown soybean^[12] destined for human consumption in tofu or other products. In Iowa, only 5 percent of the large-seeded, high-protein organic soybean was rejected from the tofu market because of seed staining in 1998. However, in 1999 rejection rates increased dramatically to nearly 50%. Soybean aphid is another pest affecting the crop in northern states. The insect was found in only one Minnesota county in 2000, but within one year, significant damage was reported throughout the state. The rapid increase in these insect and disease problems is definitely one of the management challenges associated with the relatively simple maize and soybean rotation.

ARE MAIZE-SOYBEAN ROTATIONS SUSTAINABLE?

Considering the near “miracle” impact that soybean has had during the past 50 years, many agricultural and

political leaders may consider this question heresy. Is this denial^[13] or simply a failure to consider all aspects of this agricultural system? Without question, maize and soybean have become very important crops and their production in a two-year rotation is very complementary. The machinery (tillage, planters, harvesters, etc.), grain storage, and marketing systems are very compatible, making the maize-soybean system “easier” to manage with less expense for overhead or infrastructure. But what impact has this simple rotation had on soil resources, water quality, biodiversity, wildlife corridors, and rural communities?

The question will undoubtedly be debated for some time, because of differences in how agricultural systems are defined. The boundaries could be a plant, field, farm, watershed, region, or nation. Fueling the debate are observations that the two-year maize-soybean rotation is associated with 1) fewer and larger farm operations, 2) fewer livestock farms, 3) more pest problems, 4) increased iron chlorosis, 5) narrow profit margins resulting in greater government loan deficiency payments (LDPs), and 6) increased soil erosion and further degradation of soil quality. Some argue that this is no different than during the 1950s when an average of ten Wisconsin dairy farms went out of business each day.^[14] However, others^[15] conclude that to help shape a sustainable future, it is important to understand where we are and how we got here.

Economically, the 1999 and 2000 prices for soybean crops averaged \$173 per metric ton,^[3] the lowest price since 1972 when gasoline prices were \$0.07 L⁻¹ (\$0.25 gal⁻¹). Assuming operating costs (\$196 ha⁻¹) and overhead costs (\$416 ha⁻¹) were similar to those for 1998,^[4] soybean farmers lost approximately \$60 ha⁻¹ each year. To reduce overhead, producers turn to economies of scale and become more reliant on government subsidies. This results in even larger operations and a further reduction in the number of farms and farm families.

Environmentally, maize-soybean rotations grown using conventional tillage and residue management practices often result in greater soil erosion because prior to mid-July and again in the autumn there is very little crop growth or residue and therefore minimum soil surface protection from intensive rainstorms. The increased erosion and lack of surface residues have a negative effect on soil quality through their effect on soil structure and tilth. Furthermore, the small amounts of water use prior to mid-June for maize or mid-July for soybean can lead to increased drainage and runoff of spring rainfall. This reduces water-use efficiency and can contribute to nitrate leaching or loss of phosphorus and organic matter through runoff.

Ecologically, the loss of crop diversity and dominance of maize-soybean rotations leads to a loss of habitat for insects, birds, and small animals. Greater numbers and

diversity of wildlife are generally considered highly favorable in a rural ecosystem and contribute substantially to the rural quality of life.^[13] Increased crop diversity also helps sustain a better balance among insects and can often minimize the severity of various pests.

The sociological impact of having maize-soybean rotations dominate the landscape is more subtle and indirect than the other effects, but as the number of farms and farm families decrease there is a measurable decline in the viability of small, rural communities. Student numbers and church memberships decrease, requiring consolidation and merger; the number of businesses declines; and fewer local youth remain after high school graduation. Producers also begin to bypass the local community as inputs are purchased from larger regional outlets where prices are cheaper.^[13] Collectively, these trends have contributed to the “hollowing out” of rural communities and, if they continue, will threaten the vitality of rural America as we know it.

CONCLUSION

Balancing the benefits of maize-soybean rotations with the ecological, environmental, and social losses will not be easy. However, the process that led to the development of soybean may serve as a model for the future. Public and private investment in research and technology were critical drivers in making soybean a source for literally thousands of bio-based products. Therefore, if natural (i.e., soil, water, air, biological, and landscape), human (i.e., intellectual, experiential, values, and leadership), social (e.g., trust, relationships, attitudes), and financial resources were invested in more diverse cropping systems and in managing land and human resources at community or watershed boundaries, the outcome could be much different than if we continue to pursue consolidation and simplification. Increased crop diversity could enable maize and soybean to achieve more of their genetic potential by minimizing stress. Greater crop diversity across rural landscapes would enhance esthetics and quality of life, and could result in significant improvements in soil, water, and air quality. The new vision for North American agriculture would be the production of the right crop in the right place at the right time based upon natural resource, climate, and market conditions.

Cropping Systems: Slash-and-Burn Cropping Systems of the Tropics

Ken Giller

Wageningen University, Wageningen, The Netherlands

Cheryl Palm

Columbia University, Palisades, New York, U.S.A.

INTRODUCTION

This article describes the key features of slash-and-burn agriculture (otherwise known as shifting cultivation). Such systems are useful in demonstrating the concept of agricultural sustainability in relation to increasing pressure on land due to population growth. The largely closed nutrient cycles under natural vegetation are opened up, resulting in losses that can only be restored through long fallows or through intensification of production.

SLASH-AND-BURN IS THE OLDEST FORM OF AGRICULTURE

In the hierarchy of farming systems, slash-and-burn (or shifting cultivation) is essentially the basic form of agriculture, and remains the perfect example to illustrate the concept of sustainability in agriculture in relation to intensity of land use. Shifting cultivation can be simply defined as the “alternation of cropping periods on cleared plots and lengthy periods when the soil is rested.”^[1] Although we tend to associate slash-and-burn with typical management systems in tropical rainforests, various types of shifting cultivation occur in areas of both forest and savanna, and were in fact the dominant form of agriculture practiced in the conversion of temperate-zone forests and woodlands. Various forms of shifting cultivation can be identified in pollen records from many parts of the world dating back several thousand years. From the great complexity of causes of tropical deforestation, agricultural clearance by smallholder farmers is but one force—currently a relatively minor one.^[2] Currently, major forces driving the clearance of forests are the exploitation of tropical timber and land clearance for commercial agriculture.

Currently about 37 million people practice shifting cultivation on 1035 million hectares of land in the tropics (Table 1). Although this is only about 3% of the agricultural population, it encompasses 22% of the agricultural land area of the tropics. Regionally, similar numbers of people practice shifting cultivation in Africa, Latin

America, and Asia. The area in Latin America is two times more than that in Africa and three times that in Asia.

THE FOUR PHASES OF SHIFTING CULTIVATION

Four main phases can typically be identified in a cycle of slash-and-burn agriculture: clearing, burning, cropping, and abandonment. The abandonment phase involves the movement of activity to a new location, sometimes in very extensive systems involving movement of whole settlements. (This is essentially a long fallow phase during which the productivity of the soil (system) recovers.) Crop-fallow systems in temperate regions are generally associated with soil left bare while the land is rested, but in most tropical regions the fallow phase is associated with the rapid regrowth of vegetation.

The clearance phase involves the felling of trees and slashing of the shrub layer (understorey). This phase usually occurs at or before the onset of the dry season so that the slashed vegetation can dry out to allow burning at the end of the dry season or beginning of the rainy season. Fire is the basic tool used to clear away the vegetation. This job would otherwise require significant time and labor. The burn has several positive and negative effects on the systems' productivity. The intensity and effects of burning depend substantially on how the vegetation and fire are managed. Particularly important factors are the length of time the cut vegetation is left to dry, and whether heaps or piles are made before burning. Piling of biomass tends to achieve a more complete burn, and leaves behind little organic matter.

The clearance and burning phases result in the opening up of what are relatively closed nutrient cycles under forest, where the perennial root system ensures efficient capture of nutrients into the vegetation and recycles through litterfall and decomposition.^[4] Elements that are readily oxidized to gases (notably C, N, and S) are lost during the burn, although the degree of nutrient loss depends on the intensity of the fire. Other nutrients—notably

Table 1 Land area and population practicing shifting cultivation in the tropics

	Million hectares	Agricultural population (millions of people)
Africa	263	11
Latin America	600	11
South and Southeast Asia	172	15
Tropical total	1035	37

(From Sanchez and Palm, forthcoming; adapted from Ref. 3.)

the basic cations Ca, Mg, and K (and to some extent P)—are returned to the soil in the ash and serve as fertilizer for the subsequent crops. As many of the soils on which shifting cultivation is practiced in the tropics are strongly acidic (often with high saturation of aluminium ions), the addition of substantial amounts of base cations can have an important liming effect and ameliorate conditions for plant growth by decreasing aluminium toxicity. Burning also increases the direct impact of rain hitting the soil. With the loss of plant cover and destruction of the litter layer, erosion can result, causing drastic loss of highly enriched surface soil.

Cropping is the third phase of shifting cultivation and is extremely variable. It can be as short as two cropping seasons on inherently infertile soils, or as long as five cropping seasons on more fertile soils.^[4] The first crops are typically fast-growing and nutrient-demanding, such as cereal crops (including maize, upland rice, sorghum, or millet). Subsequent crops tend to be slower-growing and less nutrient-demanding (such as cassava, bananas, or legumes). Characteristics of the cropping phase are a rapid decline in soil organic matter and soil fertility, described in the classic text of Nye and Greenland.^[5] This decline is often accompanied by an increase in weed pressure. Eventually the investment of labor in weeding exceeds the return in crop productivity, so that moving and clearing new plots is more favorable than continued cropping. At this point, the vegetation is left to regrow into the fallow phase. The length of fallow required to restore the original productivity of the land depends on many factors, including the length of the preceding cropping phase. Periods of at least 15–20 years appear to be necessary in West Africa.^[4,6]

Ruthenberg proposed a useful classification of systems based on the intensity of land use,^[1] where a value R is assigned for the proportion of land cultivated annually, or the proportion of time any given piece of land is held under cultivation. If the proportion of land cultivated $R = 0.15$, then the dwellings also move; if $R = 0.30$, then a greater portion of dwellings tend to be static.

When R rises above 0.33, such land uses are no longer considered to be shifting cultivation, and instead are classified as fallow systems. Systems with values of R above 0.70 are regarded as permanent farming.

SHIFTING CULTIVATION SYSTEMS ILLUSTRATE SUSTAINABILITY

The concept of sustainability of the natural resource base and agricultural production is illustrated in Fig. 1, based on the early analyses of Guillemin.^[7] The first case represents a situation where land is abundant, so that there is ample time for the land's productivity to recover to its original status before cropping (Fig. 1a). Under this scenario there is a period during which the land is rested unnecessarily. Greater productivity can be achieved when land is cropped as soon as soil productivity is restored to its earlier status (Fig. 1b). The time required to recover after each cropping phase is indicated as increasing, presumably as the rate of vegetation recovery decreases with repeated clearance. As population pressure on land increases, the length of the fallow restoration period is shortened, so that the land is cleared and cultivated before it reaches its prior soil fertility status, resulting in a productivity decline to a new equilibrium value (Fig. 1c). Although recovery of soil fertility is often stated as one of the main reasons for the fallow phase, the level of nutrients in the soil often declines during the fallow phase as nutrients are transferred from the soil to the regrowth vegetation.^[8] As such, it is the total nutrient stocks in the soil plus vegetation system that is important to the recovery of fertility.

A fairly well documented example of shifting cultivation is the Chitemene system found in northeast Zambia.^[9,10] The whole region is covered by open savanna *miombo* woodland dominated by nonnodulating legume trees belonging to the subfamily *Caesalpinioideae* of the genera *Brachystegia* and *Julbernardia*. Circular areas of land are opened by lopping the high branches from the trees, leaving trunks 2–4 meters in length in the fields. The branches are heaped into the center of the opened circle, typically an area 10 times that of the cultivated area needed to provide sufficient vegetation to obtain adequate crop yields. The predominant soils in northern Zambia are strongly acid Oxisols and the large amount of ash is important in ameliorating aluminium toxicity in the soil. The land is typically sown to the relatively nutrient-demanding crop of finger millet (*Eleusine coracana*) followed by a crop of longer duration of cassava, often intercropped with Bambara groundnut (*Vigna subterranea*). The land is then abandoned and left fallow, with trees fairly rapidly regrowing from the lopped stumps. The population pressure in this region long ago exceeded the carrying capacity of the land,^[11] so that although

Fig. 1 The theoretical relationship between the length of fallow and soil productivity. (From Refs. 1 and 7.)

Chitemene agriculture is still widely practiced, much of the population depends on permanent farming or on income from relatives living in cities.

UNDERSTANDING SHIFTING CULTIVATION

Shifting cultivation is an extensive form of food production. Various attempts to intensify agriculture in remote areas have tended to fail for reasons clearly summarized by Ruthenberg:^[1]

Fallow systems exist by soil-mining, and efforts to prevent it are usually not economic (...) given the price relations in the location and the preference of the people concerned. The return to soil-preserving measures (green manuring, compost, terracing, etc.) is too low in relation to the disutility of effort, and there is not yet the scarcity of land which would bring about a change in preferences.

As such, there is an almost inevitable degradation in the natural resource base with the intensification of shifting cultivation, until the point that the land becomes scarce and the returns in soil-preserving measures become high. This process of land degradation and subsequent investment in and recuperation of land is well described by Boserup.^[12] The search for alternative forms of sustainable livelihoods for people living on the forest margins of the tropics has been a major aim of the Alternatives to Slash-and-Burn Program (<http://www.asb.cgiar.org/>).

CONCLUSION

By combining data into simple mathematical models, substantial insights have been gained in our understanding of shifting cultivation. The first such attempt can be traced to the classical work of Nye and Greenland,^[5] who described the basis of declining soil C content, depending on the relative lengths of cropping and fallow phases. Trenbath^[13] used a wide variety of data sources from Southeast Asia to demonstrate how the length of the fallow recovery phase increased with longer periods of cropping, to the point that after six crops, vegetation recovery was deflected to anthropic savanna dominated by dense grass cover, typically of *Imperata cylindrica*. This analysis has been further developed by van Noordwijk to explore the relationships between population pressure, productivity of agriculture, and other ecosystem services such as C stocks, biodiversity, and clean water provision.^[14,15]

Cropping Systems: Yield Improvement of Wheat in Temperate Northwestern Europe

Hubert J. Spiertz

Wageningen University, Wageningen, The Netherlands

INTRODUCTION

Cereal production in Western Europe is mainly determined by wheat and barley production, with oats and rye as minor cereal crops. During the period 1996–2001 the harvest area averaged 17.4 and 11.4 Mha for wheat and barley, respectively. France, Germany, and the United Kingdom are the countries in the temperate region with the largest area of wheat production: 5.1, 2.8, and 1.9 Mha, respectively. According to the (FAOSTAT) database, average wheat yields (14% moisture) in Western Europe have increased since 1972 from 3950 to 5860 kg ha⁻¹ on average. However, in the better endowed regions of the coastal zones of Northwestern Europe, such as the Netherlands, the wheat yields increased from 4820 to 8200 kg ha⁻¹. The progress in raising yields has been even more successful in winter wheat than in spring wheat because of the much longer growing season, which allows extended duration of tillering and spikelet development as well as postfloral photosynthetic activity and grain filling.

DISCUSSION

Yields of winter wheat in regions with long days and a mild climate, e.g., Northern Germany and Scotland, currently average about 9000 kg ha⁻¹, with top yields up to 11,000 kg ha⁻¹ under conditions with optimal fertilization and no occurrence of pests and diseases. With the change in regulations on the use of pesticides and on food safety the occurrence of weeds, pests, and diseases will be less under chemical control. Fig. 1 indicates that winter wheat yields in the Netherlands since 1995 have clearly leveled off from the steady yield advance over several decades. This yield stagnation might result from a decrease in the use of pesticides and nitrogen in response both to lower cereal prices and to societal concerns about the effects of these inputs on environmental quality.

The characteristics of the climate and the soils in Western Europe were presented in *Ecosystems of the World*.^[1] Besides climate and soil quality, technological innovations have been and will continue to be an important factor in the development of European cereal

production. As a consequence of a change in the European Community's Common Agricultural Policy (CAP) the prices of cereal bulk commodities have decreased considerably during the last decade. As a result, the European policy has made a shift from quantity to quality in baking and brewing, as well as for other food and convenience and feed-related products. The priority for food quality and safety provides an opportunity to reorganize the agrifood chain according to the expectations of consumers and to make the agricultural and food sectors more competitive, while respecting safety and environmental requirements. Besides the shift from a bulk commodity to a high-quality produce used for food and feed, cereals will continue to play an important role in arable cropping systems because of the need to control soil-borne diseases without the use of pesticides.

WHEAT RESEARCH: THE CASE OF CROP PHYSIOLOGY

The yield performance of wheat has been studied on the level of single plants and even organs as well as on the level of the crop and cropping system. Fundamental research on plant development and crop growth during the second half of the 20th century in the Netherlands and the United Kingdom has been of great importance to understanding yield formation in wheat. Yield potential is defined as the yield of a cultivar adapted to a specific environment grown without biotic (pests and diseases) and abiotic (water and nutrients) stress or other yield-limiting factors.^[2] The earliest assessments of the potential yield of wheat for a defined environment were made on the basis of leaf photosynthesis measurements and theoretical assumptions about light interception, respiration, and assimilate distribution.^[3] The first estimates of potential grain yields in a temperate climate under favorable growing conditions centered around 10,000 kg ha⁻¹. These calculations of grain yield were based on a sound understanding of biophysical and physiological processes at the canopy level. Such theoretical studies and experimental evidence made it very clear that there existed a considerable gap between actual and potential grain yields.

Fig. 1 Trends in grain yields of winter wheat, spring wheat, and spring barley in the Netherlands from 1975 to 2000.

Grain yield under favorable growing conditions is mainly sink-limited, especially for wheat. From the experiments under controlled conditions it may be concluded that a 25 to 30% increase in the potential grain yield level will be possible. Potential grain yields of about 15,000 kg ha⁻¹ require a stand of at least 600 heads per m² with a minimum of 50 grains per head. Our understanding of processes governing initiation of organ development and related changes in carbon and nitrogen fluxes is much weaker than our knowledge of process controls on light interception and crop photosynthesis.

OPPORTUNITIES FOR GENETIC IMPROVEMENT

It is almost a matter of common sense that yields have limits. Within the crop, there are limits to the rates of processes that produce dry matter, and harvest index cannot be increased beyond certain limits.^[4,5] Because current wheat cultivars are already close to this theoretical threshold, the scope for future increases in potential yield by increasing harvest index is very small. Therefore, increasing biomass production must be considered, sooner or later, as the main route toward further raising potential yield.^[6] Of the total leaf nitrogen, 50 to 80% is allocated to photosynthetic machinery. Accordingly, short-term regulation and long-term acclimation of photosynthesis, with respect to nitrogen costs, are also major

subjects of ecophysiological studies for yield improvement in relation to nitrogen requirements.

The recent advances in functional genomics have allowed us to understand the detailed genetic basis of many complex traits, such as flowering time, culm length, and stay-green characteristics. Within the next few years, it is likely that other important agronomic traits will be linked to a relatively small number of key genes. This will have an impact on breeding perspectives when it is possible not only to quantify the effect of gene activity on physiology and morphology, but also to integrate these effects over the life cycle of the crop.^[7]

In the future, more emphasis should be given to defining new ideotypes that are adapted to milder temperatures during winter and spring and to temperature extremes during flowering and grain filling. Concurrently, breeding should be more focussed on improving the composition of the grain in relation to the demands of the food processing industry and consumer demands.^[8] The protein demand of such high-quality grains can only partially be met by reallocation of nitrogen from the vegetative parts. A substantial amount of nitrogen uptake must occur during the postflowering period.

CROP AND CANOPY MANAGEMENT

During the first five decades of the last century, yields of cereals stagnated because the risk of lodging and infes-

tations of pests and diseases placed limits on increasing nitrogen supply to cereal crops. A breakthrough came when the yielding ability of new varieties could be expressed under controlled management practices: split-dressings of nitrogen, use of chlormequat to improve lodging resistance, and the use of systemic pesticides and fungicides.^[9] In the period from 1970 to 1990, annual increases in actual wheat yields were about 2.5% instead of the historical 0.5 to 1%, which may be considered as the European “green revolution.” This achievement was the result of a technology package that increased biomass production by means of enhanced photosynthetic longevity of the canopy of high-yielding cultivars.

The synergism between the genetic improvement of wheat cultivars and improved crop management resulted in higher biomass yield and an increase in the harvest index as well. This additive effect stimulated farmers to boost wheat yields by increasing inputs under the favorable economic conditions for growing cereals in the European Union. It turned out that farmers could considerably reduce inputs, without risk of a yield penalty, by precision management. The strategic research on growth, development, and yield formation of cereals has contributed to research-based crop management with a time- and dose-specific crop protection and nitrogen fertilization approach, thereby securing yield performance and stability in Northwestern Europe.^[1] At issue is whether this approach will allow *continued* increases in yields, however, as farmers are motivated by policies and incentives to reduce inputs of fertilizers and pesticides in response to societal interests in the protection of environmental quality and natural resources.

CONCLUSION

In Europe, wheat has been the model crop for studying progress made by breeding, as well as for pioneering studies on actual and potential crop production. In the future, more insight into gene-plant-crop-environment interactions will contribute to a better and earlier assessment of the yield potential and stability of new genotypes. Molecular-based plant breeding has become so powerful in modifying the genetic base of a genotype that plant breeding can no longer rely only on testing of the new material in field plots. New, advanced methods of evaluation under standardized conditions with the use of crop models are needed.

The transformation from high-input cereal production to an ecologically based “green” or “organic” crop pro-

duction has had a huge impact on cereal research, breeding, and management practices. It is the start of a new era, in which knowledge of gene expression can be linked to better understanding and monitoring of crop functioning under optimal and stress conditions. Based on real-time monitoring of the crop, fine-tuning of the time, space, and dose management in will become possible. The aim will be to produce healthy food with a controlled use of natural resources and external inputs.

Crops and Environmental Change

Jørgen E. Olesen

Danish Institute of Agricultural Sciences, Tjele, Denmark

INTRODUCTION

Crops are directly affected by any changes in the external environment, which can influence crop development, growth, and resource use efficiency. These environmental changes include changes in climatic conditions (primarily temperature and rainfall), levels of atmospheric CO₂, SO₂, NO_x, ozone, and ultraviolet-B (UV-B) radiation. Depending on the character of the change and the current climate and soil conditions, these changes may be beneficial, neutral, or detrimental to crop yield and quality. Agricultural crops also contribute to environmental change by solute and gaseous emissions affecting environment at local to global scales. These emissions include nitrate leaching, phosphorus losses by erosion, and gaseous emissions of ammonia, nitrous oxide, and methane.

GLOBAL ENVIRONMENTAL CHANGE

Global change is defined in this article as actual and prospective anthropogenic changes in land use, atmospheric composition, nutrient deposition, climate, and UV-B radiation. The earth is undergoing rapid environmental changes because of human actions. The natural rates of nitrogen addition and phosphorus liberation to terrestrial ecosystems have been doubled, and atmospheric concentrations of CO₂, CH₄, and N₂O have been increased to 40%, 130%, and 17%, respectively, above preindustrial levels. The atmospheric concentration of these greenhouse gases are projected to further increase, leading to a global warming of 1.7 to 5.4°C by 2100.^[1] Stratospheric ozone depletion leads to increased (UV-B) radiation. At local to regional scales emissions of NH₃, SO₂, and NO_x may lead to plant damages, soil acidification, and eutrofication. Photochemical reactions with air pollutants lead to the formation of tropospheric ozone. Many of these emissions and effects are related to land use changes.

CLIMATE IMPACTS ON CROPS

Crop production is based primarily on photosynthesis, and is thus dependent on incoming radiation. However, the potential for production set by the radiation is greatly modified by temperature and rainfall. The main effect of

temperature is to control the duration of the period when growth is possible in each year. Also, other processes linked with the accumulation of dry matter (leaf area expansion, photosynthesis, respiration, etc.) are directly affected by temperature. Rainfall and soil water availability may affect the duration of growth through effects on leaf area duration and the photosynthetic efficiency through stomatal closure (Table 1).

There is an optimum temperature range for cool climate crops such as wheat, potato, and soybean of 15–20°C and for warm climate crops such as rice and maize of 25–30°C.^[2] However, there is considerable variation between crops and cultivars in their critical low and high temperatures. For determinate crop species, which include most annual crops and many of the perennial ones, crop duration is determined by thermal time. For these crops a temperature increase will reduce the duration of crop growth and thus biomass accumulation often leading to lower yields (Fig. 1). For nondeterminant species, which include managed grasslands and biannual crops such as beets, a temperature increase will often increase the duration of crop growth in cool and temperate climates, leading to higher yields (Fig. 1).

Changes in seasonal rainfall distribution and intensities will in most cases be more important for crop production than changes in the annual amount. Drought stress or excessive moisture may lead to crop failure, or more timely rainfall may be beneficial to crops in more arid areas. Crop yield and quality responds in nonlinear ways to changes in temperature and rainfall. Such responses are often most pronounced in marginally suitable crop areas. The result is that increased variability of temperature and rainfall reduces in average yields in addition to increasing yield variability.^[3] Overall, climate change is expected to increase yields at high- and mid-latitudes, and lead to decreases at lower latitudes. The global food supply is expected to be relatively unaffected. However, regional and continental effects may be severe.^[4]

EFFECT OF OTHER ENVIRONMENTAL CHANGES

Plant photosynthesis responds strongly to CO₂ concentration.^[5] However, the response depends on the photosynthetic pathway, and the increased photosynthesis with

Table 1 Sensitivity of cropping systems to changes in selected environmental conditions

Component	Temperature	Rainfall	CO ₂	O ₃ /SO ₂ /NO _x
Plants	Growth duration	Dry matter growth	Dry matter growth Water use	Dry matter growth

Soil	SOM decomposition Nutrient cycling	Soil erosion Nutrient leaching	Litter input to soil	Acidification
Pests/diseases	Proliferation of pests	Bacterial and fungal infections	Host biomass quality	
Weeds	Herbicide effectiveness	Herbicide effectiveness	Crop competition	

elevated CO₂ is strongest for C₃ crops (Fig. 1). CO₂ enrichment also reduces stomatal aperture and stomatal density, causing a reduction in crop transpiration. The resulting effects of these responses to higher CO₂ are

Fig. 1 Simulated average yield of winter wheat and cut grassland with changes in temperature for baseline (350 ppmv) and 50% higher (525 ppmv) atmospheric CO₂ concentration using the CLIMCROP model on loamy sand soil in Denmark.

increasing resource-use efficiencies for radiation, water, and nitrogen.^[6] The highest response is seen for water-use efficiency, and this effect is seen in both C₃ and C₄ species. C₃ species capable of N₂-fixation have shown particular high growth stimulation to elevated CO₂.^[7]

Plant photosynthesis is sensitive to high UV-B irradiance. However, crops are generally resistant to increased UV-B radiation, and realistic UV-B irradiances in the field do not appear to have any significant effects on crop photosynthesis.^[8] Increased tropospheric ozone concentration reduces photosynthesis through damage to the photosynthetic systems. In Europe, a doubling of tropospheric ozone concentration has been shown to reduce wheat yields by 9%.^[9] High concentrations of SO₂ and NO_x have also been found to reduce photosynthesis and plant growth.

INTERACTIVE AND INDIRECT EFFECTS

Positive effects of elevated CO₂ in absolute terms are usually enhanced by increasing temperature and light. At higher CO₂ levels, damage to plant growth from air pollutants such as NO_x, SO₂, and O₃ is partly reduced because of reduced stomatal conductance.^[5,9]

Crops depend on soils for water and nutrient supply. Soil organic matter plays a key role in building and sustaining soil fertility. Increased temperature will increase the turnover rate of organic matter with the risk of long-term reductions in soil fertility (Table 1). The weather also influences the practicality of managing soils and crops properly. This often determines the range of profitable crops that can be grown.

The majority of pest and disease problems are closely linked with their host crops. This makes major changes in plant protection problems less likely. However, increased temperature is more favourable for the proliferation of insect pests and many diseases in warmer climates. Unlike pests and diseases, weeds are also directly

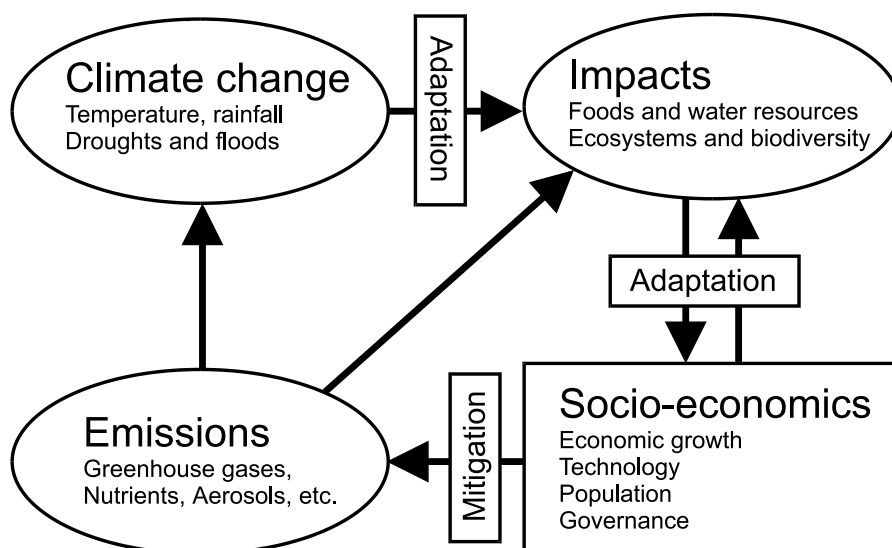

Fig. 2 Adaptation is the influence of emissions, climate change, and other factors on crop production systems and their environment, whereas mitigation is the attempt of society to prevent or reduce such impacts through emissions reductions.

influenced by changes in atmospheric CO₂ concentration. However, the competitive balance between the crops and the weeds depends on the specific interaction. The control of weeds, pests, and diseases is also likely to be affected by these changes.

ENVIRONMENTAL EFFECTS OF CROP PRODUCTION

Crop production is itself a major contributor to gaseous emissions of CH₄, NH₃, N₂O, and NO, which causes environmental problems at local (NO and NH₃) to global (CH₄ and N₂O) scales. Emissions of nitrates by leaching and phosphorus by leaching and surface runoff are also negatively affecting surrounding natural ecosystems through eutrofication. Most of these emissions are closely linked with the intensity of agricultural production.^[10,11]

ADAPTATION AND MITIGATION TO CHANGE

The negative impacts of environmental change can be reduced through adaptation of cropping practices and agricultural systems (Fig. 2). Several adaptation strategies have been proposed involving both short-term adjustments of production systems (e.g., sowing date, cultivar choice, fertilizer, and pesticide inputs) and long-term adaptations involving major structural changes (e.g., land use, crop choice, land management, and irrigation systems).

Mitigation involves reducing the environmental emissions, and agriculture has a range of options to do so.

Greenhouse gas emissions may be reduced, either directly by reducing energy use and emissions of methane and nitrous oxide or by substitution of fossil energy use and carbon sequestration in soils.^[11] Leaching and erosion losses of nitrates and phosphorus can be reduced through improved crop and soil management aimed at closer nutrient cycles.^[10]

CONCLUSION

Crop production is affected by environmental changes occurring at local to global scales. The changes may be both beneficial and detrimental, but effects are largest in regions that are currently marginal for a given crop. Adaptations in land use and crop management to the environmental changes will be necessary. As part of these adaptations, measures to reduce the emissions of environmentally harmful gases and solutes should also be considered.

Cross-species and Cross-genera Comparisons in the Grasses

Ismail M. Dweikat

University of Nebraska, Lincoln, Nebraska, U.S.A.

INTRODUCTION

The grass family (Poaceae) contains about 10,000 species, 700 genera, and six sub-families. Although other angiosperm families contain more species and more genera, the Poaceae exceeds all other families in ecological dominance. Grasses are believed to have originated in the late Cretaceous period more than 66 million years ago, and they now populate almost every land habitat known in both temperate and tropical regions. Members of this family include some of our most important agricultural food and feed crops, wheat (*Triticum* spp.), maize, (*Zea mays*), rice (*Oryza sativa*), barley (*Hordeum vulgare*), oats (*Avena sativa*), sugarcane (*Saccharum* spp.), rye (*Secale cereale*), pearl millet (*Pennisetum glaucum*), and sorghum (*Sorghum bicolor*).

Genomic comparison studies among grass species have become quite extensive and a remarkable amount of information regarding genomic relationships within the grass family is now available. A graphic summary of comparative mapping data among grasses, greatly simplified, has become known as "The Circle Diagram," because of the method used to associate expressed gene sequence maps of different grass species on one radial axis. The diagram shown includes twelve species from four subfamilies: Pooides (wheat and oat), Panicooids (maize, sorghum, sugarcane, and foxtail millet), Oryzoids (rice), and the Chlorinoids (finger millet). The extraordinary pattern that emerges visually illustrates that all the grasses in the four subfamilies contain genes in the same order despite huge differences in their DNA content and chromosome numbers. In fact, it is possible to establish that a limited number of rice linkage groups is sufficient to summarize the marker arrangement on the 12 rice, seven wheat, and 10 maize chromosomes. However, these types of comparisons also reveal a reasonable frequency of large chromosomal rearrangements often shared by particular lineages of grass species.

Evidence is accumulating that much of the fortyfold variation in genome size among the grasses is due to variation in the prevalence of one specific class of repetitive DNA, retrotransposons, both active and ancient. Retrotransposon elements account for more than 70% of the total maize genome. Despite the huge difference in ge-

nome size, chromosome number variation from 2–19, and their ancient origin, comparative mapping reveals a remarkable degree of synteny (conserved clustering of gene/unique sequences) among closely related grass species. The extensive conservation of gene content and order among grass chromosomes has led to the proposal of a single progenitor genome structure for all grasses.

RICE: THE MODEL GRASS SPECIES

In the past, categorization of living organisms was based on morphology and anatomy. However, as genetic knowledge has improved, classifications are increasingly reliant on genomic differences among species. With advances in biotechnology, molecular techniques facilitate the classification more rapidly and precisely. According to the theory of evolution, it is believed that all species have evolved from the same ancestor, which has subsequently mutated to create a specific identity for each species. In the order of evolution, closely related species should have more similar genomes than distant ones, and the ancestor should have a smaller and simpler genome organization than its descendants, in which repetitive DNA has accumulated to result in increased genome size. Deletion of a chromosome fragment can occur, but this generally is disadvantageous to survival. Hence, genome size tends to enlarge rather than lessen over time. Based on these assumptions, rice, which has the smallest genome (430 mbp) of the grass family, is proposed to be a grass ancestor and a model for studying comparative genetics and evolution of the grass family. [Figure 1](#) shows a minimized (four subfamilies) phylogenetic tree and includes most of the cultivated grass species. The family exhibits large variation in DNA content among the diploid grasses, the 1C genome size (DNA content of the unreplicated haploid set of chromosome) varying by fortyfold.

Among rice species exists remarkable genome uniformity. Comparative studies of *O. sativa* and the wild species *Oryza officinalis* shows that marker order in both genetic maps is largely conserved.^[1] Likewise, Aggarwal et al.^[2] fingerprinted more than 23 species of wild rice using AFLP markers to investigate their phylogenetic

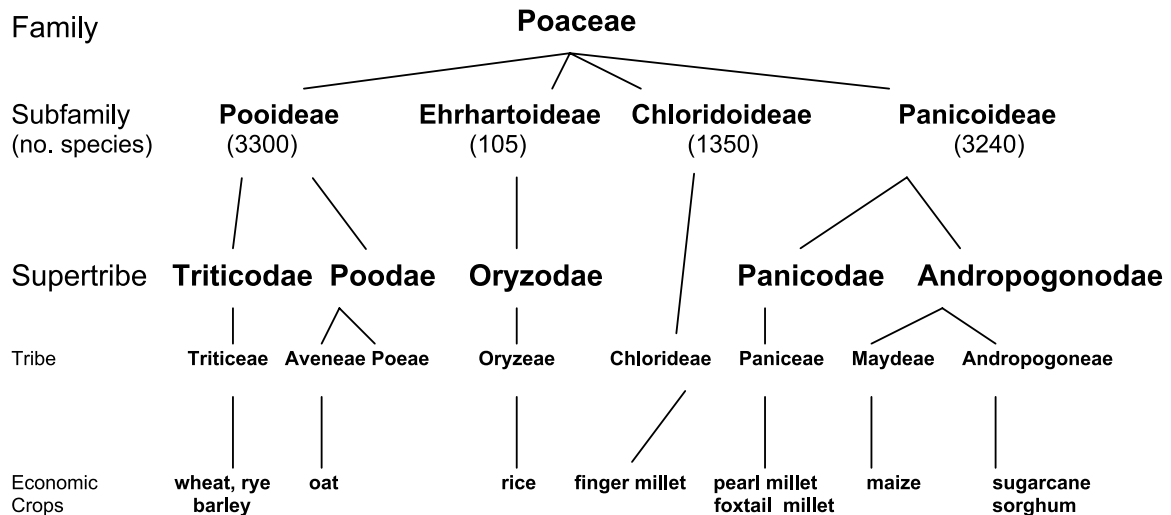

Fig. 1 Simplified taxonomy of the cultivated grass species.

relationships and concluded that all the species originate from one common ancestor.

STRIKING GROSS GENOMIC SIMILARITY IS EVIDENT WITHIN THE POOIDE SUBFAMILY

Genetic linkage maps can be compared among species using a common set of DNA probes. Comparison among the molecular maps of *Triticum* spp. indicates that the orders of molecular markers on the linkage map of these species, detected with the same probes, were essentially homosequential. Consequently, consensus maps that represent the unified linkage maps of each chromosome of these species can be constructed. This RFLP cross-mapping exposed the previously unrecognized generality that genes and their linear arrangement along the chromosomes of different cereal species are remarkably conserved.^[3-5] Initially, this finding was restricted to close relatives, e.g., within *Triticaceae* cereals, between *Oryza* species, and between maize and sorghum. However, recent evidence suggests that this conservation has been maintained over long evolutionary periods to extend across the entire grass family (Fig. 2).

Wheat, a hexaploid, is postulated to have originated from the combined genomes of three diploid species, represented by present-day *Triticum monococcum*, *Triticum uratu*, and *Triticum tauschii*. These three genomes of wheat were shown to be highly collinear (conserved in order of genes or markers). Apart from a few translocations that occurred early in the evolution of the hexaploid wheat, chromosomes of the A, B, and D genomes are found to be entirely collinear.^[6] The A, B, and D genomes within hexaploid wheat have not undergone extensive gene loss or

rearrangement since polyploid formation. Likewise, comparison of *Hordeum bulbosum*, a wild relative of barley, and cultivated barley (*H. vulgare*) reveals a high level of conserved synteny between the two species.^[7,8]

Advances in genomic analysis of the grasses has encouraged researchers to expand their vision to what might be possible if they examine species further out on the evolutionary tree. The goal of these efforts is to maximize information transfer among species using knowledge of their relationships at different levels. The conserved gene orders and the feasibility of sharing DNA probes and primers across species has greatly extended the power of mapping analysis of corresponding chromosomal regions to more distant species.

In the *Triticaceae* tribe, wheat, barley, and rye share a basic chromosome number of 7, with similar DNA content. A consensus map was developed for the *Triticaceae* based on a common set of markers mapped onto the respective linkage groups of *Triticum aestivum*, *Triticum monococcum*, *Triticum tauschii*, and *Hordeum* species.^[7-9] Significant syntenic relationships and conserved gene order are evident within the tribe. Likewise, only a few well-defined rearrangements distinguish the rye and wheat genomes at this level of analysis.^[9] The close relationships that exist among the *Triticaceae* species has even allowed the transfer of genomic and cDNA clones from one species to another.

MORE DETAILED GENOMIC ANALYSIS WITHIN THE PANICOID SUBFAMILY

In the *Andropogoneae* tribe, maize and sorghum both have a chromosome number of 10. In comparisons with an

Fig. 2 Genomes of 12 grass species aligned to form one consensus map. Each circle represents the chromosomal complement of a single grass genome. The alignment of seven genomes was arranged relative to rice, the smallest known grass genome. The arrows indicate inversions and translocations, relative to rice, postulated to describe present day chromosomes. Locations of telomeres (■) and centromeres (▲) are shown where known. Hatched areas indicate chromosome regions for which very little comparative data exist. L, long arm; S, short arm; T, top of chromosome; B, bottom of chromosome; and pt, part (3). (View this art in color at www.dekker.com.)

ancient species such as maize, differences between homologous chromosome sets emerge that involve major genomic rearrangements, although most appear to be associated with small local events.^[10] Maize is considered to be an ancient polyploid that has, during its evolution, undergone genomic diploidization.^[11] In accordance with the polyploid ancestry of maize, a rice linkage group corresponds to two different maize chromosomes.^[12] Comparative mapping between maize and sorghum similarly confirms the duplicated nature of the maize genome. Most sorghum chromosomal segments are found to be collinear to pairs of duplicated regions in maize, with finer chromosomal rearrangement also evident between the two genomes. Sugarcane linkage groups also show syntenic relationships to the duplicated regions of maize. However, the genomes of sugarcane and sorghum appear to be much

more closely related to one another, with respect to chromosome organization, than either is to maize.^[13]

Sugarcane possesses one of the most complex genome organizations of the grasses. Sugarcane germplasm is composed of polyploid, aneuploid clones derived from interspecific hybridization between two species, *Saccharum officinarum* ($2n = 80$) and *S. spontaneum* ($2n = 40-128$). In spite of this enhanced genomic complexity and ploidy, a high degree of collinearity exists among all *Saccharum* species.^[14]

The extensive genomic similarity evident among grass species by DNA mapping studies has led logically to detailed cross-species comparative sequencing efforts that involve orthologous chromosome segments. Several such studies, comparing maize with sorghum and rice, and wheat with barley and rice, have provided important

insight to the events that differentiate grass genomes and likely participate in the speciation process. Although at the gross chromosomal level genome organization is remarkably conserved, gene sequences demonstrate over 20% alteration in organization or content, distinguishing even closely related species.^[15] These extensive small genomic rearrangements include deletions, duplications, translocations, and inversion events. Consequently, at a finer level of analysis, genomic synteny is surprisingly low.

COMPARATIVE MAPPING AS A TOOL FOR GENE ISOLATION

The evolutionary implications of genome collinearity were elegantly demonstrated in the mapping of major loci involved in the domestication of sorghum, maize, and rice several years ago. Paterson et al.^[16] showed the influence of convergent selection for important agronomic traits over the evolution of these crops, with corresponding quantitative trait loci (QTLs) identified to control the same complex traits in species that diverged over 65 million years ago.

With data derived from global comparative mapping endeavors, several groups have now reported the identification of putative orthologous loci in a range of grass genera. Lin et al.^[17] reported that QTLs with major effects on height and flowering in sorghum have counterparts in homeologous segments of the rice, wheat, barley, and maize genomes. Pereira and Lee^[18] similarly identified genomic regions affecting plant height in sorghum and maize. Quantitative trait loci (QTL) controlling the important agronomic traits such as shattering and dwarfing, seed size, and photoperiod sensitivity genes are also collinear between grass species.^[6,18,19] Harrington et al.^[20] mapped starch branching enzyme III in rice and used comparative maps to predict the location of this enzyme in maize, oat, and wheat. The maps that provide the basis for combining the genetic information available in these crops are based on probes that hybridize across the cereals.

A map-based cloning approach in rice has been used for the isolation of the wheat *Phl* gene that controls chromosome pairing.^[21] Likewise, Asnaghi et al.^[22] utilized the synteny among sorghum, maize, sugarcane, and rice to determine the map location of a sugarcane rust-resistance gene. Synteny in the vicinity of *rpg4*, a barley stem rust-resistance gene, was investigated with rice and barley molecular markers. This strategy was successful in physically and genetically positioning the locus.^[23]

With the sequencing of the rice genome, the ability to locate important genes of interest within physically defined intervals will be greatly enhanced. Efforts are now underway to develop collections of rice insertion mutants. Thus, it will soon be feasible to clone loci

efficiently in rice of major agronomic importance based on their functional identification. With these genomic tools in place, it will also be possible to assess fully and exploit the genomic synteny that exists among the grasses.

CONCLUSION

Comparative mapping in the grasses has revealed extensive genome collinearity at the gross chromosomal level between the studied species. However, analyses conducted at a finer scale suggest a high degree of repeat expansion, small-scale deletion/insertions, inversions and translocations distinguishing species. These alterations should not, for the most part, impose major limitations on the use of comparative mapping for gene cloning and fine-scale mapping of important traits. Comparative analysis of closely related grass species that differ in genome size has revealed both the sources of genome size differences and the utility of small genome species for cross-species gene localization efforts. The availability of the genome sequence of rice spurs a wealth of comparative and functional studies in all cereal species. Although the conservation of microsynteny between rice and the other cereals is often incomplete, the possibility to use the rice sequence as a source of markers and candidate genes will play an important role in future gene cloning and function assignments.

Crown Gall

Thomas J. Burr

Cornell University, Geneva, New York, U.S.A.

INTRODUCTION

Crown gall is a plant disease characterized by the development of fleshy or woody galls on plants. The galls, or plant tumors, may develop on roots, at the crown, or on aerial parts of the plant. Generally, they develop on woody plant tissues and not on green growing shoots. Crown gall affects more than 90 families of plants and occurs worldwide. Infected plants may grow poorly and die prematurely. The unsightly appearance of crown gall is especially important in nursery operations where affected plants are usually discarded, resulting in great economic loss. Crown gall is particularly important on fruit and nut crops such as almonds, cherries, peaches, raspberries, and grapes. It is also important on ornamentals such as cypress, euonymus, forsythia, hibiscus, lilac, privet, rose, virburnum, and willow.

Crown gall is caused by bacteria belonging to the genus *Agrobacterium*, a member of the family Rhizobiaceae, and therefore related to *Rhizobium* spp. that are involved with fixation of atmospheric nitrogen in the nodules of legume plants. *Agrobacterium* spp. are gram-negative, aerobic, motile bacteria. It was recently proposed that the genus *Agrobacterium* be eliminated and the present species be placed in *Rhizobium*; however, the acceptance of the new nomenclature by bacteriologists is still being debated. Currently, within *Agrobacterium* there are four recognized plant pathogenic species: *A. tumefaciens*, *A. rhizogenes*, *A. rubi*, and *A. vitis*. The first two species occur on a wide range of hosts, whereas *A. rubi* causes cane gall on *Rubus* spp., and *A. vitis* causes disease only on grape. As scientists continue to isolate and characterize bacterial strains from crown gall-infected plants, it is becoming clear that additional host-associated species of *Agrobacterium* are likely to be discovered.

PATHOGEN BIOLOGY AND THE INFECTION PROCESS

Pathogenic (gall-forming) and nonpathogenic forms of *Agrobacterium* spp. are commonly detected in association with plants and in soils. In some cases, such as grape, the bacterium may be disseminated in propagation material that appears to be healthy. There are selective culture

media that facilitate the isolation and identification of the bacteria. Colony growth is characteristic on the media and isolates are examined subsequently for their ability to cause galls on various plants such as sunflower, tobacco, and tomato. Other biochemical and physiological tests are also used to confirm *Agrobacterium* species.^[1] Analysis of characteristic DNA sequences in the bacterium by polymerase chain reaction (PCR) is also useful for identifying species and for determining whether strains carry genes that are associated with gall formation (see the following).

The process by which *Agrobacterium* infects plants has been a very active and exciting research area for many years. Following are few of the major discoveries related to crown gall infection: 1) in 1958 it was determined that during infection the bacterium transfers a tumor-inducing factor to the plant, after which, galls can be cultured in the absence of the bacterium and without added hormones;^[2] 2) crown gall tumors produce amino acid derivatives called opines;^[3] and 3) infections result from transfer of part of the bacterial Ti plasmid (the T-DNA) into the plant where it is expressed.^[4] The T-DNA is bordered by specific DNA recognition sequences and is composed of genes that are expressed in the plant, including those that encode the production of the plant hormones auxin and cytokinin. Thus, infected plant cells have increased hormone production resulting in rapid and uncontrolled plant cell growth that leads to gall development (Fig. 1).

Many of the steps involved in transfer of the T-DNA to the plant have been identified, for which process there are excellent reviews.^[5,6] A general scheme of the infection process is shown in Fig. 2. In general, galls develop at sites on plants where wounds have occurred. Wounds may play several functions, including the release of chemicals such as sugars and phenolic materials that are sensed by the bacterium. Prior to infection, the bacterium attaches to plant cells. Then, following perception of the chemical signals, pathogenicity-related genes in the bacterium are activated, thereby initiating the process of preparing the T-DNA for its transfer to the plant cell. Steps include extracting the T-DNA from the Ti plasmid in a single-stranded form (the T-strand) and the binding of certain proteins (VirD2 and VirE2) to the T-strand that facilitate its transfer and protect it from enzymatic degradation. Other genes encode proteins (VirB1 to VirB11) that build a pore in the bacterial membrane, through which the T-strand can

Fig. 1 Crown gall disease on trunks of grapevines. (View this art in color at www.dekker.com.)

travel on its way to the plant. A pilus (threadlike channel) connecting the bacterium to the plant cell has been visualized through which the T-strand probably travels on its way into the plant cell. Although an impressive number of discoveries have been made concerning *Agrobacterium* infection, additional research is necessary to completely understand the infection process.

Agrobacterium can be considered a natural genetic engineer of plants. It is the only known example of the occurrence of interkingdom transfer of DNA (from a bacterium to plant). This amazing phenomenon has been utilized to genetically engineer plants with genes for crop improvement. In this case, the disease-associated T-DNA genes are removed from the Ti plasmid and substituted with genes to be expressed in plants. Examples of such genes are those for virus resistance and herbicide tolerance, and those that make plants resistant to insect feeding.

Other key discoveries related to *Agrobacterium* infection were that molecules known as opines are produced by infected cells (in the galls) and that the bacterium has the ability to utilize the opines as selective nutrient sources.^[3]

Fig. 2 Crown gall infection process. After the bacterium attaches to the plant cell, the VirA–VirG regulatory proteins sense plant wound signals and induce expression of other *vir* genes. VirD2 attaches to the 5' end of the T-strand, which migrates through the pore made by multiple VirB proteins. In the plant, the T-strand is coated with VirE2, migrates through the nuclear pore, becomes integrated in the plant chromosome, and is expressed.

Certain opines also function as signals for conjugal transfer of Ti plasmids. Genes for opine synthesis reside on the T-DNA and are therefore transferred on the T-strand to the plant during infection. Genes for catabolism of opines are on the Ti plasmid, outside the T-DNA. Therefore crown galls provide the bacterium a nutritional environment whereby it has a selective niche for survival and growth. Many types of opines associated with Ti plasmids of *Agrobacterium*, including octopine and nopaline, have been identified.

Scientific examination of collections *Agrobacterium* strains make it apparent that there is a significant level of genetic diversity even within a species. Strains may differ in the opine genes they carry. Diversity has also been evaluated by determining the differences in the structures of Ti plasmids and by genetic fingerprinting of certain regions of the bacterial chromosome. Ti plasmids may have multiple T-DNA regions, all carrying different components of genes that are essential for gall formation. Genetic elements such as insertion sequences are also found in Ti plasmids and on the bacterial chromosome. Significant progress has been made in predicting phylogenetic relationships within *Agrobacterium*.^[7] Recently, the complete genome of *A. tumefaciens* strain C58 was completed and published.^[8,9]

DISEASE CYCLE

Agrobacterium survives in soil and in association with plants and plant debris. It is often disseminated along with plants that appear to be healthy. In such cases it may persist in soil clinging to plants, in latent infections, or as an endophyte in the vascular system. In plants such as grape, the bacterium can be isolated from sap that is collected from bleeding plants in the early spring. Crown gall typically develops at wounds on roots or at the crown of plants, but on some hosts, such as grape, it is prevalent on trunks. The specific cells plant that are infected by the bacterium appear to be those involved in wound-healing. Galls are soft and fleshy during their early development and subsequently become necrotic and dry, at which time it is difficult to isolate the bacterium from them.

CONTROL OF CROWN GALL

Plant varieties often differ greatly in their susceptibility to crown gall. For example, wine grapes, *Vitis vinifera*, are generally quite susceptible, whereas *Vitis labrusca* and hybrid varieties are often more resistant. Such differences in varietal susceptibility have been noted for other plant species as well. When considering control strategies, therefore, it may be possible to select plant varieties that

are resistant. Another consideration in disease management is to avoid injuring plants. This may involve selecting proper planting sites where plants will be less prone to freeze injury or using cultivation practices that minimize wounding. Although *Agrobacterium* is sensitive to antibiotics such as streptomycin, treating plants with bactericides is not generally recognized as an effective control. Similarly, fumigation has not been effective for eradicating *Agrobacterium* from soils. One reason for the failure of chemical controls may be that the bacterium resides within plant tissues where it is unlikely to contact chemicals applied on the plant or to soil.

One highly successful way to prevent crown gall is with biological control (see also Management of Bacterial Diseases: Biological Control). In the early 1970s a nontumorigenic strain of *Agrobacterium* (strain K84) was discovered in Australia.^[10] This strain produces at least one antibiotic (agrocin 84) that is lethal to many strains of pathogenic *Agrobacterium*. Roots of plants are soaked in a suspension of K84 cells prior to planting as a means of protecting infection sites. A genetically modified form of K84 (strain K1026) was developed by deleting genes that would allow K84 to transfer genes associated with agrocin production to pathogenic forms of the bacterium (which then become resistant to the biological control). K84 and K1026 are sold commercially in several regions of the world and have been proven effective for controlling crown gall on several types of plants.

CONCLUSION

Crown gall is a disease of worldwide importance on many different plants. Four plant pathogenic species of *Agrobacterium* are recognized, and diverse tumorigenic and nontumorigenic strains exist in association with plants and in soil. Disease control is through selection of resistant varieties, cultural practices, and biological control, which has been quite successful. *A. tumefaciens* causes crown gall by transferring a portion of its Ti plasmid, the T-DNA, to the plant where it is integrated into the plant genome and is expressed. Gene expression leads to increased plant hormone production resulting in gall formation. This natural ability of *Agrobacterium* to function as a gene vector has been harnessed by scientists for the genetic engineering of numerous plant species.

Research on crown gall and its causal bacterium have yielded many exciting discoveries related to mechanisms of disease and plant-microbe interactions. Continued *Agrobacterium* research is focused on how bacteria communicate with each other, what plant genes are associated with infection, and how improvements can be made to the *Agrobacterium* plant transformation system. Results of

such research will also likely lead to effective controls for crown gall.

Cytogenetics of Apomixis

Hans de Jong

Wageningen University, Wageningen, The Netherlands

INTRODUCTION

Apomixis in plants is a natural alternative to sexual reproduction, in which embryos are formed without paternal contribution and, hence, produce offspring that are genetically identical to the mother. This clonal reproduction through seeds is accomplished by circumventing the reductional part of female meiosis and fertilization. It has been described for more than 400 polyploid species (0.1% of all angiosperms) and is common in the *Rosaceae*, *Poaceae*, and *Asteraceae*. Apomixis is a complex reproduction pathway with three main modes: 1) adventitious embryony, 2) apospory, and 3) diplospory. Adventitious embryony, in which embryos with suspensors are formed directly from somatic tissue, is found in citrus. In aposporous apomicts, somatic ovary cells develop via unreduced embryo sacs into unreduced embryos, whereas in the diplosporous type, meiosis in the megasporocyte is incomplete, giving rise to unreduced gametes that later develop into unreduced embryo sacs. In addition, apomicticlike traits were described for various species, including alfalfa, barley, lily, and potato, which exhibit only components of apomixis such as $2n$ gamete formation, female and male parthenogenesis, and aberrant endosperm formation.

Apomixis is especially significant for its potential to develop a breeding system that can capture and fix heterosis and propagate complex traits in seed crops, including those that determine the health and nutritional value of foodstuffs. However, apomixis is very rare among crop species and so far, all attempts to transfer apomixis to cultivated plants by sexual crosses have resulted only in partially fertile, agronomically unsuitable addition lines with one or more alien chromosomes. Research groups worldwide now join efforts to understand better the genetics, molecular organization, and embryological development of apomixis and to transfer the trait from apomictic model species into crops, e.g., *Pennisetum squamulatum* to pearl millet, *Tripsacum* to maize, *Paspalum* to rice, *Taraxacum* to lettuce, and *Boechera* (*Arabis*) to *Arabidopsis*.

METHODOLOGY

In most natural apomicts, the mode of reproduction is related to its ploidy level, which means that diploids are

sexual and polyploids apomictic (Fig. 1).^[1,2] Bulk-segregant analysis of populations obtained from a sexual \times apomictic cross therefore can detect molecular markers linked to the apomictic genes. Although RAPDs, AFLPs, RFLPs, and SCARs are favorites for linkage studies, SSRs (microsatellites) are superior because multiple molecular variants per locus can distinguish homologous chromosomes in a polyploid cross. RFLPs with cDNA probes previously mapped in maize, rice, and other grass species take advantage of the known genomic synteny observed in grass genomes.

Determining chromosome numbers in polyploid and aneuploid populations requires a time-consuming analysis of chromosome preparations. Now this technique is generally replaced by flow cytometry, which has been shown to be most effective for the screening of $2n$ pollen and seed samples.^[3] However, bright field and Nomarski-DIC microscopy remain irreplaceable for more detailed assessment of meiotic chromosome behavior, spindle formation, and cell dynamics in male and female organs, as well as embryo developmental alterations in cleared whole-mount preparations of anthers and ovules (see Fig. 2).

Where genetic and physical mapping have produced bacterial artificial chromosomes or other large insert-vectors containing chromosomal regions with markers tightly linked to the apomictic components, the region can be mapped directly on the chromosomes by Fluorescence in situ Hybridization (FISH). This molecular cytogenetic technique elucidates the position of the apomixis trait with respect to centromere, telomere, and nucleolar organizer regions. The positions of apomictic-linked sequences in heterochromatin are of special interest, as these chromosome regions are rich in repetitive DNA and often prone to gene silencing.

GENETICS OF APOMIXIS

Genetic studies of apomixis are tedious and time-consuming due to variation in the expression (penetrance) of the apomixis trait, the complex mode of polyploid inheritance, the need for microscopic assessment of the gamete and embryological phenotype, and the need for extensive progeny tests. Because apomixis occurs in

Fig. 1 The common dandelion (*Taraxacum officinale*) is a well-known apomictic representative of the Compositae family. Triploid and tetraploid apomictic forms are distributed in northern and central Europe, whereas the diploid sexual forms are more frequent in the southern part of Europe. (View this art in color at www.dekker.com.)

several plant families, it is tempting to believe that their origin is polyphyletic, each with their own specific features and mechanisms. In pioneering studies, parthenogenesis was found to be strictly associated with apospory and, hence, inherited as a single Mendelian trait. Recent investigations favor a model with a few tightly linked dominant genes responsible for at least unreduced female gamete formation and parthenogenetic development of the embryo in the absence of fertilization.^[4] In *Pennisetum squamulatum*, a chromosomal region containing 14 molecular markers linked to apospory and hemizygous in apomictic genotypes was found to be highly conserved with collinearity in the related apomictic buffelgrass species *Cenchrus ciliaris*.^[5] In dandelion (*Taraxacum officinale*), sexual diploids pollinated with apomictic triploids revealed apomictic recombinants with diplospory and autonomous endosperm development but lacking parthenogenesis.^[6] Similar examples of such apomictic recombinants, *Erigeron annuus* and *Poa pratensis*, suggest that the different elements of apospory were indeed controlled by separate gene systems. Additional genetic analyses in *Taraxacum* demonstrated that a dominant trait linked to an SSR marker and located on one of the NOR chromosomes appears to control diplospory. Because this marker is absent in sexual diploid progeny, it was postulated that the apomixis loci are linked to recessive lethals and cannot be transmitted through haploid pollen.

Comparative mapping with maize or rice markers in *Brachiaria decumbens*, *Tripsacum dactyloides*, and *Paspalum simplex* showed a clear lack of recombination in the region associated with the apospory locus, which in the corresponding sexual diploids cover a region ranging from

15 to 40 cM. In *B. decumbens*, apospory was found to be inherited as a single Mendelian locus that is embedded in a chromosomal region homologous to maize chromosome 5 and rice chromosome 2. *Tripsacum* is an important donor of apomixis to maize, and various intergeneric hybrids between them were produced for transferring the apomictic traits to the crop species. Bulk-segregant analysis revealed few RFLP markers that cosegregated with diplospory from *T. dactyloides*. Their restriction fragments were previously mapped on the distal end of chromosome 6 of maize. In a similar approach, the apospory locus in *B. decumbens* could show synteny with the homologous regions in maize chromosome five and rice chromosome 2. In *P. simplex*, apomixis is inherited as a single genetic unit on a large chromosome region that shows synteny of five markers from the telomeric region of rice chromosome 12 and one marker located on rice chromosome 8.

No natural apomicts have been described for wheat, but a synthetic sexual "Salmon" line was produced with the capability of parthenogenesis. In this system, a line with a T1BL·1RS translocation chromosome that was transferred into *Aegilops caudata* or *Ae. kotchyi* cytoplasm displayed autonomous embryo formation due to the synergy of a cytoplasmic factor and two nuclear genes.^[7]

Apomixis is very rare in the Brassicaceae, but the *Boechera holboellii* (*drumondii*) complex is one important representative that is a close relative of the dicot model plant for molecular biologists, *Arabidopsis thaliana*, which brings a huge treasure of molecular and genetic knowledge directly on female meiosis and the embryological aspects of apomixis. The *B. holboelli* complex is widespread in North America and Greenland

Fig. 2 Normarski-DIC photomicrographs of female and male organs of a triploid apomictic dandelion. **a** Ovary with dyad containing an unreduced megaspore and a degenerating megaspore. **b** Pollen sac with dyads of unreduced gametes and tetrads of reduced microspores. Bar equals 10 μ m.

where apomictic forms occur even on the diploid level. Polyploidy and aneuploidy are associated with apomixis, and genetic analysis of independently derived aneuploid apomicts always indicates the presence of the same chromosome, which has undergone morphological changes and no longer pairs at meiosis with its putative progenitors.

SEGREGATION DISTORTION OF APOMIXIS LOCI

Most studies on apomixis demonstrated unequivocally that apomixis and diploidy are mutually exclusive. The general hypothesis assumes that the loci for apospory or diplospory are linked to recessive lethals and so are not transmitted to diploid progeny through haploid gametes. Various transmission studies of markers linked to apospory traits further revealed the following explanations for the absence of apomixis in diploids: 1) selection against haploid gamete formation; 2) meiotic drive, in which the apomictic trait containing chromosome remains as a univalent at metaphase I and always ends up in the diploid gamete; 3) postzygotic lethality.^[8]

FUTURE PROSPECTS

Current research on apomixis focuses on 1) the genetics and molecular mechanisms of how apomixis is regulated in naturally apomictic species and 2) the identification of individual components of apomixis (nonreduction of the chromosome number, parthenogenesis, and the control of endosperm development) in well-characterized sexual model systems such as *Arabidopsis*, rice, and maize. If the molecular bases of apomictic components are sufficiently elucidated and its DNA sequence characterized, traits can then be transferred to crop species by genetic transformation, thus avoiding long breeding programs and hybridization barriers that prevent introgression of the desired trait from unrelated species. Further cytogenetic research is also needed to elucidate the role of unsaturated meiotic chromosome pairing in epigenetically changing the chromosome regions for triggering apomictic pathways. When chromosome regions with apomixis-linked markers have single-copy sequences sufficient for FISH studies, cytogenetic mapping of the region on the chromosomes will then be possible. We also need to understand how apomixis traits can be expressed and transmitted and to what extent these processes are sex-specific. Many of the aforementioned apomicts have sexual relatives with recently sequenced genomes (*Pas-*

palum-rice, *Boechera-Arabidopsis*) or for which extensive EST libraries are available (*Taraxacum*-lettuce). The genome collinearity and sequence similarity between these species will further accelerate fine mapping and gene identification efforts.

Drought and Drought Resistance

Graeme C. Wright
Nageswararao C. Rachaputi

Queensland Department of Primary Industries, Kingaroy, Australia

INTRODUCTION

Drought can be considered as a set of climate pressures that can result from a combination of heat, aerial, or soil water deficits, as well as salinity. The diversity of drought created from these phenomena has led to the selection of numerous types of resistance mechanisms that operate at different levels of life organization (molecule, cell, organ, plant, and crop). Decades of research have been dedicated to the understanding of these mechanisms, with a premise that the improved understanding would contribute to the long-term improvement of plant and crop production under drought conditions.^[1]

DISCUSSION

This article will concentrate on crop production, and in that context drought is a term used to define circumstances in which growth or yield of the crop is reduced because of insufficient water supply to meet the crop's water demand. During the 1960s to 1980s most of the drought research was dedicated to understanding the mechanisms of survival and growth under drought conditions. It is only in fairly recent times that attention has been given to recognizing the complex nature of drought and to separating the *productivity* of crop plants under drought from *survival* mechanisms. Drought resistance in modern agriculture requires sustainable and economically viable crop production, despite stress. However, plant survival can be a critical factor in subsistence agriculture, where the ability of a crop to survive drought and produce some yield is of critical importance.

Hence, in the context of agricultural production, drought resistance in a crop can be best defined in terms of the optimization of crop yield in relation to a limiting water supply.^[2] Multitudes of options exist for farmers to alleviate the effects of drought on crop yield, depending on the probability of drought. These can be categorized into management and genetic options, although they can be integrated into a package to manage drought in the target environment. The basis of most management technologies adopted by farmers revolves around opti-

mizing water conservation and its subsequent utilization by the crop. Examples include the use of deep tillage to increase rainfall infiltration, stubble retention to minimize soil evaporation,^[3] and intercropping.^[4] Genetic options include the use of the best locally adapted varieties or landraces, as well as relaying and intercropping varieties with varying phenology to exploit differences in timing and severity of drought patterns.^[5]

Future advances in crop drought resistance and associated improvements in productivity under drought are most likely to come from genetic improvement programs that can apply the wealth of knowledge created over the past century. As Richards^[6] states, however, it will never be possible to *overcome* the effects of drought, any progress is likely to be slow, and the gains will only be small. The following sections will therefore concentrate on opportunities and emerging technologies for the improvement of drought resistance in crop plants, using genetic enhancement.

DROUGHT RESISTANCE TRAITS

Levitt^[7] has proposed a terminology for drought resistance and its subdivision into different categories based on different mechanisms. These three categories of drought resistance have been widely accepted, and they continue today in a slightly modified form to provide a framework for evaluating potential traits for use in crop breeding programs.^[8–10] They are drought escape, dehydration postponement, and dehydration tolerance.

Drought Escape

Matching the phenology to the expected water supply in a given target environment has been an important strategy for improving productivity in water-limited environments.^[11] In most crop species there is large genetic variability in phenological traits, and these traits are highly heritable and amenable to selection in large-scale breeding programs.^[12] Matching phenology has proven to be a highly successful approach in environments that

have a high probability of end-of-season drought stress pattern.^[13]

Dehydration Postponement

Crops use a variety of mechanisms to maintain turgor in leaves and reproductive structures despite declining water availability. They can effectively regulate water loss from leaves via stomatal control, with large varietal differences in stomatal conductance in response to leaf water potential recorded in cereals^[14] and grain legumes.^[15]

Production of abscisic acid (ABA) has been implicated as a mechanism behind stomatal control.^[16] Other benefits of ABA, including maintenance of turgor in wheat spikelets and subsequent grain set, have also been reported.^[17] Subsequent stimulation of research activity into the use of the ABA trait in crop breeding programs has followed. However, Blum^[18] recently concluded that while ABA is undoubtedly involved in plant response to drought stress and even perhaps in desiccation tolerance, its value in the context of drought resistance breeding is still questionable.

Osmotic adjustment (OA) has been reported as an important drought-adaptive mechanism in crop plants where solutes accumulate in response to increasing water deficits, thereby maintaining tissue turgor despite decreases in plant water potential.^[19] OA has been shown to maintain stomatal conductance, photosynthesis, and leaf expansion at low water potential,^[20] as well as reducing flower abortion^[21] and improving soil-water extraction despite declining water availability.^[22,23] More recent research has confirmed that OA is directly associated with grain yield in a number of crops, including wheat,^[24,25] sorghum,^[26] and chickpea.^[27]

Dehydration Tolerance

The ability of cells to continue metabolism at low-leaf water potential is known as dehydration tolerance. Membrane stability and the associated leakage of solutes from the cell^[28] provide one measure of the ability of crop/genotypes to withstand dehydration. Sinclair and Ludlow^[29] have suggested that the lethal water potential is a key measure of dehydration tolerance, with significant variation among crops and cultivars observed. Some stages of the plant's life cycle are less susceptible to large reductions in water content. For instance, prior to establishment of a large root system, seedlings may often survive large reductions in water content.^[30] Protection against lethal damage in seedlings and seeds is correlated with the accumulation of sugars and proteins.^[31] Proline has also been implicated in cellular survival of water deficits, and has also been involved in osmotic adjust-

ment. Its role as a selection trait for enhanced drought resistance has been questioned.^[32] Although the work on drought resistance mechanisms has produced a few promising leads, their application in practical breeding programs has been limited.

HEIRARCHY OF DROUGHT RESISTANCE TRAITS

Richards^[6] suggests there are two major principles to consider when identifying critical traits to use in breeding programs aimed at improving productivity under drought, namely, the influence of the trait in relation to time scale and to level of organization.

Time Scale

Traits that influence drought resistance in crops can span a wide range of time scales. Short-term responses to water deficit, for example, include many of the processes covered earlier (heat-shock proteins, stomatal closure, OA, ABA), which Passioura^[2] suggests are often primarily concerned with "metabolic housekeeping." Although these processes are important, they tend to be associated with crop survival rather than with events that influence crop productivity. At the other end of the time scale are longer-acting processes such as control of leaf area development, which can be modulated by the crop to adjust water supply to prevailing demand.^[33] It is not always clear which processes are operating to control these balances, but presumably hormonal signals are involved. Passioura^[2] argues that researchers need to distinguish between traits linked to short-term responses that might be important for overall drought resistance and those that are unimportant when integrated over longer time scales.

Level of Organization

The capacity of the trait to influence yield is related to the level of organization (molecule–cell–organ–plant–crop) in which the trait is likely to be expressed.^[34] Richards^[6] cites an example that despite the doubling of crop yields since 1900, the rate of leaf photosynthesis, which is expressed at the cellular-organ level, has remained the same or decreased. Increases in leaf area during this period have been largely responsible for the yield increases. It is concluded that the closer the trait is to the level of organization of the crop the more influence it will have on productivity (Fig. 1).

Fig. 1 The hierarchy of processes leading to crop yield.

DROUGHT RESISTANCE TRAITS IN TERMS OF THE PASSIOURA WATER MODEL

Passioura^[2,34,35] argues that there are no traits that confer global drought resistance. Also, given the earlier discussion which clearly suggests that short term responses to drought stress operating at the cellular level may have no bearing on the yield of water-limited crops, crop productivity is best analyzed from the top down. Here the thinking has shifted from understanding defense mechanisms for survival to applying this knowledge to optimize economic productivity under a given water-limited condition.

Passioura proposed that when water is the major limit, grain yield (GY) is a function of the amount of water transpired by the crop (T), the efficiency of use of this water in biomass production (WUE), and the proportion of biomass that is partitioned into grain, or harvest index (HI), thus:

$$GY = T \times WUE \times HI \quad (1)$$

It was argued that individual traits could be assessed in terms of their contribution to each of these functional yield components and thereby increase yield under drought. The identity has provided a framework to more critically identify and evaluate important drought resistance traits. The following examples demonstrate the utility of this approach.

In a number of crops, improvement in the WUE trait has been achieved via selection for carbon isotope discrimination,^[36] or correlated surrogate measures.^[37–39] Readers are referred to recent reviews for more details on this subject.^[6,40,41]

In maize, increased partitioning to the grain (or higher HI) has been brought about by using an ideotype selection index that focused on a reduction in anthesis to silking interval.^[42] Grain yield of the final selections increased by 108 kg/ha/cycle and came about by an increase in HI, with no change in final biomass relative to the parents.

Wright et al.^[43] proposed that estimates of each of the water model components for a peanut crop could be derived from simple and low-cost measurements of total and pod biomass at harvest, from estimates of WUE from correlated measures of specific leaf area, and by reverse-engineering the TDM component of the water model, such that $T = TDM/TE$. A selection study is being conducted on 4 peanut populations, in which a selection index approach utilising T, WUE, and HI is currently assessing the value of these traits in a large-scale breeding program in India and Australia.^[44]

CONCLUSION

Although drought is commonly referred to as “prolonged water deficit” periods during a crop’s life, it is indeed a complex syndrome with various climate pressures operating together in infinite combinations, resulting in significant reductions in crop performance. Historically, options for managing agricultural drought have revolved around management techniques such as deep tillage, mulching, intercropping, etc. However, future options for drought management will increasingly be based on the genetic improvement of crops for targeted environments. With genetic options, matching phenology to water

availability in target environments has proven to be highly a successful approach. Although our understanding of drought resistance mechanisms has improved significantly, it is essential to distinguish the traits linked to short term responses from those which are important when integrated over longer time scales.

Drought Resistant Ideotypes: Future Technologies and Approaches for the Development of

Nageswararao C. Rachaputi

Graeme C. Wright

Queensland Department of Primary Industries, Kingaroy, Australia

INTRODUCTION

Historically, agriculture has been based on the commodity market. However, in addition to increased production of commodities, future global markets will require “safe” food products. Global phenomena such as increasing scarcity of irrigation water, global warming, increasing populations, and increased consumer awareness about food safety will continue to mount pressure on crop breeding programs to improve the productivity as well as the quality of dry land crops. Hence there is an urgent need for crop scientists to develop new and novel approaches to designing and developing suitable crops and varieties that are well adapted to drought environments.

IDEOTYPE

The ideotype concept, which involves pyramiding drought resistance traits to create an “ideal” genotype, remains an as yet unrealized aspiration: to improve crop yield by breeding by design.^[1] The development of an ideotype for a given drought environment is a complex task requiring integration of knowledge of the environment, the potential capacity of the plant, its constitutive traits, and its adaptive responses to the specific levels and timing of stress—all in the context of final productivity.^[2] However, recent progress in information technology, crop simulation modeling, and biotechnological approaches offers some exciting possibilities for better integration of current knowledge of drought resistance to complement conventional breeding approaches. This article describes some of those emerging technologies, which hopefully can improve the success rate of crop breeding programs engaged in the development of drought-resistant ideotypes.

Using Simulation Modeling to Characterize Target Population of Environments (TPEs)

Careful consideration must be given to assessing the importance of a specific trait in each target environment. For example, where deep soil-water reserves are available

on soils with high water-holding capacity, one would expect that genotypes with extensive root traits would be better adapted. Characterizing the target environment, therefore, becomes a critical requirement in any successful crop improvement effort. Simple soil–water balance models that require easily gathered inputs such as daily rainfall, pan evaporation, and estimates of soil-water holding capacity and rooting depth, allow ready estimates of crop-available water and/or relative transpiration.^[3,4] This historical analysis can be further evaluated using more sophisticated crop modeling, which allows the pattern of seasonal crop water stress to be quantified for specific environments in a probabilistic framework. Differences in the amount and frequency of rainfall, in combination with differences in soil water-holding capacity for a range of seasons and sites, can be easily combined and integrated using these techniques.^[5] Wright^[6] uses the approach to define the most likely drought stress patterns occurring in the rainfed peanut production areas in Queensland. The relationship between crop thermal time and a crop water stress index (or relative transpiration) derived from the model allowed explicit quantification of the seasonal crop water stress patterns over 85 years of historical climate data for this site. Cluster analysis allows similar stress patterns to be grouped, such that the 85 years of data can be clustered down into 5 groups (Fig. 1). Such an analysis then allows the breeder to gain some insight into the probability of likely stress patterns at specific sites. These analytical techniques also highlight how characterization of a water-limited environment in terms of a probabilistic framework can greatly assist the breeder in defining breeding objectives and the drought characteristics that may be the most appropriate for the target environment.

Analysis of Physiological Traits in an Analytical Model Framework

Crop analytical models described by Wright and Rachaputi (2002) in this encyclopedia enable the “dissection” of yield into a small number of independent physiological components that effectively integrate numerous complex processes into fewer “biologically meaningful”

Fig. 1 Changes in calculated relative transpiration with growing degree days from long-term climatic data at Kingaroy, Queensland, Australia for (a) two groups of years showing terminal droughts, and (b) three groups of years showing different intermittent droughts.

parameters. In a practical breeding program the genotype-by-environment interaction ($G \times E$) can potentially be reduced by applying these integrated parameters that contribute to the yield, rather than using yield alone, which is known to have a high $G \times E$ interaction.^[7] Each sub-component of these relationships represents an integrated function of a number of developmental, morphological, physiological, and biochemical attributes.^[8] Any attribute thought to be beneficial for drought adaptability should then be evaluated in terms of its functional relationship and strength of correlation to one of the yield components.

The key to utilizing these analytical relationships in crop improvement programs is critically dependent on the ability to obtain reliable measurements for each attribute for the large number of genotypes within large-scale breeding programs.^[9] Obtaining reliable data for the parameters in the relationships for the large number of plots (genotypes) has been recently addressed, following some novel and pragmatic approaches to quantify the parameters.^[7,10] A more thorough coverage of this topic is reported in Turner et al.^[11]

Simulating Traits and Breeding Approaches Using Crop Models

Crop models allow the opportunity to quantitatively assess the value of hypothetical genotypes with desired levels of a given trait(s) under different environmental and management conditions. A number of workers have assessed the impact of varying levels of expression of traits in grain sorghum, including osmotic adjustment (OA), greater water extraction, phenology, radiation use efficiency, tiller production, and staygreen (e.g., Refs. 12–14). A limitation of this approach is that traits are considered physiologically independent and do not take into account the genetic correlations among traits that are known to occur. There is a lack of information on the extent of genetic variation, genetic correlations, and physiological mode of action for many putative traits.^[9,14] Targeted experimentation is necessary to define these parameters, along with necessary changes in model structure to accommodate known physiological linkages. Boote et al.^[15] suggest that simulation analysis may be used in the future to help determine which genetic traits would be most amenable for molecular geneticists to manipulate in order to maximize yield and returns for specific environments.

Gene-to-Phenotype Modeling

Research into gene-to-phenotype modeling in plant breeding has recently commenced in a number of laboratories around the world. While the major focus of much drought research has been to determine the molecular basis of adaptation to drought environments, much of the work is limited to response at cellular level rather than crop adaptation, with often-overrated claims of potential benefits to agriculture. Research on functional controls of crop plants requires an understanding of the gene-to-trait-to-phenotype adaptation. Researchers at the University of Queensland and the Agricultural Production Systems Research Unit in Queensland have recently initiated a program on modeling plant adaptation and plant breeding that integrates world-leading quantitative genetics research (QU-GENE) and crop modeling (APSIM) simulation platforms.^[16] The aim is to determine the best breeding methods that will find the optimal combinations of genes and cropping system management to exploit target environments. The major research challenge lies in linking understanding of the plant functional basis of phenotype expression to gene function, given that large numbers of genes and complex gene networks are involved in the genetic architecture of these complex traits.^[17]

Experimental data is used in QU-GENE to define the gene-trait and gene-gene interactions and the gene-marker associations for the entire population of possible

genotypes. APSIM takes trait values for all combinations and, using weather and soil data for any number of years and locations in the target environment, simulates the entire genotype–environment landscape for expressed target traits and their pleiotropic and epistatic effects on yield. A QU-GENE module samples the population and applies a selection methodology (e.g., mass, recurrent, pedigree, indirect, marker-assisted, or combinations of these). Millions of combinations of different methods and/or method parameters are evaluated to identify those that are most efficient in accumulating superior gene combinations. This simulation platform is the result of many years of experimental work in crop physiology and plant breeding. This technology will become a major tool in the future to conduct “virtual” plant breeding, using hypothetical parents and making selections for a given trait or combination of traits, and conducting virtual multilocation studies. These tools should also give physiologists and breeders the opportunity to cooperatively decide on the optimal selection and breeding strategy for yield (and quality) improvement in a given environment.

Transgenic Technologies

In situations where specific technical challenges are difficult to handle through traditional crop breeding, transgenic approaches may offer exciting new possibilities for developing new ideotypes suitable for hostile environments, including drought, salinity, nutrient toxicities, and heat. The genes that confer resistance to these complex stresses might have to be isolated from other plants or organisms and introduced into the desired crop species or varieties to develop a genetically modified plant (ideotype) with desired resistance qualities.

A genetically modified (GM) plant is one that contains rDNA or has been developed through the use of genetic engineering or rDNA technology. GM plants are also referred to as GE (genetically engineered), transgenic, or rDNA (recombinant DNA) plants. In simple terms, the development of a GM plant involves two steps: 1) isolating the gene that encodes the desired trait, and 2) introducing the gene into the recipient plant. The gene can be a synthetic construct or a sequence taken from a donor organism. An additional “tracker” gene is added to the gene for the desired trait to allow the new trait to be tracked throughout the process of producing a GM plant. Two common types of tracker genes are those that confer either antibiotic resistance or herbicide resistance. Once the tracker gene has been added to the gene for the desired trait, the genetic construct must be inserted into the recipient plant cells.

The introduction (or insertion) of the gene into recipient plant cells is commonly done either by involving

bacterium-mediated transfer of DNA or by shooting (or projecting) DNA into the cells of the recipient plant.

Plant cells that incorporate the donor DNA into their genome are transformed or genetically modified. Following the gene insertion process, the plant cells are then grown in a medium that contains an agent to help identify only those plant cells that are genetically modified. The cells are induced to form plants using plant growth hormones. Only transformed plants that have incorporated the donor DNA will show the characteristic of the tracker gene; nonmodified plants will not. The plants that have the characteristic of the tracker are then verified as containing the DNA for the desired trait.

Although the technology has been successfully tested to develop GM plants with insect pest and virus resistance, the literature suggests that there has been limited research into development of GM plants with resistance to abiotic stresses such as drought and heat.^[18] Unfortunately, most of the traits contributing to drought resistance involve multiple genes and complex interactions among them. It will probably be some time before multigene-governed traits are successfully introduced into cultivated species and dry land farmers benefit from the growing of such transgenic crops. While transgenic technology holds promise for the future, we believe that in the short term successes in improving drought adaptation of cultivated crops may be derived from marker-assisted selection and breeding approaches.

CONCLUSION

This article highlights the need for developing a drought-resistant ideotype approach to designing crop genotypes for water-limited environments. Such an approach would require integration of current knowledge with more recently developed innovative tools such as crop simulation models and gene-to-phenotype modeling to assess the value of individual traits in the target population environments. Future research on gene-to-phenotype modeling will develop software-based tools to construct genotypes with desired traits and develop knowledge on how to use them in “virtual” breeding programs to assess the performance of progeny in target environments. Major challenges lie ahead in linking the understanding of the plant functional basis of phenotype expression to gene function, given that there are large numbers of gene networks operating in the plant architecture. In situations where specific technical challenges are difficult to handle through traditional crop breeding, transgenic technology may offer great possibilities for developing plants with tolerance to complex stresses such as salinity, drought, nutrient toxicities, and heat.

Echinacea: Uses As a Medicine

Mario R. Morales

Purdue University, West Lafayette, Indiana, U.S.A.

INTRODUCTION

Echinacea was one of the main medicinal plants used by Native Americans before colonization. It was used to treat infections, snakebites, wounds, inflammations, and several other ailments. Later, lay European settlers incorporated echinacea into their list of home remedies. It was not until the 1880s that the plant was prescribed by physicians. Echinacea became quite popular and was subjected to intensive research from 1887 to 1937. The popularity of echinacea declined when sulfa remedies were discovered in the 1930s. Echinacea surged in popularity again in the 1980s, which stimulated intensive investigation.

The chemical composition of echinacea is complex. Several components, especially caffeic acid derivatives, alkylamides, polysaccharides, and glycoproteins, are responsible for its medicinal properties. Immunostimulatory, anti-inflammatory, and antibiotic properties of echinacea have been demonstrated through in vitro and in vivo experiments. Clinical studies have not been conclusive, but they suggest that echinacea may be effective in treating but not preventing upper respiratory tract infections. Plant preparations will be more effective if taken at the onset of the infection.

HISTORY

Native Americans were aware of the medicinal qualities of echinacea before the arrival of the first Europeans. They used the plant to treat a broad spectrum of ailments, especially upper respiratory tract infections (URTI). Upon arrival, colonists readily incorporated echinacea into their list of home remedies. During the 18th and 19th centuries, echinacea was a popular medicinal plant, well accepted by lay people but rejected by medical doctors. Professional interest in the plant started in 1887, when physicians recognized the medicinal qualities of the plant and added it to their list of prescribed plant remedies. Echinacea became quite popular and was intensively studied from 1887 to 1937.^[1] With the discovery of sulfas (antibiotics) in the 1930s, the use of echinacea declined dramatically in the United States. Scientific and commercial interest in the plant moved to Germany, where Gerhard Madaus, a

pioneer in medicinal plant research, began experimentation and large-scale cultivation of *E. purpurea*.^[1] Echinacea became popular again in the United States in the 1980s and 1990s. A 1990 survey showed that 60 million Americans (34% of the population) used at least one of 16 alternative medicines. The Dietary Supplement Health and Education Act of 1994 (DSHEA), which deregulated the dietary and herbal industry, allowed public access to a large diversity of products in several formulations and combinations and helped to increase this figure to 83 million (44%) by 1997. Annual sales of echinacea products increased from \$80 million in 1997 to more than \$300 million in 1999.

The genus *Echinacea* (*Asteraceae*) has nine species, all native to North America, but only *E. purpurea*, *E. angustifolia*, and *E. pallida* (Fig. 1) are used medicinally. The plant is herbaceous and perennial with large, coarse, and ovate to lanceolate leaves and attractive composite flowers with colorful rays at the top of 0.4–1.2 m-long stems.

PHARMACOLOGY

The chemical composition of echinacea is complex. The most relevant constituents are caffeic acid derivatives, alkylamides, polysaccharides, and glycoproteins.^[2] Concentration of these compounds varies according to species, plant part (roots, leaves, stems, flowers), and mode of processing. The curative properties of echinacea may not be due to the effect of a single compound but perhaps to the synergistic effect of several of them combined. These compounds are reported to enhance the immune system and provide echinacea with antiviral, antibacterial, fungicidal, insecticidal, and anti-inflammatory properties. However, the action mechanism, bioavailability, potency, and synergism of these compounds remain unclear and need further investigation.

Caffeic Acid Derivatives

Several caffeic acid derivatives (echinacoside, cichoric or chicoric acid, caftaric acid, chlorogenic acid, cynarin)

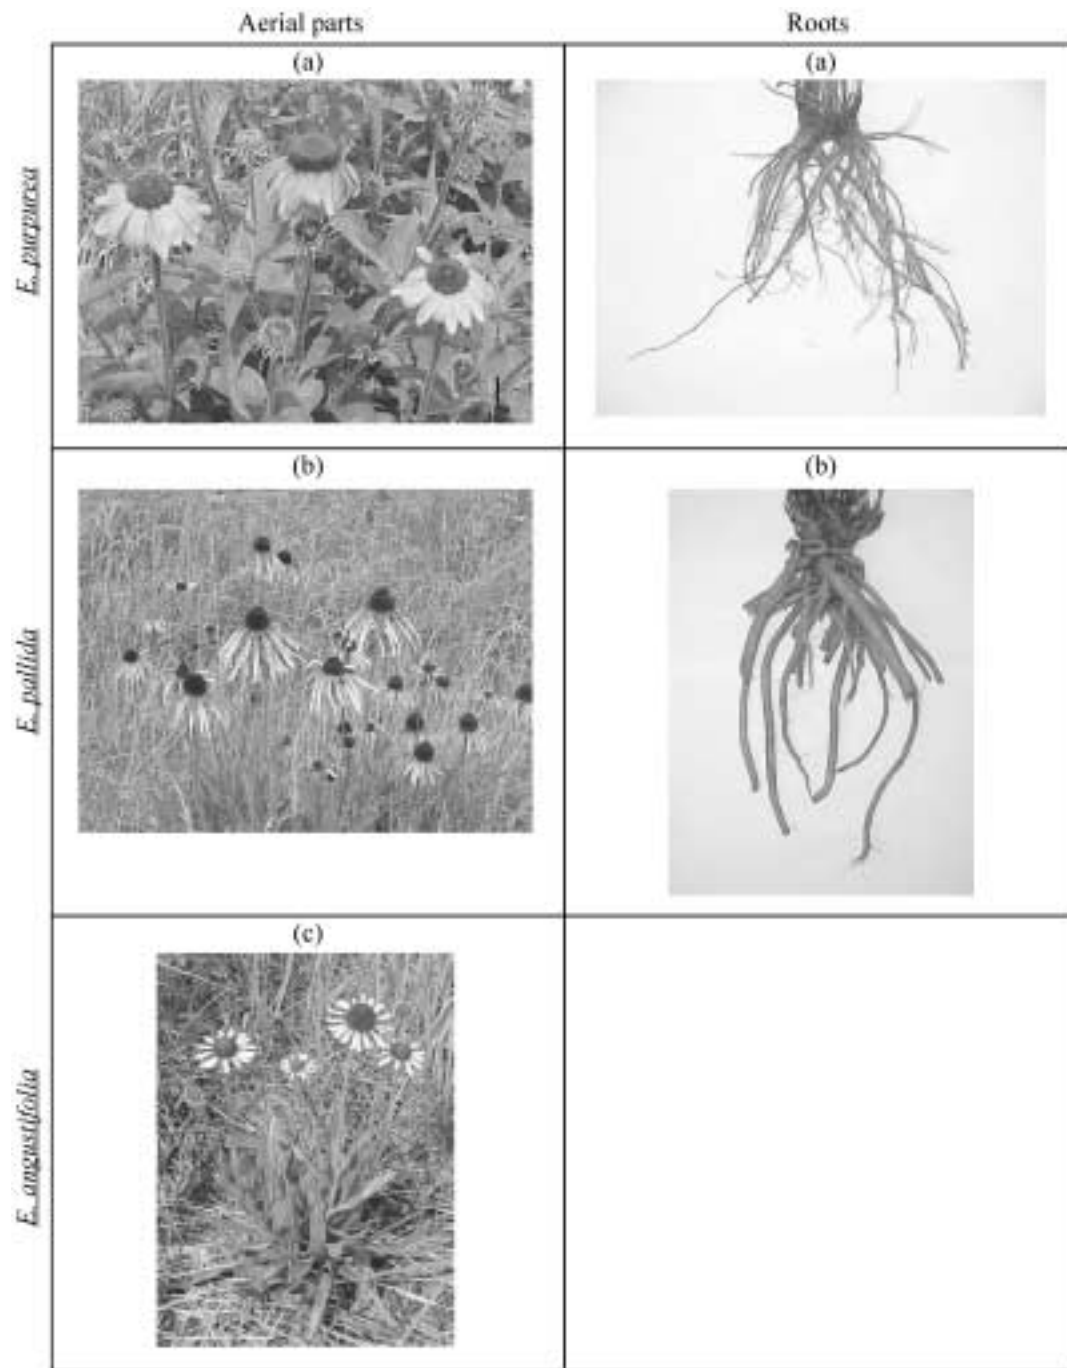

Fig. 1 Aerial parts and roots of *E. purpurea* (a) and *E. pallida* (b), and aerial parts of *E. angustifolia* (c) growing in central Indiana. (View this art in color at www.dekker.com.)

have been isolated from the echinacea plant. Echinacoside contains two molecules of glucose and one molecule each of rhamnose, caffeic acid, and catecholethanol. It is present in the roots and flowers of *E. angustifolia* and *E. pallida* but absent in *E. purpurea*. Echinacoside has a weak antibiotic activity. Cichoric acid is abundant in roots

and flowers of *E. purpurea*, while caftaric acid is present in *E. purpurea* and *E. pallida*. Chlorogenic acid is present in *E. angustifolia* and *E. pallida*. Cynarin, found only in *E. angustifolia* roots, could be used to differentiate *E. angustifolia* from *E. pallida*. The three echinacea species were found to have antioxidant activities and free-radical

scavenging capacities, probably due to the content of caffeic acid derivatives.^[3] Cichoric acid is a powerful stimulant of the immune system and stimulates phagocytosis in vitro and in vivo^[4] and inhibits human immunodeficiency virus type 1 (HIV-1) integrase.^[5] Echinacoside has a low antibacterial and antiviral potency but does not have immunostimulatory properties.^[6]

Alkamides (Alkylamides)

Echinacea alkamides are mainly isobutylamides of highly unsaturated carboxylic acids with olefinic and/or acetylenic bonds.^[7] Fourteen of them were identified in *E. angustifolia*, eleven in *E. purpurea*, and six in *E. pallida* roots.^[8] Alkamide levels were much higher in dried roots (2.65–3.28 mg/g) than in dried leaves (0.10–0.18 mg/g) of *E. purpurea*.^[9] The isomers dodeca-2E,4E,8Z,10E/Z-tetraenoic acid isobutylamides (tetraene alkamides 8/9) have been found to be the most abundant in roots (43–49% of total alkamides) and the aerial part (55–76% of total alkamides) of *E. purpurea*.^[9,10] Since they have shown less bioactivity than the total alkamide extract, it is not clear yet which of the *E. purpurea* alkamides has the most immunostimulatory activity; this alkamide remains to be identified.^[9] Alkamide fractions stimulate phagocyte activity in vitro and in vivo^[11] and work as anti-inflammatory agents by inhibiting cyclooxygenase and 5-lipoxygenase.^[12] It was found recently that 100 mg/ml of several *E. purpurea* alkamides inhibited cyclooxygenase-I and-II in the range of 36–60% and 15–46%, respectively, and that this dose killed 100% of the mosquito *Aedes aegyptii* larvae.^[13]

Polysaccharides and Glycoproteins

Two polysaccharides, PS I (4-O-methyl-glucuronoarabinoxyln) and PS II (acidic arabinorhamnogalactan), were isolated by systematic fractionation from the aqueous extract of the aerial parts of *E. purpurea* and were found, by pharmacologic testing, to stimulate phagocytosis in vitro and in vivo and enhance the production of oxygen radicals by macrophages. However, the extent to which these compounds occur in echinacea preparations is not completely known. Methods to routinely detect pharmacologically active polysaccharides in echinacea preparations still need to be developed. Glycoproteins isolated from *E. purpurea* and *E. angustifolia* roots contain proteins (ca. 3%), the sugars arabinose (64–84%) and galactose (2–5%), and glucosamines (6%). *E. angustifolia* and *E. purpurea* roots contain similar amounts of glycoproteins, while *E. pallida* contains less.

IN VITRO AND IN VIVO STUDIES

In vitro and in vivo studies have demonstrated the potential of echinacea compounds as stimulants of the immune system. For instance, the polysaccharide arabinogalactan activated macrophages to cytotoxicity against tumor cells and the microorganism *Leishmania enriettii* and induced the macrophages to produce tumor necrosis factor (TNF-alpha), interleukin-1 (IL-1), and interferon-beta-2 (IFN-beta-2), all potent enhancers of natural-killer (NK) cells.^[14] Root extract administered to leukemic mice at the onset of the tumor induced a 2.5-fold increase in the absolute number of splenic NK cells after nine days of treatment and the survival of 1/3 of the mice beyond the three months of the experiment.^[15] The stimulatory action of echinacea phytochemicals on NK cells and monocytes, both mediators of nonspecific immunity and well-demonstrated killers of virus-containing cells, was also demonstrated by Sun.^[16] Recently, mixtures of purified cichoric acid, polysaccharide, and alkylamide from *E. purpurea* were able to increase the phagocytic activity and phagocytic index of the alveolar macrophages in a dose-dependent fashion in an in vivo study.^[17] However, the oral intake of freshly expressed juice of echinacea herbs by healthy humans did not enhance the phagocytic activity on polymorphonuclear leukocytes or monocytes and did not influence the production of TNF-alpha and IL-1 beta by stimulated monocytes,^[18] proving that oral intakes are probably not effective.

Tests of the anti-inflammatory and wound-healing properties of pure echinacoside and *E. pallida* and *E. purpurea* root alcohol extracts applied topically on rats found echinacoside and the *E. pallida* extract to be markedly effective at reducing the edematous process after 48 and 72 hours, and while rats in the control and *E. purpurea* groups still showed signs of inflammation and open wounds, rats in the echinacoside and *E. pallida* extract groups had no signs of inflammation and had enhanced wound healing at the end of the experiment.^[19] Echinacoside's antihyaluronidase activity and type III collagen protection from damage caused by free radicals had been previously reported.^[20]

CLINICAL STUDIES

Clinical studies in humans have been inconclusive regarding the efficacy of echinacea for the prevention and treatment of URTI, colds, and flu mainly because of lack of standardization of the plant preparations and deficiencies in design and/or experimental methodology. Melchart et al.^[21] reviewed 26 controlled trials, 18 randomized and 11 double-blind, that were published from 1961 to 1992. Six trials studied echinacea for treatment URTIs and six

for prophylaxis of URTIs, with eleven trials concluding that echinacea was superior to the control. Most of these studies, however, were of low methodological quality, and the claim that echinacea was efficient for the treatment or prevention of URTIs or the common cold was unclear in all but one, which administered 900 mg/day of an ethanolic extract of *E. purpurea* root and concluded that the preparation was effective in relieving URTI symptoms.^[22]

In 1999, Barrett et al.^[23] published a review of 13 new trials on the use of echinacea for treatment or prevention of URTIs; the trials were randomized, double-blind, and placebo-controlled. There were nine treatment trials, and eight of them concluded that echinacea is beneficial against URTIs. There were four prevention trials, but none of them reported significant evidence that echinacea was effective in preventing URTIs. These studies also had methodological deficiencies, but the reviewers concluded that echinacea might be effective in the treatment but not the prevention of acute URTIs. Several clinical studies published later support this conclusion. Three preventive studies, the first evaluating two ethanolic extracts from the roots of *E. purpurea* and *E. angustifolia* on 289 healthy individuals,^[24] the second measuring the effects of the expressed juice from the aerial parts of flowering *E. purpurea* plants on 108 participants,^[25] and the third assessing the effectiveness of an echinacea preparation with 0.16% cichoric acid content,^[26] failed to significantly reduce the frequency, duration, or severity of the common cold symptoms. Two treatment studies, one evaluating the trade drug Echinaforce (6.78 mg of *E. purpurea* extract, 95% herb and 5% root), a concentrated fresh plant extract (48.27 mg of *E. purpurea*, 95% herb and 5% root), and a fresh plant extract (29.60 mg of *E. purpurea* root)^[27] and the second the herbal tea preparation Echinacea Plus[®], a blend of leaves, flowers, and stems of *E. purpurea* and *E. angustifolia* plus a water-soluble dry extract of *E. purpurea* root,^[28] found that Echinaforce, the concentrated *E. purpurea* extract, and Echinacea Plus[®] were significantly effective at reducing and relieving cold and flu symptoms when given at the early onset of the infection.

PROCESSING

The content of active compounds in echinacea preparations varies considerably because of genetic variation, planting location, growth conditions, maturity at harvest, crop storage conditions, parts of the plant used, processing system and conditions, type of preparation (tablet, capsule, tea, expressed juice, chemical extractions), and dosage. These factors determine the level of potency and

efficacy of the echinacea preparations. Cichoric acid is highly susceptible to oxidation and degrades almost completely during the preparation of fresh plant pressed juices. Water extracts from ground echinacea tops and roots lose within seconds more than 50% of the phenolic compounds. Losses are due to the effect of the enzyme polyphenol oxidase (PPO); extraction with 70% ethanol denatures the enzyme.^[29] Echinacea juices extracted in the presence of 50–100 mM ascorbic acid and stabilized with 40% ethanol have high contents of cichoric acid and good long-term stability.^[30] Most echinacea tinctures have 20–25% alcohol, which may destroy polysaccharides such as arabinogalactan while other active ingredients remain intact and active. It was found recently that the addition of citric acid, malic acid, or hibiscus extract to glycerin extracts of *E. purpurea* greatly improved the stability of the caffeic acid derivatives and that the stability was dependent on the concentration of the antioxidant added.^[31] Supercritical fluid extraction shows potential for the recovery of alkylamides from dried echinacea roots.^[32] If fresh echinacea is not processed immediately, it should be freeze-dried to avoid enzymatic degradation and destruction of the active compounds.

STANDARDIZATION

Standardization of medicinal plants should guarantee the concentration, therapeutic effectiveness, stability, and consistency of the active compounds in the preparation. On occasion, standardizations have been made based on compounds with no medicinal value. *E. angustifolia* root preparations have been standardized using echinacoside content, but echinacoside does not seem to be a major medicinal component, which renders the standardization useless because it says nothing about the major active medicinal compounds. Many active compounds in most medicinal plants act additively or synergistically, which makes standardization more difficult. The roots of *E. purpurea* have more than 80 compounds, and to measure the intrinsic and additive therapeutic properties of all of them would be almost impossible. Some studies are now concentrating on using arabinogalactan as a marker to standardize echinacea.

CONCLUSION

Echinacea has curative properties that were recognized first by Native Americans and then by American colonists and Europeans. In vitro and in vivo studies have demonstrated that this plant possesses immunostimulant, anti-inflammatory, and antibiotic properties, which are

due to the presence of caffeic acid derivatives, alkylamides, polysaccharides, and glycoproteins in roots and aerial parts. Results from clinical studies have been mixed because of deficient experimental design, inappropriate drug processing, and lack of good standards. Scientists agree that echinacea may be effective for the treatment but not the prevention of URTIs and colds. More research is needed on the physical, chemical, and medicinal properties of the active components in order to develop useful standardizing procedures. It is also important to improve the design of the clinical studies to more accurately evaluate the curative properties of echinacea.

Ecology and Agricultural Sciences

Jon K. Piper

Bethel College, North Newton, Kansas, U.S.A.

INTRODUCTION

Modern industrialized agriculture has been enormously successful in terms of producing high yields. Over the past several decades, agricultural output has steadily increased, and will need to continue increasing to meet the demands of the growing human population. In recent decades, however, critics have pointed to several unfortunate environmental consequences of modern agriculture. These include soil erosion, contamination of the off-farm environment, and heavy reliance on nonrenewable resources. As far back as the 1930s, proponents of permanent or sustainable agriculture began calling for an imbuing of “ecological principles” into agricultural philosophy and practice. There are several notable examples where this environmental ethic has taken hold in the agricultural establishment, yet many areas still need improvement in order to protect the environment while ensuring a safe and permanent food supply for the indefinite future.

THE PRACTICE OF AGRICULTURE AND THE NATURE OF AGRICULTURAL SCIENCES

Agriculture is one of civilized humankind’s oldest activities. Arguably, the practice of agriculture in all its forms has changed the face of the earth more than any other enterprise. As much as 23% of the Earth’s land surface is presently devoted to row-crop agriculture, converted pastureland, and urban settlements.^[1] In contrast to hunting–gathering systems, in which societies partake of nature’s bounty without appreciably changing the structure of wild ecosystems, agriculture manipulates the landscape to maximize production of harvestable products.

In the modern era, the agricultural sciences have included agronomy, horticulture, and—somewhat more holistically—range management, forestry, and soil science. The goals of the agricultural establishment are to ensure a reliable, nutritious, and affordable food supply while providing economic opportunities for farmers by expanding global markets. An additional, implied purpose is to maintain the long-term health and productivity of agricultural, forest, and range lands. This dual purpose may be exemplified by two of the largest agencies within

the United States Department of Agriculture. The Agricultural Research Service supports research that seeks to maximize agricultural production; the Natural Resources Conservation Service addresses the protection of such critical agricultural resources as soil and freshwater.

Modern agriculture has certainly benefited most segments of society. For consumers in developed nations, it provides a dependable supply of relatively inexpensive, high-quality food. Although people in less-developed countries have not always partaken of this bounty reliably or equitably, in general the Green Revolution has forestalled widespread starvation within the growing world population. Multinational food corporations, large-scale and corporate farming operations, and the companies that supply them with seed, chemicals, and machinery have all profited particularly well.

The priority for most university researchers within agriculture programs has been to maintain a steady increase in yield via “improvements” in chemical fertilizer technology and delivery, genetics, and machinery. Accessing these improvements, however, often requires large capital investments by farmers.

THE PROBLEM(S) OF AGRICULTURE

Agriculture is by nature extractive, altering ecosystems to emphasize useful products and in the process reducing local biodiversity. The natural world can accommodate this practice where human population density is low, people are nomadic, and technology is primitive. In subsistence forms of agriculture, by which a farmer mainly grows enough food for the immediate family, each person’s effect on the landscape is small. There are several examples, however, in which preindustrial societies depleted or despoiled their environmental resource base, leading to their collapse. This has led some writers to characterize the issue as “the problem *of* agriculture” rather than “the problems *within* agriculture.”^[2] Either way, the process of environmental degradation has only been exacerbated by improving agricultural prowess in machinery, chemicals, irrigation, and the ability to farm fragile and otherwise marginal landscapes.

The various negative consequences of modern agriculture have been well documented.^[3] The environmental

failures include soil erosion, loss of native habitat, contamination of surface- and groundwaters, harmful effects of biocides on non-target organisms, salinization, evolution of pest resistance to pesticides, and depletion of nonrenewable resources. Moreover, modern agricultural policy and practice have led to the destruction of rural economies and increasing domination of the global food industry by fewer and fewer corporate entities. For example, from 1940 through the 1980s, the number of farms in the United States dropped from over 6 million to around 2 million, and average farm size increased correspondingly.^[4]

In short, in recent decades there has been growing criticism of the agricultural research establishment's apparent disregard for ecological considerations and the health and value of rural culture. Indeed, the focus of much agricultural research tends to be short-term and narrow, placing the natural world lower on its list of considerations or even ignoring it entirely.

THE NATURE OF ECOLOGICAL SCIENCE

Ecology is the scientific study of the relationships between organisms and the biotic and abiotic components of their environment. Traditionally, ecologists have focused on wild organisms in settings relatively unaffected by human activity. Ecology's greatest contribution to modern scientific thought probably is the concept of the ecosystem, the integration of the living and the nonliving worlds via linkages of energy flow and nutrient cycling. From a human society perspective, this concept means that what we do to the natural world we ultimately do to ourselves.

An important subdiscipline within ecology is the field of applied ecology. The purpose of applied ecology is to use the techniques of ecological study to understand and improve resource use in human-managed systems. Such an ecological perspective has greatly benefited such areas as soil conservation, range management, fisheries management, and forestry. The application of ecological principles to the development and management of agricultural systems is called agroecology.

THE "MARRIAGE" OF ECOLOGY AND AGRICULTURE

As long ago as 1938, Herbert Hanson, then president of the Ecological Society of America, called for an "invasion" of ecology into the realms of agriculture and resource conservation.^[5] The rationale was that the science of ecology provides the concepts that are needed for achieving harmonious relationships among human beings, their domesticated plants and animals, and the environments

that sustain them. Furthermore, natural areas serve as the standards or benchmarks against which such practices as agriculture, grazing, or logging should be measured.

With the rise of the modern environmental movement in the 1960s and 1970s came a blending of ecological holism into agricultural thinking, thus creating a new ethical foundation for farming. This concept of sustainability involves a reorientation of human values, from a short-term technological world view to a longer-term ecological world view. Farming was no longer to be just about producing food, but increasingly about conserving elements of the natural environment. In addition, the sustainable agriculture movement incorporated a social agenda as well as an ecological directive.^[6] Hence, the basis of the new farming would be not only technical but also cultural and spiritual, since technical efforts alone had failed to bring about stability in the farming sector.

During the 1980s, agroecology became a legitimate scientific field in its own right.^[7,8] Hence, farms are considered as ecosystems that should comply with regional ecological guidelines regarding energy cycles, food webs, biodiversity, and a tendency toward ecological stability with the highest possible yield. Relevant ecological concepts include cropping systems that mimic natural succession, nutrient recycling, rotations that enhance the soil community, and natural methods of fighting pests and diseases.

By the end of the 20th century, several varieties of sustainable agriculture had become commonplace. Each to a large extent incorporates a holistic, more ecological ethic and a sense of respect for nature and rural society. For example, organic farming refers to practices that seek to avoid the use of synthetic herbicides, pesticides, and fertilizers, while at the same time building soil organic matter. Permaculture, a system that originated in Australia, emphasizes small-scale technology and the individual farm as a self-sufficient unit. Permaculture integrates people and the landscape to provide food, energy, and shelter in a systematic way.^[9] The term natural systems agriculture has been applied to the concept of agricultural systems that mimic the structure and function of natural ecosystems.^[10] The best-known example is the notion of perennial grain polycultures that mimic North American prairie ecosystems. The potential benefits of such systems include protection against soil erosion, efficient nutrient cycling, and biological management of insect pests, pathogens, and weeds.

Nature provides several crucial services for humanity's agriculture—it purifies the air and water, harbors insects and vertebrates that pollinate crops or consume many agricultural pests, and provides soil organisms that convert crop residues to humus and assimilable plant nutrients. Agricultural ecosystems are embedded within larger natural systems with which they exchange

organisms and materials. Thus, they can not be divorced from the greater natural systems of which they are a part. The major question is whether our agricultural systems can be redesigned to run harmoniously with—instead of in opposition to—the larger system.

AN AGENDA FOR THE 21ST CENTURY

By the close of the 20th century, proponents of sustainable agriculture had successfully established their ideas as legitimate solutions for many of the problems confronting modern farming and food production. Legislation has helped to reduce soil erosion, decrease water pollution, protect prime farmland and ecologically sensitive areas, and provide additional income to farmers. The agricultural establishment now formally acknowledges that environmental concerns must be balanced with the economic concerns of farmers, agribusinesses, and consumers. However, a great deal more still needs to be accomplished in reforming agriculture along environmental lines.

Industrialized humanity has proceeded as though the raw materials of our economy were discrete entities and not parts of larger, complex, interacting systems. We have kept careful ledgers on the benefits, but generally not on the environmental costs of our activities. We have mined energy and mineral resources, harvested forests, farmed virtually every arable acre, and used bodies of water as though there would be no significant effects downstream. Sustainable agriculture is a system that for generations to come will not only be productive and profitable but must also conserve resources, protect the environment, and enhance the health and safety of the citizenry. Specifically, this means maintaining renewable resources at their current levels, avoiding the production of wastes beyond the environment's capacity to assimilate them, protecting the Earth's biodiversity, and reducing the dependence on nonrenewable resources while maintaining the capacity to ensure an acceptable standard of living long into the future.

Ecology: Functions, Patterns, and Evolution

Fernando Valladares

Centro de Ciencias Medioambientales, Madrid, Spain

INTRODUCTION

Ecology is the study of living organisms and their environment in an attempt to explain and predict. While natural history involves the accumulation of detailed data with emphasis on the autecology of each species, the objectives of ecology in general and of functional ecology in particular are to develop predictive theories and to assemble the data to develop general models. Functional ecology has three basic components: 1) constructing trait matrices through screening of various plant and animal species, 2) exploring empirical relationships among these traits, and 3) determining the relationships between traits and environments.^[1] Studies in functional ecology encompass a wide range of approaches, from individuals to populations; from mechanistically detailed to deliberately simplified, black-box simulations; and from deductive to inductive.^[2] Functional ecology is concerned with the links between structure and function, the existence of general patterns among species, and the evolutionary connections among these patterns. And functional ecology is, above all, timely and pertinent, because the environmental degradation associated with human development is rapidly destroying the very systems that ecologists seek to understand. If we are to anticipate the extent and repercussions of global change in natural habitats, we first need to understand how organisms and ecosystems function.

EXPLORING THE MECHANISMS: FROM PHYSIOLOGY TO ECOPHYSIOLOGY AND FUNCTIONAL ECOLOGY

The study of plant functions has largely followed a reductionistic approach aimed at explaining the functions in terms of the principles of physics and chemistry. However, plant physiology, which is focused on molecules, organelles, and cells, has not been able to provide reliable predictions of the responses of vegetation to changes in their environment, due to the multiple interactions involved in the responses of plants and the hierarchical nature of plant organization.^[3] The realization of the fact that the responses of higher organizational

levels are not predictable from the dynamics of those of smaller scales led to the advent of plant ecophysiology, which is focused on organs—a more relevant scale of organization to address questions regarding plant performance. Ecophysio­logists have primarily focused on the structural and functional properties of leaves. Leaves display wide variation in morphology and physiology, including differences in specific mass, carbon and nitrogen investments, stomatal densities, optical properties, and hydraulic and photosynthetic characteristics. The emphasis of ecophysiological studies on leaves is due to the profound implications of the interactions between leaf structure and function for the performance of plants in natural habitats.^[4,5] However, the traditional ecophysiological approach proved to be insufficient in predicting plant distribution and responses to changing environments, which led to the development of functional plant ecology.^[6] Functional ecology is centered on whole plants as the unit of analysis, encompassing a range of scales of organization from organs to whole organism architecture, and is based on a much broader conception of plant functions than that formulated by the earlier practitioners of ecophysiology.^[7]

THE SEARCH OF GENERAL PATTERNS: COMPARATIVE ECOLOGY

Since elucidation of the range of possible functional responses of plants is not possible with the use of model organisms, such as those typically used in plant physiology, functional ecology arises as an essentially comparative science. Ideally, functional ecology deals with traits measured on a large number of species in order to minimize the influence of the peculiarities of the autecology of each species. Two main approaches have been followed to find general ecological patterns in nature: 1) screening, that is, the design of bioassays for a trait or a set of traits measured simultaneously on a large number of species, as in the classic study by Grime and Hunt^[8] of the relative growth rate of 132 species of British flora, and 2) empiricism, or the search for quantitative relationships between measurable dependent and independent variables (e.g., correlations among pairs

of traits or traits and environments) producing quantitative models using traits and not species, as in the general revision of leaf traits by Reich et al.^[4] Models using traits are more general than those based on species and can be more easily transferred to different floras.^[1] The question arises as to which trait must be measured. A possible answer can be obtained by analyzing the basic functions that organisms perform (i.e., resource acquisition, the ability to tolerate environmental extremes, and the ability to compete with neighbors) and then either looking for traits which measure these functions or carrying out direct bioassays of them. The most common limitations of this kind of study are the difficulties in finding unambiguous linkages of a trait to a specific function, and the so-called phylogenetic constraints that are due to the fact that phylogenetic proximity among species can influence their functional similarities.

Individual plants demonstrate important degrees of phenotypic variation, which must be considered in comparative studies. No two individuals of the same species exhibit the same final shape or functional features, regardless of how similar the genotypes of two individuals may be.^[9] Part of this variation is due to phenotypic plasticity, that is, the capacity of a given genotype to render different phenotypes under different environmental conditions, and part is due to other reasons (ontogenetic stage, developmental instability). Plants of the same chronological age can be ontogenetically different, so interpretation of differences in phenotypic traits will depend on whether comparisons are made as a function of age, size, or developmental stage.

EXPERIMENTAL ECOLOGY

Broad-scale comparisons must be driven by hypotheses and must be based on robust statistical designs. However, the finding of statistically significant patterns is no guarantee of underlying cause-and-effect relationships, which must be tested experimentally. Gradient analysis, where functional responses are examined along a clearly defined environmental gradient, is a powerful approach to exploring the relationships between plant function and environment, but it is prone to spurious relationships when there is a hidden factor covarying with the factor defining the gradient.^[3] Inferences from gradient analysis and broad-scale comparisons are statistical in nature and must be confirmed experimentally.

Experiments are designed to test hypotheses, but sufficient knowledge must be available to specify more than a trivial hypothesis before thorough experimentation can be undertaken.^[2] Unfortunately, this is not the case for many natural systems. Although experiments are a

common practice in physiology and ecophysiology, where mechanisms can be explored and hypotheses tested under relatively well-controlled conditions, they are less common in functional ecology studies, especially when hypotheses must be tested in natural habitats. Experimental design should meet a number of standards that are not easy—and in certain cases not possible—to meet in field ecology. The controls should be randomly intermixed with the treatments, both in space and time, and both the control and the experiments must be replicated enough. Replicates are not easy to find in natural scenarios, and when they can be found they are frequently not truly independent of one another, leading to a weak experimental design due to pseudoreplication. In addition, multiple causality and indirect effects, which significantly complicate the interpretation of results, are commonplace in ecology. However, experimental ecology is burgeoning despite all this adversity, because experiments are irreplaceable elements in achieving relevant progress in our understanding of ecological processes, as has been revealed by a number of experimental manipulations of natural populations.^[10]

EVOLUTIONARY ECOLOGY

Functional ecology eventually leads to evolutionary ecology. Trends in functional traits across species and mechanisms linking cause and effect contribute to our understanding of evolutionary processes, especially when they are considered on a time scale long enough to allow for changes in gene frequencies, the essence of evolution. Whereas functional ecology is interested in the immediate influence of environment on a given trait, evolutionary ecology is aimed at understanding why some individuals have left the most offspring in response to long-term consistent patterns of environmental conditions. Functional ecology, focused on an ecological time scale (*now* time), asks questions of “how?” and is concerned with the proximate factors influencing an event. Evolutionary ecology is focused on an evolutionary time scale (geological time), asking questions of “why?” and concerned with the ultimate factors influencing an event. Neither is more correct than the other, and they are not mutually exclusive because ecological events can always be profitably considered within an evolutionary framework, and vice versa.^[10]

There are five agents of evolution: natural selection (differential reproductive success of individuals within a population); genetic drift (random sampling bias in small populations); gene flow (migration movements of individuals among and between populations with different gene frequencies); meiotic drive (segregation

distortion of certain alleles that do not follow the Mendelian lottery of meiosis and recombination); and mutation. Of these agents, only natural selection is directed, resulting in conformity between organisms and their environments.^[10] Darwin's theory of natural selection is a fundamental unifying theory, and the many studies that have been carried out over the last century in support of it demonstrate the power of the rigorous application of the genetic theory of natural selection to population biology.

Economic Impact of Insects

David Pimentel

Cornell University, Ithaca, New York, U.S.A.

INTRODUCTION

Insects, plant pathogens, and weeds are major pests of crops in the United States and throughout the world. Approximately 70,000 species of pests attack crops, with about 10,000 species being insect pests worldwide. This article focuses on the economic consequences for agriculture, but it is important to establish that there are serious consequences for humans and other animals in the food chain from insects, topics that can't be explored in detail in this entry.

SCOPE OF PROBLEM

There are approximately 2500 insect and mite species attacking U.S. crops. About 1500 of these species are native insect/mite species that moved from feeding on native vegetation to feeding on our introduced crops. Thus, an estimated 60% of the U.S. insect pests are native species and about 40% are introduced invader species.^[1,2] Both groups of pests contribute nearly equally to the current annual 13% crop losses to insect pests, despite all the insecticides that are applied plus other types of controls practiced in the United States. Most or about 99% of U.S. crops are introduced species; therefore, many U.S. native insect species find these introduced crops an attractive food source.^[3] For example, the Colorado potato beetle did not feed originally on potatoes but fed on a native weed species. Although the center of origin of the potato is the Andean regions of Bolivia and Peru, the plant was introduced into the United States from Ireland, where it has been cultivated since the mid-17th century.^[3] Today, the Colorado potato beetle is the most serious pest of potatoes in the United States and elsewhere in the world where both the potato and potato beetle have been introduced.

An estimated 3 billion kg of pesticides are applied annually in the world in an attempt to control world pests.^[4] Approximately 40% of the pesticides are insecticides, 40% herbicides, and 20% fungicides. About 1 billion kg of pesticides are applied within the United States; however, only 20% are insecticides.^[4] Most

or 68% of the pesticides applied in the United States are herbicides.

Despite the application of 3 billion kg of pesticides in the world, more than 40% of all crop production is lost to the pest complex, with crop losses estimated to be 15% for insect pests, 13% weeds, and 12% plant pathogens.^[4] In the United States, total crop losses are estimated to be 37% despite the use of pesticides and all other controls, with crop losses estimated to be 13% due to insect pests, 12% weeds, and 12% plant pathogens.

The 3 billion kg of pesticides applied annually in the world costs an estimated \$32 billion per year or slightly more than \$10 per kg. With about 1.5 billion ha of cropland in the world, it follows that about 2 kg of pesticides is applied per ha, or \$20 per ha is invested in pesticide control.

INSECT PESTS

Note that despite a tenfold increase in total quantity (weight) of insecticide used in the United States since about 1945 when synthetic insecticides were first used, crop losses to insect pests have nearly doubled from about 7% in 1945 to 13% today.^[1] Actually, the situation is a great deal more serious because during the past 40 years the toxicity of pesticides has increased 100- to 200-fold. For example, in 1945 many of the insecticides were applied at about 1 to 2 kg per ha; however, today many insecticides are applied at dosages of 10 to 20 grams per ha.^[1]

The increase in crop losses to insect pests from 7% in 1945 to 13% today, despite a 100–200-fold increase in the toxicity of insecticides applied per ha, is due to changes in agricultural technologies over the past 50 years.^[2] These changes in agricultural practices include the following: 1) the planting of some crop varieties that are more susceptible to insect pests than those planted previously; 2) the destruction of natural enemies of some pests by insecticides (e.g., destruction of cotton bollworm and budworm natural enemies), thereby creating the need for additional insecticide applications; 3) insecticide resistance developing in insect pests, thus requiring additional applications of more toxic insecticides; 4) reduction in

crop rotations, which caused further increases in insect pest populations (e.g., corn rootworm complex); 5) lowering of the Food and Drug Administration (FDA) tolerances for insects and insect parts in foods, and enforcement of more stringent “cosmetic standards” for fruits and vegetables by processors and retailers; 6) increased use of aircraft application of insecticides for insect control, with significantly less insecticide reaching the target crop; 7) reduced field sanitation and more crop residues for the harboring of insect pests; 8) reduced tillage that leaves more insect-infested crop residues on the surface of the land; 9) culturing some crops in climatic regions where insect pests are more severe; and 10) the application of some herbicides that improve the nutritional makeup of the crop for insect invasions.^[2]

The 13% of potential U.S. crop production represents a crop value lost to insect pests of approximately \$35 billion per year. In addition, nearly \$2 billion in insecticides and miticides are applied each year for control. Ignoring other control costs, combined crop losses and pesticides thus total about \$37 billion per year.^[3]

Total crop losses to insects and mites worldwide are estimated to be approximately \$400 billion per year. Given that more than 3 billion of the 6.2 billion people on earth are malnourished, this loss of food to insect and mite pests each year, despite the use of 3 billion kg of pesticides, is an enormous loss to society.

INSECTICIDE AND MITICIDE PEST CONTROLS

In general, insecticide and miticide control of insects and mites return approximately \$4 for every \$1 invested in chemical control.^[1] This is an excellent return, but not as high as some of the nonchemical controls. For example, biological pest control has reported earnings of \$100 to \$800 per \$1 invested in pest control. It must be recognized that the development of biological controls, although highly desirable, are not easy to develop and implement.

Both in crops and nature, host plant resistance and natural enemies (parasites and predators) play an important role in pest control. In nature, seldom do insect pests and plant pathogens remove more than 10% of the resources from the host plant. Host plant resistance, consisting of toxic chemicals, hairiness, hardness, and combinations of these, prevents insects from feeding intensely on host plants.^[5] Some of the chemicals involved in plants resisting insect attack include cyanide, alkaloids, tannins, and others. Predators and parasites that attack insects play an equally important

role in controlling insect attackers on plants in nature and in agroecosystems.

INSECT TRANSMISSION OF PLANT PATHOGENS

Insects with sucking mouthparts, such as aphids and plant bugs, play a major role in the transmission of plant pathogens from plant to plant. It is estimated that about 25% of the plant pathogens are transmitted by insects. The most common pathogens transmitted are viruses. These pathogens include lettuce yellows and pea mosaic virus. Fungal pathogens are also transmitted by insects. For example, Dutch elm disease is transmitted by two bark beetle species that live under the bark of elm trees. In infected trees, the bark beetles become covered with fungal spores. When the beetles disperse and feed on uninfected elm trees, they leave behind fungal spores that in turn infect the healthy elm trees.

ENVIRONMENTAL AND PUBLIC HEALTH IMPACTS OF INSECTS

Some insect species have become environmental and public health pests. For example, the imported red fire ant kills poultry chicks, lizards, snakes, and ground-nesting birds. Investigations suggest that the fire ant has caused a 34% decline in swallow nesting success as well as a decline in the northern bobwhite quail populations in the United States. The ant has been reported to kill infirm people and people who are highly sensitive to the sting of the ant. The estimated damages to wildlife, livestock, and public health in the United States is more than \$1 billion per year, with these losses occurring primarily in southern United States.^[3]

In another example, the Formosan termite that was introduced into the United States has been reported to cause more than \$1 billion per year in property damage, repairs, and controls. As it spreads further in the nation, the damages will increase.^[3]

CONCLUSION

Insect and mite pests in the United States and world are causing significant crop, public health, and environmental damages. Just for crop losses in the United States, it is estimated that insect and mite species are causing \$37

billion per year, if control costs are included. World-wide crop losses to insects and mites are estimated to be \$400 billion per year. The public health and environmental damages in the United States and world are estimated to be valued at several hundred billion dollars per year.

Ecophysiology

Luis Balaguer

Universidad Complutense de Madrid, Madrid, Spain

INTRODUCTION

Plant ecophysiology is science that shares with other disciplines its focus on plant performance under field conditions, but differs from them in its ecosystem approach. The main challenge in ecophysiology is to scale up, from physiological processes at the organ level to whole plants, canopies, landscapes, and even to a global level. Across these levels, ecophysiological studies deal with the response to stress, disturbance, or interactions among organisms. Progress is directed toward assessing plant response to finer-scale patterns of biotic, spatial, and temporal heterogeneity. Species characterization on the basis of their responses to different factors and at different organization levels enables arranging species into functional groups, each of which represents a type of plant homeostasis in a changing environment. Understanding of these patterns is significantly limited by the difficulty of dealing with the disparities in the spatial and temporal scales used. The significance of physiological processes to explain plant community composition and ecosystem dynamics is constrained by taxon- and site-specific factors. Ecosystem processes are sensitive to initial conditions, interactive effects, and long-term restrictions. Future research on ecophysiology should give special attention to below-ground plant performance, long-term effects of short- to medium-term events, multiple trophic interactions, feed-forward response to environmental stress, and the reliability and accuracy of regional scale predictions.

PLANT ECOPHYSIOLOGY

Plant ecophysiology is a discipline included in the interface of botany, plant physiology, and ecology. This intersection, widely considered, includes the study of the function and performance of plants in their environment. Within such a broad scope, there is a gradient from autecology, at the boundaries of pure physiology, to synecology, at the boundaries of pure ecology. Closer to autecology, environmental physiology has been defined as the physiology of acclimation, and so it involves a consideration of optimal patterns of response to limiting resources, such as light, CO₂, water, or nitrogen. Optimization is thus its central theme. In contrast, the studies in

physiological ecology or ecophysiology are based on an ecosystem approach.

Few authors distinguish between physiological ecology, as a discipline centered on the characterization of the plant role in the community, and ecophysiology, devoted to the study of the plant role in the ecosystem.^[1] According to this distinction, the former discipline aims to characterize plant niche and the latter to describe the effects of environmental, phenological, morphological, and physiological processes on mass and energy exchange through a plant. Such differentiation is in consonance with the acknowledgment of two types of analytical problems: defining plant tolerances and describing plant performance.^[2]

Most researchers, however, consider both terms synonymous, aiming to integrate, rather than segregate, both perspectives. In this conception, ecophysiology endeavors to explain ecological processes in physiological terms.^[2] The scientific challenge is to scale upward, from organs to whole plants, canopies, landscapes, and even to a global level. At the ecosystem level, this scaling up constitutes an alternative approach to the conceptual simplification implicit in the big leaf models, which do not consider the internal heterogeneity of the system. On a global scale, ecophysiological scaling finds alternative models to those derived from the climate envelope approach, which assume that the predicted climate changes will only shift the geographical distribution of plant communities considered as homogeneous and invariable units. Progress in ecophysiology is directed toward assessing plant response to finer-scale patterns of biotic, spatial, and temporal heterogeneity across ecosystems. In consonance, there has been a shift from an earlier ecophysiological perspective, focused on the acclimation of plants to stable environmental gradients, to an increasing interest in the analysis of the mechanisms by which plants exploit gaps, patches, favorable microsites, and transient events.^[3]

GRIME'S TRIANGLE

Ecophysiological studies are related to at least one of the three axes of Grime's triangle: stress, disturbance, and competition.^[4] Stress is defined as the extent to which any combination of environmental conditions reduces plant performance.^[5] Among them, those whose effects have

been most commonly studied are drought, salinity, nutrient shortage, extreme irradiance, and temperatures. Disturbance is defined as the extent to which any change in the resource base in a habitat induces a change in plant population response.^[6] Disturbances are, among others, clearing of vegetation, changes in land use, pollution, fires, flooding, hurricanes, landslides, trampling, and the action of herbivores and pathogens. Ecophysiological studies deal not only with the thresholds of resistance but also with plant strategies to withstand stress and disturbance. In this context, strategy is understood as the constitutive character syndrome and the complex suite of inducible responses that allow occupation of a particular environment. Plant strategies can be considered the equivalent of behavior in animals, and thus ecophysiology shares with ethology this subject matter and the interest in its ontogeny and phylogeny. The comparative analysis of plant performance in response to stress or disturbances groups plant species in three categories: tolerants, which endure unfavorable environmental conditions and resist their effects; avoiders, which trigger inducible mechanisms that prevent deleterious effects; and evaders, with a life cycle or metabolic activity restricted to favorable periods. Some authors consider this latter category as a particular case of the avoidance strategy.^[7]

In relation to the third axis of Grime's triangle, ecophysiology is concerned with any kind of interaction between organisms, including competition. These interactions among individuals change in intensity and even in direction over space and time, ranging from obligate facilitation to exclusion.

The descriptive study of the response to stress, disturbance, and interaction with other organisms enables the ordering of plant species into functional groups, which allows a theoretical reduction of the diversity of species to a more limited number of functions and structures. On this basis, ecophysiological studies attempt to connect biological diversity with ecosystem functioning. Their conclusions are relevant for modeling the dynamics of plant communities in the context of ecological succession, and also for predicting ecosystem drifts triggered by disturbances.^[8]

GLOBAL IMPACT

Ecophysiology has a key role in the understanding of the potential effects of global change and contributes new insights to restoration ecology. The value of ecophysiology in this context derives from its potential to characterize homeostatic adjustments at different scales. On a temporal scale shorter than an individual lifetime, homeostasis is limited to the flexibility of plant response to stress, disturbance, or biotic interactions. Homeostasis at

the individual level can involve reversible adjustments to rapid environmental fluctuations (environmental tracking), the ability of a single genotype to express different phenotypes in response to different environments (phenotypic plasticity), or the ability to adjust the performance of established modules in response to environmental changes (acclimation).^[6] On a temporal scale longer than the lifespan of a single generation, homeostasis involves adaptation, which is a process of genetic change whereby the average state or the range of variation of a feature becomes prevalent because of its selective value.^[9] At this level, ecophysiology is concerned with the analysis of the physiological basis of population divergence and ecotypic differentiation.^[2]

However, conceptual difficulties arise from the contrasted magnitudes of the spatiotemporal scales that are relevant in the plant ecophysiological approach. The complexity of the scaling up lies not only in the increasing number of units, components, or modules involved, but mainly in the intrinsic control mechanisms that arise at each level. These regulatory mechanisms do not emerge from the assembling of individual components but from the interactions among them. Neglecting this principle constitutes one of the most common sources of error in ecophysiology. An example is to assume an invariable adaptive value of physiological processes from the organ level to the interpretation of plant communities and ecosystems. This assumption emanates from erroneous faith in the power of natural selection as an optimizing agent, without considering the phylogenetic, developmental, and architectural constraints that derived from scaling up to the organism level.^[10] When these constraints are acknowledged but dismissed as unimportant or inscrutable, it is often erroneously accepted that every single trait necessarily reports a benefit just limited by the costs imposed by its integration into complex organisms, communities, or ecosystems. This notion of suboptimality is what Gould and Lewontin have termed the Panglossian Paradigm.^[10] Physiological factors are not enough to explain how the potential pool of plant species comes down to those that actually form part of a community in a particular site at a given instant of time. Historical filters have to be necessarily considered if the output of ecophysiology is to account in physiological terms for the ways plants can live where they do (Table 1).^[5]

CONCLUSION

Future directions in ecophysiological research will address current gaps in knowledge. Some areas have been neglected due to the fact that scientific progress in this field has been severely limited by methodological constraints. The first area that deserves attention is the

Table 1 Taxon- and site-specific constraints that limit the significance of physiological processes to explain plant community composition and ecosystem dynamics

Taxon-specific constraints	Site-specific constraints
<p style="text-align: center;"><i>Sensibility to initial conditions</i></p> Plant species can be older than the current suite of environmental conditions, and many of their traits have not been selected for their current functions.	<p style="text-align: center;"><i>Sensibility to initial conditions</i></p> The iterative nature of the ecological succession determines the dependence of the composition of every plant community on the local availability of plant species.
<p style="text-align: center;"><i>Interactive effects</i></p> Plant traits are genetically and physiologically linked. Selective pressures promote character suites or syndromes.	<p style="text-align: center;"><i>Interactive effects</i></p> Interaction with other organisms contributes to determine the distribution of plant species. This ecological sorting should not be equated with selection.
<p style="text-align: center;"><i>Long-term restrictions</i></p> Evolution of individual species is limited by phylogenetic constraints.	<p style="text-align: center;"><i>Long-term restrictions</i></p> Current composition, structure, and function of plant communities are affected by disturbance regimes and irreversible transitions, such as climate changes.

characterization of below-ground plant performance. Secondly, most of the ecophysiological research has been undertaken with seedlings, saplings, or short-lived plant species, and over limited periods of time. A major challenge is to assess the relevance of short- to medium-term events in long-lived woody plants. Exciting new insights are also expected from the characterization of tritrophic plant-insect-herbivore-natural enemy systems, with clear implications for the biological control of pests, as well as from the study of plant response to likely changes, that is plant sensing and reaction to environmental cues in a feed-forward manner. Finally, the ultimate goal of ecophysiology, still far from achieved, is to provide regional-scale predictions accurate and reliable enough to be useful for managers and policy makers.

Emerging Fungal and Oomycete Plant Pathogens

John H. Andrews

Plant Pathology Department, University of Wisconsin,
Madison, Wisconsin, U.S.A.

Abstract

Within the constraints provided, this entry reviews very briefly the current status of Asian soybean rust and 'sudden oak death'. Emphasis in both cases is placed on their emergence in the USA. Both situations are used to illustrate some major principles of the ecology of infectious disease.

INTRODUCTION

The spectrum of major infectious diseases of plants, animals, and humans is a changing one. The causes for the changes are complex. Each case of an emerging or retreating disease is unique, but all are related broadly to alterations in the causal organism, the host population, or the environment. In recent years, the public has become aware of numerous emerging or resurging medical threats such as AIDS, SARS, tuberculosis, monkeypox, and West Nile fever. Here we examine two emerging plant diseases—Asian soybean rust (ASR) and “sudden oak death” (SOD). We conclude with brief comments on the ecology of infectious disease as illustrated by these examples.

ASR

ASR, caused by the fungus *Phakopsora pachyrhizi*, was first documented in Japan in 1902.^[1] Shortly thereafter it was reported in several other countries in Asia and Australasia, where the pathogen is considered to be endemic, followed by India in 1951; Hawaii and the African continent in the mid-1990s; and South America, most notably Brazil, in the early 2000s. In November 2004, soybean rust was found in continental U.S.A. in Louisiana and subsequently in several Gulf coast states. Airborne propagules (urediniospores) of the pathogen likely were introduced to North America by winds moving northwards from South America during the active hurricane season of 2004.^[2] Analogously, the northerly movement of regional air masses during each growing season will move the pathogen annually upwards from the southern states into the major central US soybean producing area.^[2,3]

The severity of ASR in North America will depend on several factors^[2,3] such as: 1) the extent to which inoculum can overwinter and increase on various hosts in early spring months in the Gulf Coast States (the fungus cannot overwinter where temperatures persist below freezing. Unlike most rusts, ASR has a very

broad host range, including some 95 wild and cultivated plant species, mostly legumes); 2) the prevailing summer weather patterns in the central north–south corridor of the U.S.A.; and 3) the summer climate, especially temperature and moisture, in the central states, which will determine where conditions are favorable for disease development. US commercial varieties lack appreciable resistance to ASR. Breeding programs are intensifying, but for the immediate future, the main means of control will be fungicides. Based on its impact elsewhere, ASR is projected to have a significant effect on soybean production and management costs in the U.S.A.^[1,3] An economic model^[3] projects possible net economic losses from \$640 million to \$1.3 billion in the first year following introduction and annual losses thereafter of between \$240 million to \$2.0 billion.

SOD

During the mid-1990s, tanoak (*Lithocarpus densiflorus*), coast live oak (*Quercus agrifolia*), California black oak (*Q. kellogii*), and Shreve's oak (*Q. parvula* var. *shrevei*) in coastal California were discovered to be dying from an unexplained cause. Since then, the extent of mortality has increased to include tens of thousands of trees in several oak species principally in a 350 km region north and south of San Francisco Bay, though the distribution extends discontinuously more than twice this distance from Big Sur (Monterey County) in the south to Curry County, Oregon.^[4,5] In the early 2000s, the pathogen was described as *Phytophthora ramorum*, an aggressive, apparently exotic oomycete associated with many hosts including ornamentals (below). This turned out to be the same agent that had recently been reported from rhododendron and viburnum in Europe.^[5–8]

Invasion of oak and tanoak occurs typically on the lower trunk, inducing a bleeding canker that kills the tree.^[6] Infection of tanoaks (but not of true oaks) may also involve small branches, stems, or leaves, on which the pathogen subsequently sporulates.^[5,6]

Remarkably, *P. ramorum* also affects to a greater or lesser extent the above ground portions, in particular the foliage, shoots, and twigs in many instances, of almost all other woody plants associated with oaks (to date some 40 genera in 12 families of trees, shrubs, and ornamentals) in forests and nurseries in North America and Europe. Disease involving these foliar hosts is known as “ramorum leaf blight” or “ramorum shoot dieback.” Among the nonoak hosts more-or-less affected in California are canopy trees of immense commercial and ecological importance such as coast redwood (saplings and basal sprouts) and Douglas fir (sapling branch tips), as well as dominant understory vegetation including madrone, bay laurel, manzanita, and rhododendron.^[6,7,9] It is noteworthy that there are other recently discovered aerial *Phytophthoras* causing disease symptoms similar to *P. ramorum* on oaks, other canopy trees, and on understory vegetation. These include *Phytophthora nemorosa* and *P. pseudosyringae* in the Pacific Northwest and *P. kernovii* sp. nov. (formerly *Phytophthora* taxon C) in the U.K.^[7-9]

The epidemiological significance of the large host range is that susceptibility of the nonoaks, rather than the oaks themselves, appears to drive the epidemic. Extremely high inoculum potential (sporangia, zoospores, and chlamydospores) is associated with the foliage of some of these reservoir hosts, especially bay laurel. Inoculum is produced in the wet, temperate winter seasons characteristic of Mediterranean climates. The propagules then move by wind and rain to overwhelm the oaks, which are themselves an epidemiological dead-end as, unlike the case for tanoaks, sporulation apparently does not occur on these trees.^[6,7,10] The wide host range also means that commercial shipment of ornamentals can spread the pathogen. *P. ramorum* is found in soil and streams, which are potential avenues for long-range dissemination, though the significance of these inoculum reservoirs is still unknown.^[7,10]

The geographic origin of *P. ramorum* is unknown.^[5,8,9] The oomycete is heterothallic with sexual crossing possible (but generating a high proportion of aborted oospores) between the A1 and A2 mating types, the former of which is found almost exclusively in Europe and the latter in North America. Genetical and circumstantial evidence to date suggests independent introductions to both continents from an unknown source in approximately the same time frame, possibly from contaminated ornamentals.^[7,8] Genetic inspection of isolates thus far, including amplified fragment length polymorphism (AFLP) and microsatellite analysis, indicates that *P. ramorum* is a monophyletic group with two distinct lineages.^[7,9] The European isolates represent unique but closely related AFLP types, evidently having arisen by mutation or mitotic recombination, clustering into a few subclades. A single clone

dominates the North American lineage. In a few cases, A1 and A2 isolates have been obtained from the same nurseries in Oregon, Washington, and British Columbia; recently, phenotypically unique isolates with intermediate genotypic characteristics of both types were obtained from symptomatic ornamentals from nurseries in Washington and California.^[11,12]

As is the case for ASR, there is great concern for further spread of SOD beyond the Pacific coastal range, as well as in Europe. In North America, susceptible vegetation is widely distributed both within California outside the existing range of the disease and extending north into Canada.^[4,7] A key question is whether SOD will devastate the major stands of oak in eastern North America. Spread of the epidemic will depend on prevalence of foliar hosts and conducive local environmental conditions, in particular, temperatures permissive of overwintering and moisture conditions favoring sporulation. Knowledge of the biology of the pathogen and epidemiology of SOD is still rudimentary. Specific controls, other than quarantines designed to mitigate spread, are to date largely experimental. Some success has been achieved at the individual tree level with phosphite fungicides injected into or applied onto the trunks of trees and, in localized areas where the pathogen has recently invaded, by eradication. This involves cutting and burning infected trees together with surrounding susceptible understory vegetation and chemical treatments to prevent resprouting.^[7]

CONCLUSIONS

The two diseases and their respective pathogens illustrate important and rather different principles in the ecology of infectious diseases. ASR is essentially a demonstration on a global scale of the march of a pathogen across continents. This is largely because of highly effective dispersal of infective units by airborne means into new habitats where the invader becomes established if local conditions (in this case primarily available hosts and climate) are favorable.

SOD illustrates the explosive potential of a novel pathogen and the complicated epidemiological pattern that ensues when components of agroecosystems (in this case ornamentals and the nursery trade) interact with those of natural and urban ecosystems (wild and managed parks and woodlands, and residential areas). The pathogen may be an exotic invader from a distant land where it lives a benign existence with an as yet unrecognized host. Alternatively, although less likely, it may have arisen indigenously by mutation or recombination (the genome sequence discounts a hypothesis of interspecific hybridization^[9]). Regardless, the natural history of *P. ramorum* illustrates that ecological niches, including for pathogens the dimensions of host and

geographic range, as well as virulence, are a plastic property subject to significant expansion or contraction.^[13]

Endosperm Development

Philip W. Becraft

Iowa State University, Ames, Iowa, U.S.A.

INTRODUCTION

The endosperm is the “other” product of double fertilization; one pollen sperm fertilizes the egg to produce a zygote, while the other sperm fertilizes the central cell to produce the triploid primary endosperm cell. Endosperm development is often overlooked because it represents a dead-end, often transitory, tissue. However, endosperm development is proving to be unexpectedly interesting, entailing many novel and highly specialized processes. The list includes novel cytoskeletal behavior, cytokinesis, cell wall formation, and cell cycle regulation. Questions of cell fate acquisition and signaling, programmed cell death, and morphogenesis also apply. Given the importance of cereal grains to human and livestock nutrition and industrial uses, understanding the fundamental processes of endosperm development has great potential for application to grain improvement.

TYPES OF ENDOSPERM DEVELOPMENT

There are three types of endosperm development: cellular, nuclear, and helobial. In cellular development, mitosis is accompanied by cytokinesis from the outset. In contrast, nuclear development undergoes a period of free nuclear division leading to a multinucleate syncytium; cytokinesis and cellularization ensue later. In helobial development, the first division includes cytokinesis. Subsequently, one of the daughter cells continues the cellular pattern of development, with mitosis accompanied by cytokinesis, while the other daughter undergoes a period of free nuclear division. This review will focus on nuclear development, which is the most common among crops and other well-studied plant systems.

The endosperm can also be either transitory or persistent. The most obvious example of a persistent endosperm is in cereal grains where the endosperm is the major seed storage tissue and composes the bulk of the seed. In other plants, the cotyledons assume the primary storage function, and most of the endosperm degenerates during seed development. Still other plants are intermediate with both endosperm and cotyledons participating in food storage.

EPIGENETIC REGULATION OF ENDOSPERM DEVELOPMENT

Endosperm development is normally triggered by fertilization. The inhibition of endosperm development prior to fertilization appears to require chromatin-level gene regulation because mutations in polycomb group genes, including *MEDEA*, *FIE*, and *FIS2*, allow fertilization-independent seed and endosperm development. These genes are imprinted such that only the maternal copy is transcribed in the fertilized seed.^[1] In addition, the normal balance of maternal to paternal chromosomes is important to endosperm development because, in unbalanced situations, several cell types including basal transfer cells and aleurone cells fail to differentiate properly and seeds usually abort.

SYNCYTIAL DEVELOPMENT AND CELLULARIZATION

The early syncytial divisions appear ordered because Barbara McClintock showed that clonal sectors form reproducible patterns, dividing the endosperm in halves, quarters, and so forth. Phragmoplasts form between daughter nuclei, but a cell wall is not deposited, indicating that cytokinesis is blocked by inhibiting phragmoplast function rather than formation. As free nuclear divisions progress, the central vacuole enlarges, restricting the nuclei to the periphery of the coenocyte. Radial arrays of microtubules surrounding each nucleus divide the cytoplasm into nucleo-cytoplasmic domains and create a regular spacing pattern (Fig. 1).

At the onset of cellularization, a novel form of cytokinesis occurs whereby cell plates form between non-daughter nuclei in the absence of mitosis. Phragmoplasts develop where the radial microtubule arrays from neighboring nuclei meet, and cell plates are deposited perpendicular to the outer endosperm cell wall. The cell plates coalesce to form tubular cell walls, or alveoli, around each nucleus. The microtubular arrays extend centripetally as the alveolar walls continue to grow inward. The nuclei then undergo periclinal mitotic divisions, each contributing a daughter nucleus toward the interior. This division is

Fig. 1 Cellularization. (A, B) Endosperm nuclei undergo mitotic divisions without cytokinesis. (C) Radial microtubule arrays divide the endosperm into nucleocytoplasmic domains. (D) Cell walls form between the nuclei, creating alveoli. (E) Alveolar nuclei undergo a periclinal division accompanied by cytokinesis. The result is a cellular peripheral layer and an alveolar interior layer. (View this art in color at www.dekker.com.)

accompanied by cytokinesis, yielding a cellular peripheral layer and an alveolar interior layer (Fig. 1). This process reiterates in the internal layer until the interior is completely filled and cellular.

Subsequent development varies, depending on whether the endosperm is persistent. In *Arabidopsis*, most of the endosperm degenerates as it is displaced by the growing embryo. In cereals, extensive cell division occurs after cellularization. Divisions initially occur throughout the endosperm but then become localized to the periphery as internal cells accumulate storage products and undergo maturation. Thus, there is a general maturation gradient with the most mature cells at the interior and the young, actively dividing cells at the periphery.

CELL FATE SPECIFICATION

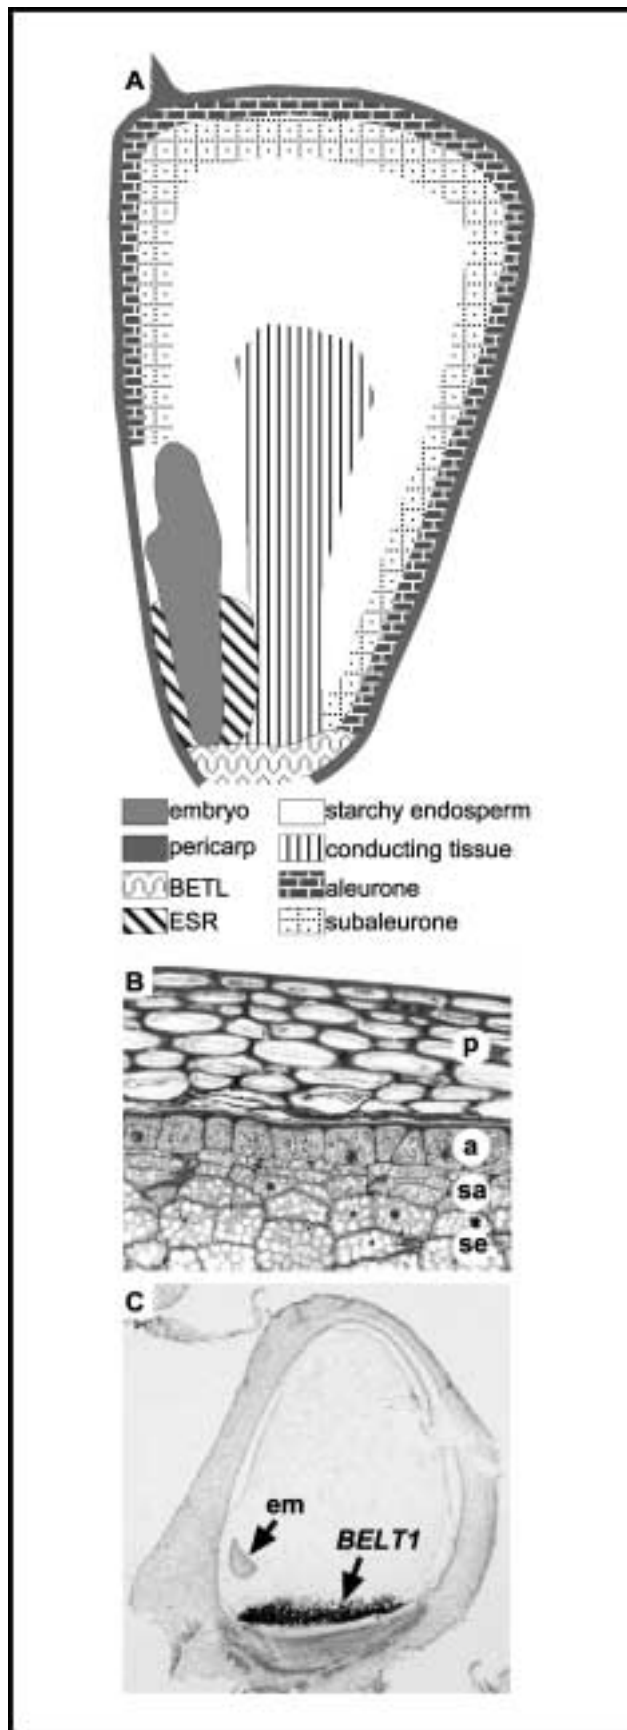

The highly specialized endosperm of cereal grains contains three major cell types (Fig. 2). At the base of the endosperm, near the attachment site to the maternal plant, is the basal endosperm transfer layer. These cells are specialized for the uptake of solutes and nutrients from the plant, for the developing grain. The aleurone is the outermost layer of cells surrounding the periphery of the endosperm. While performing some storage functions, the major function is to secrete digestive enzymes that break down storage products in the endosperm for the germinating seedling. The majority of the endosperm consists of starchy endosperm cells, the primary site of starch and storage protein deposition. The starchy endosperm can be

subdivided into several cell types with specialized morphological characteristics or gene expression patterns. The subaleurone is the meristematic region at the periphery of the endosperm, just internal to the aleurone layer. A specialized region called the “embryo surrounding region” expresses several genes of unknown function called *ESRs*.

The molecular mechanisms that specify the identities of the various cell types found in the endosperm are not yet understood.^[2,3] Positional information is present at very early stages because in barley, maize, and *Arabidopsis* various transcripts or reporters are localized to specific regions of the syncytial endosperm. *ZmMRP1* transcript is localized to the basal region of the precellular maize endosperm and codes for a transcription factor that drives expression of *BETL* genes in the basal transfer layer.^[4] *ESR* transcripts are also expressed in a localized region of the early cellular maize endosperm, about four days after pollination (Fig. 2).

Not all cell fate decisions are restricted to early stages. Aleurone cell fate remains plastic throughout endosperm development. Positional cues are required to specify and maintain aleurone identity up through late cell divisions. Disruption of the ability to perceive or respond to these cues causes aleurone cells to switch identity to starchy endosperm. Restoration of endosperm cells' ability to perceive the positional cue late in development allows the acquisition of aleurone fate.

Two genes involved in the aleurone cell fate process are known in maize. Mutations in either gene result in partial or complete loss of the aleurone layer. The *crinkly4*

gene encodes a receptor kinase that is hypothesized to function in the perception of the cue that specifies aleurone cell identity. The *dek1* gene encodes a novel membrane-localized calpain protease.^[5] Genetic evidence suggests that the *crinkly4* and *dek1* gene products function in related processes, but whether the gene products function in the same signal transduction pathway is not yet clear.^[6]

STORAGE PRODUCT ACCUMULATION

As cells of a cereal endosperm mature, they begin to accumulate storage products. The major storage products are starch and protein. Starch accumulates in highly ordered grains located in amyloplasts.^[7] The mechanisms of starch synthesis and deposition are surprisingly complex. Starch grains contain two types of starch molecules, unbranched amylose and branched amylopectin. Packing of starch molecules into crystalline grains involves the coordinated activities of starch synthases, starch branching enzymes, and starch debranching enzymes, but how the cooperative activity of these enzymes leads to the observed starch structure is poorly understood.

Maturing cells also accumulate storage proteins in protein bodies.^[8] Storage proteins greatly impact the nutritional value of grains, as well as their flour and baking characteristics. Globulins are storage proteins found in all seeds and are soluble in saline buffers. Prolamines are specific to cereals and are only soluble in denaturing solvents due to their hydrophobicity. Several types of protein bodies are found in endosperm, some derived directly from endoplasmic reticulum and others vacuolar. Each contains mixtures of storage proteins whose assembly into protein bodies is accomplished through interactions among the constituent proteins. Storage protein genes show differential expression in various cell types and in different regions of the starchy endosperm, contributing to the different properties observed in various regions of grains.

As cells accumulate storage products, their volume enlarges greatly. Concomitantly, cells undergo chromosomal endoreduplication. This genomic amplification

(View this art in color at www.dekker.com.)

might be required to support the large size and high metabolic activity of endosperm cells. Endoreduplication is accomplished by incompletely understood modifications to the cell cycle, leading to an inhibition of M-phase.

MATURATION

In a mature cereal grain, all the endosperm cells die except the aleurone. As starchy endosperm cells complete storage product accumulation, they undergo programmed cell death. This occurs progressively from the interior out toward the periphery, following the general pattern of cell division and storage product accumulation. Programmed cell death is stimulated by the hormone ethylene.

The aleurone survives to serve as a digestive tissue during germination, secreting amylase to hydrolyze the starch stores and make glucose available to the growing seedling. Mature seeds dehydrate to levels that would be lethal to normal plant cells. Maturation includes a specialized genetic and physiological program that confers desiccation tolerance to the aleurone and embryo. A set of proteins called dehydrins accumulate and are thought to act as protectants, stabilizing membranes and maintaining protein structures. Maturation is promoted by the hormone abscisic acid (ABA) while gibberellic acid (GA) inhibits maturation and promotes the germination process.^[9] The VIVIPAROUS1 transcription factor is central to the maturation process; *vp1* mutants are ABA insensitive, fail to undergo maturation and desiccation tolerance, and directly enter germination.

CONCLUSION

The deceptively simple endosperm is proving to be as complex and interesting as it is important. Recent technical advances, the availability of genome sequences of *Arabidopsis* and rice, and the coordinated efforts of multiple groups coming to bear on questions of endosperm development are sure to produce exciting progress in the near future.

Environmental Concerns and Agricultural Policy

Floor Brouwer

Agricultural Economics Research Institute, Wageningen UR, The Hague, The Netherlands

INTRODUCTION

Europe and North America are key producers of food in the world market and major users of crop protection products. For a number of commodities (e.g., cereals, oilcrops, potatoes, and citrus fruit) they have a considerable share of global food production. Western Europe and North America also account for more than half of the world market of agrochemicals. The E.U., U.S.A., Japan, and Brazil account for about three-quarters of the global market of agrochemicals. When treated properly, the use of crop protection products extends the lifetime of food products in the agrifood chain. Also, food can be supplied in a more uniform manner and have a better appearance. However, residues of these products may harm the natural environment by contamination of groundwater resources, surface waters, and soils, as well as spray drift affecting air quality and biodiversity. A major challenge to agriculture is to internalize these social costs of production properly in farm management practices. Environmental policy measures are taken across the globe to control such external effects of production on the natural environment.

Agricultural policy is a main area of public intervention in the agricultural sector, and the use of crop protection products is therefore also affected by such policy measures. Market and price support measures have encouraged the use of crop protection products. More recently, however, efforts have been made to internalize environmentally harmful effects of crop protection products into farming practices, and reforms of agricultural policies could stimulate farmers to change their practice.

Agricultural and environmental policy measures could both support the effort to reduce pressure on the natural environment, and their interactions with the use of crop protection products are of major societal interest. This is the subject of the current contribution.

PATTERNS OF USING CROP PROTECTION PRODUCTS

During the 1990s, producers of crop protection products were faced with stagnant or even declining markets (at

least in the developed countries) and with more stringent environmental constraints applied to agriculture.^[1] Total use of crop protection products in the E.U. amounted to some 325 million kg of active ingredients during the early 1990s, which dropped to slightly below 300 million kg in 1996 (Table 1). The declining trends during the first half of the 1990s seems to have reversed in the years thereafter with patterns of use rising again. Some divergent trends are observed across Member States. The European Commission has developed a strategy with the objective of reducing the impact of crop protection products on human health and the environment and, more generally, more sustainable use of such agrochemicals.^[2]

In addition to reforms of agricultural policy (price reduction of cereals, with set-aside requirements and the introduction of direct payments), several factors have also contributed to the downward trend in the E.U.:

- Product innovations that have allowed for the provision of new compounds requiring lower dosages. Several active ingredients have been authorized for agricultural use and entered the market during the 1990s. Such chemical substitution allows for a smaller dosage to suffice for treating plants compared to what was used in the past. This type of innovation has been observed on broader scales, and many developed countries faced a diminishing (e.g., Japan) or slow growing (e.g., U.S.A.) market.
- Improved technologies to target application better. The application of the MLHD-approach (Minimum Lethal Herbicide Dosage), for example, allowed for a considerable reduction in the use of herbicides. Mechanical weed-control methods also replaced agrochemicals. Also, aerial spraying is one of the most restricted practices in developed agriculture that contributed to the improved application.^[3]
- Improved farm management practices, including the use of Integrated Crop Management (ICM) practices and Integrated Pest Management (IPM) practices. Environmentally related agricultural programs have been initiated in several countries (e.g., Canada, U.S.A.) to reduce usage of crop protection products through research, education, technology transfer, and the encouragement of more widespread use of IPM and ICM.

Table 1 Sales of crop protection products by member state (in tons of active ingredients)

Country	1991	1996	1999	(kg per ha)
Belgium	9,969	10,403	9,202	6.6

E.U.-15	325,653	299,826	326,870	2.6

(From Eurostat, New Cronos (2002).)

- National mandatory reduction schemes, including specific measures developed in the context of environmental policy, have also contributed to the reduction of usage of agrochemicals.
- Market incentives also stimulate environmental awareness of agricultural producers. Such efforts might respond to government regulation and to consumer preferences of environmentally friendly products.

ENVIRONMENTAL CONCERNS: RISKS AND HAZARDS

Environmental concerns on the agricultural use of crop protection products tend to cause concern in a large number of countries. They may cause contamination of groundwater resources and surface water by leaching, run-off, and spray drift. Aerial spraying of crop protection products and the contamination of surface water is an issue in several countries, as are potential threats to non-target species and to human health (especially from residues in drinking water). In addition, human health concerns are due to residues in food. A comparison of environmental standards among main traders in the world market indicate that crop protection products are a main issue, being a high priority in policy in the E.U. and U.S.A.^[4]

Monitoring in the E.U. indicates that water quality standards could be exceeded in between 5 and 25% of the samples taken in regions with intensive arable production

and horticulture. Standards for pesticides in drinking water are part of the Drinking Water Directive 80/778/EEC, and a limit of 0.1 µg per litre applies to individual pesticides and 0.5 µg per litre for the sum of all pesticides. Such limits are not based on toxicological criteria, but in fact are a surrogate for zero detection. Human health concerns in the U.S.A. mainly relate to residues in food. Harmful effects on water quality related to the use of crop protection products are a main issue in this country. The issue is identified as a problem and of significant concern in Australia, where air quality problems associated with pesticide drift are an important problem and large-scale aerial spraying is common. In contrast, it is not considered a problem for farming in New Zealand.

AGRI-ENVIRONMENTAL POLICY AND THE USE OF CROP PROTECTION PRODUCTS

Farmers do respond to changes in income and commodity prices, and agricultural policy is also an important area for consideration with the use of crop protection products. Market interventions and subsidies have been key instruments in agricultural policy for most of the developed countries. Major instruments applied are market-price support conferred through border measures (e.g., tariffs, export subsidies, quantitative and qualitative restrictions) and administrative pricing regimes, other production-linked supports such as deficiency payments, and subsidies for intermediate inputs.

It is widely agreed that market interventions and price-support measures have encouraged greater agrochemical use than would otherwise be the case. There is limited evidence of environmentally beneficial effects of reducing price support measures on agrochemical use, because the price elasticity of demand for agrochemicals tends to be low in the short run.

Falconer and Oskam^[5] suggest that the combined effects of a reduction in the intervention prices of cereals and the introduction of set-aside requirements in the E.U. reduced the use of pesticides for growing cereals by less than 10% and the use of pesticides overall by 3%. The effects of the agricultural reform measures from the late 1990s on pesticide use are estimated to be very modest. One reason for the limited reduction of pesticide use under this reform is that price decreases and set-aside schemes work in opposite directions. Pesticide use has also been reduced through acreage restrictions in the U.S.A. There, the Conservation Reserve Program (CRP) reduced crop acreage and, hence, pesticide use on land that might otherwise have remained in production. However, agricultural support programs can provide incentives to increase pesticide use on land that is not set aside.^[6]

Pesticide use in aggregate tends to be unresponsive to small price changes, though demand for individual products can be very responsive to even small price changes. Most empirical studies offer evidence on price elasticities regarding demand for pesticides of between -0.2 and -0.5 .^[7] The high price elasticity of herbicides (between -0.7 and -0.9) relates to the options available to control pests and diseases without treatment. Mechanical weed control, for example, can often substitute for herbicides. The price elasticity of demand for pesticides differs for specific crops. For cereals, for example, it could be as high as -1.1 .

Codes for Good Agricultural Practices (GAP) are developed in the context of agricultural policy to identify environmental constraints to direct payments provided to farmers. The adoption of such a code through ICM or IPM techniques might be a requirement for farmers to be eligible for full compensation to hectare payments. In such a case, farmers who were not fulfilling a condition to adopt such a Code would face withdrawal of part of their income compensation. A range of environmental constraints are currently put on farmers in the context of cross compliance.^[8] Retailers and food processors are demanding better and audited farming systems in response to the changed consumer demands. Therefore, agriculture will increasingly respond to and work with others in the agri-food chain. The adoption of ICM and IPM would qualify for such demands.

CONCLUSION

Contamination of soil, leaching of nutrients and pesticides, water extraction, and drainage pose a widespread threat to the environment. Nitrate and phosphate loading and the run-off of livestock wastes cause significant water pollution problems. Also, the excessive use of crop protection products poses a widespread threat to human health and the environment. High levels of crop protection products are associated mainly with areas of intensive arable crops and horticulture.

Societal debate that started in the late 1980s has given incentives to better control the harmful effects of plant protection products on health and the environment. Since then, the interest moved towards a more targeted and rationalized use of plant protection products. Mandatory requirements on their use increasingly tend to include farm management aspects (rather than measures to reduce total use), focus on specific measures (rather than general measures that apply to the whole agricultural sector), and link environmental quality with food safety aspects.

Epigenetic Variation and Phenotypic Diversity

E. Jean Finnegan

Estelle Jaligot

Commonwealth Scientific and Industrial Research Organisation, Plant Industry,
Canberra, Australian Capital Territory, Australia

INTRODUCTION

Epigenetic variation is a phenomenon that cannot be readily explained by classical Mendelian genetics; examples include the spontaneous occurrence of paramutation and the cycling of maize transposable elements (TEs) between active and inactive states.^[1,2] The advent of biotechnology has renewed interest in epigenetic variation. Novel phenotypic traits, conferred by the introduction of foreign DNA into a plant, are not always transmitted to the progeny even though the transgene itself segregates as predicted by classical genetics. Loss of the novel phenotype arises through inactivation of the transgene by a process known as epigenetic silencing; this potentially limits the commercial utility of transgenic plants. Transgene silencing reflects a natural defense mechanism, protecting plant genomes against the adverse effects of invading or mobile DNA.^[3] Epigenetic phenomena occur in many organisms from different kingdoms, suggesting that this is a fundamental mechanism for regulating gene expression. In this entry, we focus on the events that give rise to epigenetic variation and the phenotypic diversity that ensues.

EPIGENETIC REGULATION OF TRANSCRIPTION

Epialleles of a gene are identical in sequence but differ in activity. This is caused by heritable, but potentially reversible, differences in the accessibility of their DNA for transcription. Epigenetic regulation is mediated by at least two interdependent processes: methylation of DNA and modification of its surrounding chromatin (Fig. 1). Changes in chromatin compaction occur by repositioning of nucleosomes, recruiting other proteins, or by altering DNA topology. In particular, modification of the amino-terminal tails of the nucleosomal histone proteins, particularly histones H3 and H4, modulates gene expression by recruiting other proteins to chromatin.^[4] Many transcription factors are, or are associated with, histone-modifying proteins suggesting that chromatin structure regulates most, if not all, genes. Thus, the boundary between what we accept as normal changes in gene expression and those

associated with epigenetic phenomena, such as paramutation or transgene silencing, has become blurred.

The totipotency of plant cells suggests a high degree of plasticity in chromatin organization allowing reactivation of silenced genes. Furthermore, plant development is strongly influenced by environmental signals and by biotic or abiotic stresses. The crosstalk between developmental programs and signaling pathways must be coordinated at the level of chromatin organization, perhaps by epigenetic mechanisms. The random formation of epialleles in response to environmental or genomic stresses might then provide novel phenotypes on which selection can act.

CONTROLLING ELEMENT-INDUCED PHENOTYPIC VARIATION

Barbara McClintock proposed a role for transposable, or as she called them, controlling elements in regulating gene expression.^[5] Proof of concept came with the characterization of suppressible mutations in yeast, *Drosophila*, maize, and mammals.^[6]

The frequency of epiallele formation due to TE sequences is unknown but, given that many TE-derived sequences are located in intergenic regions or introns,^[7] these examples are likely to be the tip of the iceberg. The cycling of TEs between active and inactive states allows for the formation of epialleles whose differential expression may be advantageous to the organism under different environmental conditions.

POLYPLOIDIZATION INDUCES PHENOTYPIC DIVERSITY

Polyploidy is widespread in both vertebrates and plants (see entry on "Polyploidy"). One scholar estimates that between 50% and 70% of flowering plants have undergone one or more episodes of chromosome doubling during their evolution. The frequency of polyploidy together with the emergence of novel phenotypes in these populations suggests that polyploids have some selective advantages over their diploid progenitors. This phenotypic diversity could

Fig. 1 DNA methylation and histone modification are intimately linked. Circle 1 indicates the interdependence of DNA methylation and histone modification. DNA methylation alters histone acetylation through the recruitment of methylbinding proteins that interact, through the corepressor Sin3, with histone deacetylases. In addition, DNA methyltransferases interact directly with histone deacetylase and histone methyltransferase enzymes. DNA methylation is important for the maintenance of histone H3 lysine 9 methylation at the centromeric repeats and rRNA genes of *Arabidopsis*. Histone H3 methylation at lysine 9 is essential for DNA methylation in *Neurospora crassa* and for C_pN_pG methylation in *Arabidopsis*. Circles 2 and 3 indicate the role of small interfering RNAs (siRNAs) in direction DNA methylation and/or histone modification. Loss of these modifications can lead to loss of siRNA accumulation, suggesting that these circles may be closed as indicated by the dashed lines. The involvement of double-stranded (dsRNA) in these pathways is inferred by the requirement for an RNA dependent RNA polymerase in the maintenance of centromeric heterochromatin in yeast. Not all pathways are present in all organisms, and different pathways may affect histone modification/DNA methylation at different loci.

allow polyploids to enter new niches or to increase their suitability for use in agriculture. Various mechanisms have been proposed to account for this phenotypic variability including changes in gene expression by both genetic and epigenetic mechanisms.^[8]

The genetic instability of newly polyploid genomes must be overcome to enhance the reproductive success of polyploids with reduced fertility or those that are infertile. It is thought that polyploid genomes are stabilized by reducing the expressed gene set so that it is equivalent to that of a diploid plant, a process termed genetic diploidization. In both newly established and ancient polyploids of the Triticae, diploidization frequently involves sequence elimination and changes in DNA methylation that may lead to gene silencing.

Epigenetic silencing has been demonstrated in the newly synthesized tetraploid progeny of a cross between *A. thaliana* and *Cardaminopsis arenosa*, the likely progenitors of the naturally occurring polyploid *A. suecica*.^[9] The newly formed polyploids show considerable phenotypic instability that is associated with nonrandom changes in DNA methylation on each parental genome and by both gene silencing and gene activation. Gene silencing, giving rise to uniparental expression of homoeologous genes, is also observed in the naturally occurring *A. suecica* polyploid.^[10] In the established polyploid, about 11% of genes

showed uniparental expression compared with an estimated 0.4% of genes in the newly synthesized counterpart.^[9,10] In contrast to protein-encoding genes where silencing of one parental genome apparently occurs at random, all the ribosomal RNA genes derived from *A. thaliana* are silenced in the *A. suecica* polyploid, a phenomenon known as nucleolar dominance.^[11] Changes in DNA methylation patterns are also observed in newly formed marsupial hybrids, suggesting that combining two genomes, either plant or animal, can result in considerable disruption of normal patterns of DNA methylation.

EPIALLELES ARE FORMED IN RESPONSE TO STRESS

Phenotypic changes frequently arise when plants are exposed to a variety of environmental stresses.^[12] In the case of plants regenerated from tissue culture, cytological anomalies such as chromosomal rearrangements and altered ploidy account for some of the phenotypic changes, but there is increasing evidence implicating epigenetic changes in gene expression. Only some of the many examples of phenotypic changes in tissue-culture derived plants have been clearly associated with novel patterns of DNA

Fig. 2 The mantled flower phenotype in oil palm (*Elaeis guineensis* Jacq.). N represents the normal oil palm fruit, MW is the fruit of a weakly affected flower and MS is the fruit of a severely mantled flower. Cross sections of the fruit are shown.

methylation.^[12] Reactivation of TEs in tissue-culture derived plants is associated with demethylation of the elements, whereas loss of phlobaphene pigment in the cobs of regenerated maize plants is associated with hypermethylation of the complex *P* locus.^[12]

A novel phenotype that has the hallmarks of an epigenetic variant emerged during large-scale field trials of somatic embryo-derived oil palm (*Elaeis guineensis* Jacq.). The “mantled flower” somaclonal variant affects the formation of floral organs in both male and female flowers (Fig. 2), such that stamens and staminoids, the male floral organs, are partially or completely transformed into pseudocarpetels. This organ conversion results in partial to complete flower sterility and generally leads to fruit abortion.^[13] This phenotype does not show classical Mendelian inheritance, and there is a high frequency of reversion over time. No major genetic defects were detected in abnormal tissues, but significant alterations of both the global methylation of the genome and methylation patterns of single sequences were found in various abnormal tissues.

GENOME REARRANGEMENTS ARE TRIGGERED BY BIOTIC STRESS

Seed coat pigmentation mutants in soybean and the nivea alleles in *Antirrhinum* arose in natural populations, suggesting that DNA rearrangement influences epiallele formation. DNA elimination is a frequent occurrence in newly formed polyploids of wheat; the mechanism(s) remains unknown, but may be associated with the activation of quiescent TEs. DNA rearrangements are also associated with TE deletion/insertion. Similarly, DNA rearrangements result from the increased recombination that occurs in plants infected with viral or fungal pathogens.^[14] Recent data suggest that pathogen-induced DNA rearrangement is

mediated by a systemic signal that functions not only in somatic but also in meiotic cells.^[14]

CONCLUSIONS

Although most epialleles are formed at random in response to environmental, biotic, or abiotic stresses, there are indications that some sequences are more susceptible to epigenetic variation than others. For example, the *SUPERMAN* locus in *Arabidopsis* is subject to hypermethylation following treatment with various mutagenic agents and in plants with reduced levels of DNA methylation. Similarly, the mantled flower phenotype occurs in oil palms regenerated under different culture regimes in several laboratories.^[13] The novel phenotypes arising from epigenetic changes in gene expression may confer a selective advantage to individuals within populations or to a species in specific environmental niches. A notable example is the epigenetic silencing of a floral repressor in response to cold temperatures (vernalization), which promotes flowering in spring, maximizing reproductive success.

Epiallele formation can occur rapidly and if mediated by RNA-directed changes in DNA methylation, chromatin structure or transcript stability will affect both alleles of a locus simultaneously, leading to rapid homozygosity even in outcrossing plants. The reversible nature of epigenetic variation has the advantage that the novel phenotypic trait can be modified should the adaptive advantage be lost under changing environmental conditions. It remains to be determined just how frequently epigenetic variation accounts for acclimation or adaptation to novel environments. This question will be the subject for future research utilizing the tools that are becoming available for genome-wide surveys of gene expression coupled with surveys of histone modifications and methylation patterns.

Evolution of Plant Genome Microstructure

Ian Bancroft

John Innes Centre, Norwich, U.K.

INTRODUCTION

The evolution of gene structure has been studied for many years by the comparison of the nucleotide sequences of related genes. At the other extreme of scale, the gross organization of the genomes of related plant species has been investigated using molecular genetic markers. Such investigations have shown how individual genes evolve by changes in nucleotide sequences and how whole genomes evolve by rearrangement. The recent availability of whole genome sequences and the application of high-throughput physical mapping strategies have enabled us to investigate the intermediate-scaled organization—or microstructure—of plant genomes. Understanding the evolutionary processes involved in shaping genome structure on the scale of gene-by-gene organization is particularly important for the use of comparative positional cloning of genes in crops based on sequence information from model species. Comparative analyses of plant genome microstructure—conducted between both closely and distantly related species, and between duplicated segments within a genome—have allowed us to advance our understanding of the mechanisms involved in genome evolution. Some of the milestone comparative analyses of plant genome microstructure, focusing on the arrangement of genes, will be reviewed here and the results interpreted in relation to mechanisms involved in genome evolution.

APPROACHES TO THE ANALYSIS OF GENOME MICROSTRUCTURE

The resource of preference for the analysis of genome microstructure is complete, high-quality genome sequence. For plants, this is presently available only for *Arabidopsis thaliana*.^[1] However, high-quality sequences of large insert genomic clones (usually as Bacterial Artificial Chromosomes, BACs) can also be very valuable for comparative analyses, particularly for comparison to the genome of *A. thaliana*.^[2,3] Although the sequencing of BACs is now routine, it is an expensive

approach. Where a partial or complete genome sequence is already available from one plant, hybridization-based physical mapping approaches using BAC libraries can be used to investigate the relative conservation of genes in the corresponding segments of other plant genomes.^[4]

The evolution of genome structure is usually studied by the comparative analysis of orthologous genome segments in species descended from a common ancestor. However, we can also study the divergence of related segments that arose by duplication events and are retained by an organism. The analysis of structural evolution following genome duplication is of particular importance, as polyploidy (the amplification of whole genomes) is very common in plants.^[5]

COMPARATIVE ANALYSIS OF RELATED GENOME SEGMENTS

The most distantly related plant species used for the comparative analysis of genome microstructure are *A. thaliana* and rice, the lineages of which diverged ca. 200 million years ago (MYA). The first region of the rice genome compared in detail consisted of 340 kilobase pair (kb) of DNA and contained 56 predicted genes.^[3] Twenty-two of the genes were found to have homologues in *A. thaliana* indicative of conservation of microstructure in five parallel segments, as shown in Fig. 1. Subsequent analyses confirmed the generality of conservation of genome microstructure in *A. thaliana* and rice, but only 17% of genes conserved were in identified homoeologous segments.^[6] The lineages of *A. thaliana* and tomato diverged more recently, ca. 150 MYA. Four parallel segments of the *A. thaliana* genome were found to have conserved microstructure with a sequenced genomic clone of tomato.^[2] These findings demonstrate that comparative analysis of genome segments in very distantly related plant species is feasible. Because both analyses identified conservation of microstructure in several segments of the *A. thaliana* genome, those segments themselves must be related, permitting

the comparative analysis of duplicated segments within a genome.

Extensive duplication of the *A. thaliana* genome has been identified by the analysis of the genome sequence. This has been interpreted as the result of a tetraploidy event.^[1] that, as estimated by the extent of sequence divergence of the conserved genes, happened ca. 65 MYA.^[7] The organization of the segments related by this event differ primarily by the interspersion of conserved genes by nonconserved genes, and by rearrangements and translocations.^[1] An example of the gene-by-gene comparison of two of the genome segments from Fig. 1 is shown in Fig. 2. This comparison illustrates another unexpected feature of the *A. thaliana* genome: Tandemly repeated genes are very common, accounting for 17% of all ca. 25,000 genes of *A. thaliana*.^[1]

A. thaliana is related to the cultivated *Brassica* crops, the lineages of which diverged ca. 19 MYA. Comparative analyses of the genomes of *A. thaliana* and *Brassica oleracea* using hybridization-based physical mapping approaches identified extensive conservation of genome microstructure. There was, however, an interspersed pattern of conserved and nonconserved genes and evidence for rearrangements.^[4] Differences in genome

Fig. 1 Comparison of the presence and relative stand orientation of genes conserved in a sequenced region of the genome of rice and five segments of the genome of *A. thaliana*. (From Ref. 3.)

Fig. 2 Comparison of the microstructures of related segments of the *A. thaliana* genome. Conserved genes were identified by BLAST alignment to the complete *A. thaliana* genome sequence, updating a previously reported analysis. (From Ref. 9.)

microstructure can also be identified, again by hybridization-based physical mapping approaches, between *Brassica* species (e.g., *B. oleracea* and *B. rapa*) and within species (e.g., *B. rapa* ssp. *trilocularis* and *B. rapa* ssp. *pekinensis*) (T. van den Boogaart, D. Rana, Y.-P. Lim and I. Bancroft, in preparation), despite times since divergence among the lineages of one million years or less. The genomes of the *Brassica* species appear to be derived from a triplication of an *A. thaliana*-like genome; this complexity is thought to be associated with the rapid rate of change of genome microstructure observed in *A. thaliana* and *Brassica* species.^[8] Differences in genome microstructure, including relocation of genes in the genome, have also been identified in different ecotypes of *A. thaliana*.^[1]

EVOLUTIONARY MECHANISMS

Related genome segments, with a wide range of times since divergence, can readily be identified in plants. Comparative analyses of the most closely related genomes indicate that the events most frequently affecting genome microstructure are sequence polymorphisms and small insertion/deletion events. Such events are likely to be the result of errors in DNA replication or repair. They also provide evidence for the transposition of gene-sized DNA segments, not recognizable as transposons, to new genomic locations.^[11] It is not known what kind of transposition mechanism might bring this about. It may not be via reverse transcription of mRNA and integration into the genome (such as can lead to pseudogenes), because small clusters of genes also appear to be replicatively transposed.^[9] The relatively frequent occurrence of transposition of single genes or small gene clusters will result in a background of genes in novel genomic locations, which could confuse comparative approaches to the identification of orthologous genes.

Tandem duplication of genes is very common within plant genome;^[11] once duplicated, such tandem genes can persist in the genome. For example, Fig. 2 shows tandemly duplicated and triplicated conserved genes in genome segments that are thought to have diverged from a common ancestor 65 MYA.^[7] Presumably the duplicated genes have assumed new and selectively advantageous functions. The interspersed pattern of conserved and nonconserved genes is a striking feature of duplicated plant genome segments and is also shown in Fig. 2. Both tandem duplications of genes and interspersed loss of genes are potential outcomes of unequal crossover, depending on whether recipient or donor chromosome is inherited, respectively. The data from comparisons of plant genome microstructure are consistent with the hypothesis that unequal crossover is a very important mechanism in the evolution of genome microstructure in plants.^[8] The loss of genes from chromosome segments by unequal crossover will have no effect on the fitness of a plant if those genes are duplicated elsewhere. Thus gene duplication and polyploidy produce a genome buffered against detrimental effects of this kind of evolutionary mechanism.

Although important, unequal crossover is far from the only mechanism involved in the evolution of plant genome microstructure. Gross-scale genome rearrangement is a notable feature and appears prevalent in species with polyploid ancestry such as the *Brassica* species.^[10] Over long periods of time, the extent of reshuffling will erode the conserved blocks to a small size, such as now conserved between *A. thaliana* and rice.^[6] Other events—

such as inversions and translocations identified in duplicated genome segments—also occur, as does the apparent transposition of individual genes and small groups of genes.^[1,9] It is the combination of all of these mechanisms that shapes plant genome microstructure.

CONCLUSION

The vision is emerging of the microstructure of plant genomes evolving by a variety of mechanisms, with detrimental effects buffered by extensive genome duplication. Over time, duplicated segments will tend toward complementary gene content until redundancy is reduced to the extent that loss of genes becomes detrimental to fitness. The size of conserved blocks both within and between genomes will degenerate by rearrangement over time; transpositionlike events will further erode conservation of microstructure. Thus a proportion of genes in related genome segments will be identifiable between or within genomes, although many will not. The conservation of microstructure will often permit the identification of orthologous genes in different plant genomes, and the identification of putatively functionally redundant genes within a genome. However, there will be exceptions, even between closely related species; therefore, functional interpretation and comparative genome structural analyses must be integrated with caution. For very distantly related species, the orthology of genes will rarely be demonstrable due to the variety of mechanisms contributing to the evolution of plant genome microstructure.

Ex Situ Conservation of Genetic Resources: Characterization and Validation

Bert Visser

Wageningen University and Research Centre, Wageningen, The Netherlands

INTRODUCTION

Characterization means collecting information on morphological, agronomic, and molecular aspects of plant germplasm.^[1] Characterization may include a description of plant architecture, leaf, fruit, and seed morphotypes, nutritional aspects, certain physiological characteristics, and use purposes. Such information is helpful to plant breeders because it indicates the use potential of germplasm in breeding programs. Moreover, it is essential for genebank managers because it provides insight in the composition of the collection and its coverage of the crop gene pool. Characterization data are part of a package to which also passport data and evaluation data belong. All such data may be contained in so-called descriptor lists. A strong correlation exists between the extent of information available on a given germplasm accession and the interest in such material by potential users.^[2]

Validation serves to assure the proper identity of accessions in a collection. Characterization can be used for validation purposes as well, although there are limits to the discriminating power of characterization data.

CONSERVING PLANT GENETIC RESOURCES

Because of modern plant breeding, population growth, habitat destruction, and globalization of markets, crop genetic diversity is threatened. However, conserving genetic diversity is essential to meet current and future demands for food security and sustainable agriculture, or, in the form of plant, genetic resources are maintained in situ and on-farm, in particular, in developing countries. Plant genetic resources are also maintained in ex situ collections. Individual entries in such ex situ collections are called accessions. The largest ex situ collections are seed collections, but some germplasm is maintained in tissue culture in vitro or in the form of field collections. To promote the use of collections and to facilitate their efficient management, the accessions in these collections need to be described. Characterization and evaluation, together with the documentation of passport data,

provide such description. Passport data include the species name, local names, the country of origin, the collection site, and date. Evaluation data concern useful agronomic traits that are often subject to genotype by environment (G × E) interactions.

Whereas this contribution focuses on ex situ collections, the approach can also be applied on traditional farmers' varieties that are maintained in the field or on wild relatives conserved in protected areas in situ.

MORPHOLOGICAL CHARACTERIZATION

Characterization data concern highly heritable characters that show little interaction with the environment. Morphological characteristics form the major part of characterization data. They may include information on plant height and diameter, stem form and color, leaf form, texture and color, flower color, and seed form and color, among other characteristics. An abundant number and diversity of morphological characteristics are available for monitoring. Usually, they can be easily scored and are relatively cheap to obtain because characterization can be often combined with regeneration of seed collections, and field collections can be easily monitored for such characters. It should be realized that the absence of differences in such morphological traits between accessions cannot be interpreted as identity because major differences in physiological, agronomical, or other genotypically determined traits may occur that are not expressed in morphological differences. In conclusion, as a strategy to record identity and distinctness, morphological characterization is cheap but of low resolution.

Traditionally, some collection holders have complemented documentation of morphological characters by the establishment of instructive herbaria and showcase seed collections. Novel approaches involve the use of digital photography and computer technology to record the phenotype of accessions digitally, whether of whole plants, leaves, reproductive organs during flowering and seed setting, fruits, or seeds. Such technology also opens the way to image analysis to further add to morphological characterization.

It is clear that, in comparison to seed collections, field genebanks allow for ample characterization of the morphology of accessions in various stages of plant development because plants are available for monitoring at any time. In contrast, in vitro maintained collections need cumbersome explanation of the plant material to allow for reliable morphological characterization.

PHYSIOLOGICAL CHARACTERIZATION

For some crop collections, physiological traits have been described. This may involve the presence or level of valuable or undesirable compounds, such as erucic acid or other valuable fatty acids in the brassica complex, to which cabbages and rapeseed belong (see for example Ref. [3]), or the presence of noxious alkaloids in potato germplasm and cyanogenic compounds in cassava. In comparison with morphological characterization, in practice, the added value of such data for collection management is often low because the number of recorded characters is usually small, but the potential use value of such characterization data is much higher. Against a higher potential value generally stand higher costs to obtain such information, because generating this information often necessitates laboratory experiments. The laboratory costs vary considerably depending on the physiological trait determined.

With the rise of biotechnology and increased processing of plant products, interest of industry in such information has grown. For biotechnological applications, the taxonomic source of valuable compounds and of the

underlying genetic information is less relevant because genetic modification allows that genes, once identified, can be transferred from one species and expressed in almost all other species. It is remarkable that these biotechnological options have not yet resulted in new collection concepts, based on shared compounds or biosynthetic pathways rather than on genotypic relations as in crop collections. Some initiatives leading into this direction have recently been undertaken.^[4]

MOLECULAR CHARACTERIZATION

The development of molecular marker technology has opened the door to genotypic rather than phenotypic characterization of collections. In particular, the AFLP[®] technology and microsatellites form major instruments for such characterization. Whereas the former needs no prior sequence information, the strength of the latter is that it can reveal more variation including the presence of two different alleles of a gene present in the same individual. Few collections have yet been entirely screened with such markers by way of pilot projects. An example of a collection that has been screened with both molecular marker types mentioned above is the lettuce collection of Centre for Genetic Resources The Netherlands comprising 2300 accessions.^[5] However, the development of genomics will allow easier exploitation of marker technology and speed up molecular characterization.

Whereas most molecular characterization efforts are yet based on technology development objectives, various other objectives may also motivate the use of molecular

Fig. 1 Analysis of genetic distance of 22 AFLP genotypes observed in six different barley accessions. Sample size was 36 plants for each accession. The absolute frequency of each genotype is indicated at the end of the branches of the dendrogram.

characterization. Potato collections in Europe are currently researched using genomics in a search for useful resistance traits, in particular, against late blight disease. For this purpose, variation in resistance gene-linked sequences is analyzed in several thousands of accessions.

The use of AFLPs results in a detailed insight in the genetic distance or relatedness between accessions. An example of such analysis is shown in Fig. 1, describing the genetic distance between various genotypes occurring in a number of barley accessions.^[6] In combination with passport data and evaluation data, such information may provide clues to additional collecting activities on the one hand, and rationalization of collections that contain a high frequency of closely related or even identical genotypes (redundancy in the collection) on the other hand.^[5] In a minority of cases, it may allow discarding or merging accessions that have little added genetic information. In other cases, it may help to understand the pedigree of cultivars or farmers' varieties (Land-races). Molecular characterization also allows an analysis of intra-accession genetic diversity, and it can reveal the effects of regeneration on the genetic composition of accessions. Finally, it may help some curators in prioritizing regeneration and evaluation of certain accessions over others.

The options for molecular characterization have also opened the possibility of a paradigm shift in genetic resources management.^[7] This paradigm shift entails the description of collections not only for expressed traits, but also for other genetic information that is not expressed or which expression is camouflaged by more dominant traits. Finally, in contrast to morphological and physiological characterization, molecular characterization is fully independent of genotype \times environment interactions. If widely applied, this approach will greatly influence collection management strategies.

Molecular characterization is the most expensive type of characterization and requires specialist expertise and advanced facilities. It can only be undertaken to answer well-formulated questions to complement information obtained through morphological and physiological characterization.

THE STATUS OF CHARACTERIZATION OF GENE BANK COLLECTIONS

Lack of characterization is mentioned as the most common constraint to increased utilization of plant genetic resources. The State of the World's Plant Genetic Resources^[1] reports the presence of more than 1300 collection holdings containing more than 5 million accessions. Of these, more than 500,000 accessions are stored in field genebanks. It also

mentioned that substantial characterization had been achieved for only a small fraction of these collections, in particular, for the collections maintained in developed countries and a small number of developing countries.^[1] Such characterization almost exclusively refers to morphological and agronomic and not to physiological or molecular characterization. Therefore many countries reported the need for further characterization of collections. No more recent figures on the overall characterization of collections are available. Given the limited funds globally available for collection maintenance, it is likely that the current situation may still be similar to the situation reported for the 1990s. The documentation system, system-wide information network on genetic resources describing the CGIAR collections,^[8] indicates on-line availability of characterization data on 70% of the collections, whereas on-line availability of characterization data on European collections currently varies per country between 10% and 80% (personal communication).

VALIDATION OF ACCESSIONS

Validation is a major instrument to improve reliability of classification of genebank stocks and distributed germplasm and information. Therefore validation will add in promoting the utilization of germplasm collections. The high number of accessions maintained in genebanks, the generally limited funds available for collection management, and the technical difficulties in proper recognition of genotypes have resulted in misclassification of part of the genebank stocks. Such misclassification includes avoidable cases as mislabeling, mixing, and contamination of accessions and cases resulting from lack of knowledge to properly identify certain germplasm. All types of characterization can serve to identify misclassified germplasm, whereas molecular characterization, in particular, can serve to resolve classification uncertainties of the latter type.

CONCLUSION

Proper use of biotechnologies depends on exploitation of genetic resources and, at the same time, provides new options for the genebank community. The developments in biotechnology, genomics, and bio-informatics will contribute to improved characterization and validation of germplasm held in ex situ collections and to improved collection management. These developments also allow a revision of collection concepts based on a shift in user demands.

Ex Situ Evaluation: Core Collections

Larry D. Robertson

United States Department of Agriculture–Agricultural Research Service, Geneva, New York, U.S.A.

INTRODUCTION

The size of germplasm collections has long been recognized as one of the major impediments to their full exploitation for crop improvement. Because resources are not available for full evaluation of collections, they are poorly described, which greatly reduces the efficiency of their use.

CORE COLLECTION CONCEPT

This led Harlan^[1] to introduce the idea of the “Basic collection” in 1972 for sorghum as a working collection of lines that was to be selected based upon stratification according to race, subrace, geographical distribution, and ecological adaptation. This was proposed as a way to represent the genetic diversity of the world cultivated sorghums in a smaller, more manageable collection. This was further developed into the concept of core collections in the early 1980s when Frankel^[2] and Frankel and Brown^[3] proposed that large collections should be sampled to provide a “core collection” which would “represent with a minimum of repetitiveness, the genetic diversity of a crop species and its relatives.” They proposed that the core collection would be a smaller collection that represented the genetic diversity in the entire collection. Thus it would complement, not replace, the entire collection. The accessions that are not in the core collection would be called the “reserve.”

As mentioned above, the major impetus for the development of core collections has been to facilitate adequate evaluations of the collections through evaluation of the diversity of a representative sample of the genetic diversity of the entire collection (the core collection); resources are not available to phenotypically and genotypically characterize the thousands of accessions that are in crop collections. Use of a core collection allows for more extensive evaluation of the genetic diversity of a crop or species to provide the necessary data for breeders to select useful accessions for their crop improvement programs. Core collections are also useful for providing: 1) a starting point for evaluation for a new pest or pathogen or for newly identified useful traits; 2) the genetic materials for new crop improvement programs; and 3) a practical means of

germplasm management and distribution. By using the core collection as a standard set of germplasm for evaluation, researchers are able to combine results from a variety of different studies which provides a larger database to describe basic biological processes for a particular crop. Johnson and Hodgkin^[4] is an excellent review of the current research dealing with core collections.

There have been a number of publications on the characters to be used in developing a core collection, sampling strategies to select the members of a core collection, verification of the effectiveness of core collections in representing the genetic diversity in an entire germplasm collection, and evaluations of core collections for important agronomic traits. These topics will now be discussed.

DIVERSITY MEASUREMENTS

Frankel and Brown^[3] and Brown^[5] suggested using data on the origin and characteristics of the accessions in the collection to determine the members of the core collections. There are a number of traits that have been used in developing core collections. For many collections, taxonomy is used in developing core collections to ensure that species and subtaxa are adequately represented, such has been done for the USDA apple collection (Table 1, Fig. 1).

Most core collections are developed using a number of morphological and agronomic traits for developing subgroups. Core collections have also been developed using disease and pest resistance data along with morphological and agronomic data.^[6] Others also use passport data including climatic, ecological, and geographic information on species range to develop core collections. Grenier et al.^[7] used stratification based on eco-geographic data in developing a core collection of sorghum to avoid the effect of correlation of phenological traits with latitudinal and racial distribution of landraces during sampling for the core collection. Recently, molecular markers are increasingly being suggested for developing core collections. Most researchers agree that the more types of data used in developing a core collection, the more representative of the entire collection it will be.^[8]

SAMPLING STRATEGIES

Brown^[8] discussed types of sampling to represent a core collection and recommended using about 10% of the entire collection to form a core with stratified sampling from groups of accessions, in logarithmic or absolute proportion to the size of groups. This was predicted to retain approximately 70% of the alleles present in the entire collection. Recently, the concept of “mini core collections” which contain about 1% of the accessions in a collection that are developed in a two-stage process using the core collection as a basis for a second selection for the mini core has been proposed.^[9]

There are a number of mathematical models used for sampling for a core collection. The basic underlying method is to develop subgroups of the entire germplasm collection which are highly similar within groups with high dissimilarity between groups. Most methodologies used to develop these subgroups are based on genetic distance between accessions, where the distances between accessions within groups are low and distances between accessions in different groups are high. The second stage of the process is to sample these subgroups to provide a core collection which is representative of the entire collection. Stratified sampling from the groups of accessions, either with logarithmic or proportional representation based on group size, rather than with equal representation, has been recommended as the best strategy to follow.^[8]

The most commonly used method to group accessions to produce the subgroups that are sampled is the use of principal component analysis to define these groups using the various traits that are measured. Another common method to develop these groups is the use of stepwise and clustering analyses to develop groups of accessions that

Table 1 The core subset of the USDA apple germplasm collection, number of accessions in the core vs. number of accessions in the entire collection

are then sampled for the development of the core collection. Spagnoletti Zeuli and Qualset^[10] tested five sampling strategies for developing core collections and using stratification based upon frequency by country-of-origin or stratification by canonical variables increased frequencies from less-represented countries of origin. A number of sampling strategies have been recently tested for a series of crops, but most end up recommending the use of either logarithmic, proportional, or some variation of these methods as originally suggested by Brown.^[8]

VERIFICATION OF CORE COLLECTIONS

Once a core collection is developed it is important to validate the success of the core collection in sampling the genetic diversity present in the entire collection. The genetic diversity of core collections has been validated for a number of core collections using morphological, agronomic, eco-geographic data, and molecular marker data by calculating genetic diversity indices for the core collection and comparing these to the same parameters that are calculated for either the entire collection or a set of random subsamples of the collection. Most studies have found that core collections adequately represent the genetic diversity of the entire collection and provide a meaningful subset for crop improvement use.

CORE COLLECTION EVALUATIONS

Spagnoletti Zeuli and Qualset^[11] proposed that core collections should be evaluated primarily for characters that are useful for plant breeders, which was the primary impetus for their development. They identified four issues: 1) estimation of genetic diversity; 2) evaluation of breeding potential of exotic lines (by testing for general

Table 2 Evaluation of core collections for important traits in selected crop species

Crop	Trait evaluated	Results
Apple	Fire blight sooty-blotch, and fly speck resistance, anti-oxidants, cold hardiness	Diversity in reaction observed
Common bean	White mold resistance	Core useful for identifying useful resistance to white mold
Pea	Fusarium Wilt Race 2	14% of accessions were found to be resistant
Pea	Biomass and related characters	Significant useful variation found for improvement seed yield and total biomass production
<i>Brassica oleracea</i>	Resistance to cabbage aphid	Kale gene pool was most promising for selection of resistance
Safflower	Oil and meal characteristics	Core not fully representative of noncore but captured a large fraction of diversity for oil and meal factors
Lentil	Phenology, morphology, seed and straw yields	Significant variation for biomass, seed yield, and residue amounts
Soybean	Seed allergens	The monoclonal antibody P34 found and it may not be possible to eliminate
Barley	Feed quality	Substantial variation found
Groundnut	<i>Meloidogyne arenaria</i> resistance	Two-stage system of screening was efficient in identifying resistance

combining ability); 3) determining methods useful to identify promising parents (using multivariate analyses of quantitative and qualitative traits); and 4) using information gathered from the core collection to exploit the reserved collection more thoroughly. Because of their small size, breeders would be more willing to evaluate core collections, which should lead to multilocal evaluation information. The USDA apple core collection was planted for multilocal evaluation in 1991 to allow for evaluation for important horticultural and stress characters.^[12] As mentioned previously, core collections were envisioned as a starting point for evaluations of crops and as a basic gene pool for new crop improvement programs. Recent results from evaluation of core collections from selected crops are found in Table 2. These results show the usefulness of core collections as sources of variability for a number of traits including agronomic, quality, and disease and pest resistances.

CONCLUSION

Core collections provide a partial solution to the problem of evaluation of germplasm collections by providing a smaller, more manageable subset of the entire collection that can be thoroughly evaluated and characterized. The reduction in size provided by core collections provides the opportunity for the thorough evaluation at multiple locations the genetic diversity available in a crop collection that is available for breeders to use for crop improvement. This provides useful information that increases the efficiency of use of crop collections and provides data to select further sections of the entire collection for more thorough evaluation.

There have been numerous types of data used to develop core collections and there are a number of methodologies used to produce a representative sample for the core collection. It is important to use a wide range of traits to develop subgroups that are sampled to produce the core collection in order to have the best representation of the genetic diversity in the entire collection. The process of developing core collections is a two-stage process: 1) subgroups are determined for a crop using various multivariate statistical analyses; and 2) these groups are sampled to provide a sample of the genetic diversity of the germplasm collection. Most researchers have recommended that either a proportional or a logarithmic rather than a constant sampling of these groups be used in selecting the core collections.

Core collections have been developed as a complementary conservation strategy and not as a replacement of the entire germplasm collection of a crop. Jana^[13] urged caution in the use of core collections. While he recognized the usefulness of core collections as a practical method to encourage germplasm use and distribution, he cautioned that this should not be allowed to undermine the wealth stored in national gene banks, which are often more useful in promoting extensive utilization of genetic resources. However, as shown in Table 2, core collections have proven useful in genetically characterizing a crop for particular traits and as a starting point for selection of useful variation for many traits.

Ex Situ Genetic Resource Conservation: Plantations

N. Rajanaidu

Malaysian Palm Oil Board (MPOB), Bandar Baru Bangi, Malaysia

V. Ramanatha Rao

International Plant Genetic Resources Institute (IPGRI-APO), Serdang, Malaysia

INTRODUCTION

Plantation crops such as banana, plantain, oil palm, coconut, cocoa, coffee and tea, and rubber are normally managed as large agricultural enterprises, which produce cash crops for sale. Plant genetic resources include genotypes or populations representative of cultigens, genetic stocks, and related wild and weedy species that may be conserved in the form of plants, seeds, tissue cultures, etc. or populations in the farmers' field and in the natural ecosystem. Over the years, there has been much loss of genetic diversity, but the remaining genetic diversity in the gene pools needs to be conserved and used for crop improvement. The limitations of a narrow genetic base of many modern-day varieties are well recognized. Genetic diversity is considered to be a defense against genetic vulnerability. Two major conservation strategies are practiced to preserve genetic diversity, namely, in situ and ex situ conservation strategies. Article 2 of the Convention on Biological Diversity provides the following definitions for these categories: ex situ conservation means the conservation of components of biological diversity outside their natural habitat and in contrast, the in situ approach is about conserving genetic resources in the plants' natural habitat and includes the maintenance of reserves/protected areas, and in the case of cultivated species it is the conservation on-farm and in home gardens.

CONSERVATION OF PLANTATION CROPS: PRINCIPLES

The global importance of most of the plantation crops has resulted in a number of collecting missions in the past from which a significant number of accessions have been collected and conserved. It appears that, unlike many other crop species, the genetic resources of plantation crops have been fairly well used.

Ex Situ Conservation Methods

In the literature several methods under ex situ conservation approach have been described namely, seed conservation, field genebank, in vitro culture, cryopreservation, pollen conservation, and even DNA banks, and a significant amount of research is underway to refine these methods.^[1,2] However, as noted earlier, seed conservation is not useful for the crops under consideration and the advanced methods are still being refined. Hence, currently, the options available for the conservation of plantation crops seem to be very limited.

Field Genebanks

Many important field crops, horticultural, and forest species are either difficult or impossible to conserve as seeds or reproduce vegetatively. Hence they are conserved in field genebanks (FGBs). FGBs may run the risk of being damaged by natural calamities, infection, or neglect. Ex situ conservation of tree species using FGBs requires a substantial number of individual genotypes to be an effective conservation measure. Thus FGBs need more space, especially for large plants such as tree crops and they may be relatively expensive to maintain. However, FGBs provide easy and ready access to conserve materials for research as well as for use. For a number of plant species, the alternative methods have not been fully developed so that they can be effectively used. It is clear that establishment of FGBs will play a major role in any conservation strategy for PGR. It is one of the options of a complementary strategy for the conservation of germplasm of many plant species. At the same time, efforts to develop and refine other methods, such as in vitro conservation and on-farm conservation, must continue.^[3]

FGB has several advantages, but it has some major disadvantages, too. Some of the disadvantages are as follows:

1. It is labor and time intensive. Both these resources may be limited in the future.

Table 1 Number of palms and area occupied by field genebank at MPOB, Kluang, Malaysia

Collection	Species	Number of palms planted in the field	Area (hectares)
Nigeria	<i>Elaeis guineensis</i>	31,434	212
Zaire	<i>E. guineensis</i>	13,750	93
Cameroons	<i>E. guineensis</i>	3590	24
Tanzania	<i>E. guineensis</i>	3104	21
Madagascar	<i>E. guineensis</i>	38	1
Angola	<i>E. guineensis</i>	2507	17
Senegal	<i>E. guineensis</i>	415	3
Gambia	<i>E. guineensis</i>	246	2

Guinea	<i>E. guineensis</i>	1271	9
Ghana	<i>E. guineensis</i>	2800	19
Colombia, Peru	<i>Bactris</i>	30	1
Colombia, Peru	<i>Oenocarpus</i>	265	2
Colombia, Peru	<i>Jessenia</i>	639	5
Colombia, Peru	<i>Euterpe</i>	20	1
Others ^a	<i>Elaeis oleifera</i>	4248	29

^aIncludes material from Honduras, Nicaragua, Costa Rica, Panama, Colombia, Suriname, Brazil.

2. Extreme care in labeling and managing fields is necessary with special consideration to perenniality of coconut.
3. Many biotic and abiotic factors affect the safe conservation of germplasm and in some cases, it may be lost permanently.
4. As the volume of planting material is quite large (as either seednuts or seedlings in polybags) it is inconvenient for transportation.
5. Exchanging the germplasm materials internationally is strictly restricted by quarantine and reliable tissue/embryo culture techniques will be required for the safe movement of germplasm.

Thus it is easy to see that, to be able to conserve and utilize plantation crop genetic resources, it is necessary to complement field genebanks with other conservation methods. FGB is one of the options of a complementary strategy for the conservation of germplasm of many plant species, and efforts to develop other methods such as in vitro conservation and on-farm conservation must go on. However, with the current level of development in other methods, plantation crop genetic resources are routinely maintained in field genebanks. Other methods such as in vitro conservation, cryopreservation, pollen conservation, and even DNA banks are of limited applications at this point of time in plantation crops.

CONSERVATION OF PLANTATION CROPS: EXAMPLES

Oil Palm

Historically, the first collections of oil palm germplasm were established in Zaire, Nigeria, and Ivory Coast. Recently, the Malaysian Palm Oil Board (MPOB) has planted oil palm germplasm accessions from Africa and South America (Table 1).

As noted earlier, field genebanks need fairly large area and regular maintenance. In the case of oil palm, only 148 plants per hectare are planted. Unlike the MPOB base collection (Fig. 1), working collections of oil palm germplasm are also maintained by different public and private companies in other countries.^[4] At an experiment station on the Urubu River near Manaus, Brazil, 474 accessions of oil palm are maintained by the Centro de Pesquisa Agroflorestal da Amazonia (CPAA). Similar working collections are also found in Costa Rica, Colombia, and Indonesia.

Rubber

Rubber seeds are recalcitrant and cannot be dried and frozen for safeguarding in a seed genebank. Rubber germplasm must thus be conserved as trees in field

Fig. 1 A view of MPOB base collection of oilpalm field genebank at Kluang, Malaysia. (View this art in color at www.dekker.com.)

genebanks. Only a handful of countries maintain sizable genebanks for rubber, with Brazil and Malaysia having the largest collections. CPAA near Manaus has the most comprehensive collection of *Hevea brasiliensis*. The rubber genebank at CPAA started in 1982 and by 1988 had 1300 genotypes. CPAA also maintains 50 samples of *Hevea pauciflora*, two *Hevea guianensis*, several *Hevea benthamiana*, and one each of *Hevea nitida*, *Hevea camporum*, and *Hevea camargoana*. Malaysia also holds a sizable collection of rubber germplasm, although it is less comprehensive than the collection in Brazil. The Malaysian collection is geared more to short-term breeding objectives than to encompass broad genetic diversity of rubber. Most of the collection at the Rubber Research Institute of Malaysia (RRIM) is composed of seedlings from materials gathered during a joint Empresa Brasileira de Pesquisa Agropecuária (EMBRAPA)/International Rubber Research and development Board (IRRDB) expedition in the southern part of the Brazilian Amazon in 1981.^[5] RRIM received 35,000 seeds originating from Acre, Mato Grosso, and Rondonia. Approximately 10,000 seedlings from the seed material survived in the field nursery of RRIM. A set of these is also being maintained on Hainan Island, China.

Cocoa

Cocoa has recalcitrant seed and thus seed conservation is not relevant. Because field genebanks are costly to maintain, only a small fraction of the genetic diversity of *Theobroma* is represented in ex situ collections. The International Cocoa Genebank, Trinidad (ICGT), with 1872 clones, holds perhaps the most comprehensive collection of cocoa germplasm. The maintenance of cocoa

germplasm is essential as the loss of wild and primitive cocoa types continues due to deforestation and natural calamities such as fire and diseases.^[6]

Coffee

Despite the economic importance of coffee, only a few sizeable genebanks have been established for coffee. Coffee seeds are known to remain viable for less than 2 years even under reduced temperature and moisture conditions, so germplasm is planted in field genebanks. The largest field genebank, with 6000 accessions, is maintained at Divo, Ivory Coast. In Ethiopia, some 700 genotypes are kept at Chochie, Kefa. Smaller germplasm collections in Africa are maintained at Lyaamungu, Tanzania, and Butare, Rwanda. The largest coffee germplasm collection in Latin America is held at CATIE, Costa Rica. CATIE holds 1212 accessions of arabica coffee.^[6]

Coconut

Field genebanks are presently the most feasible ex situ conservation method that can be used for coconut and they play a major role in our efforts to conserve coconut genetic diversity. There are many field collections connected with coconut research institutes conserving 1416 accessions worldwide. To date 28 countries have established national collections to conserve important coconut germplasm. Many of these countries are being assisted through the Asian Development Bank (ADB)-funded project to collect additional germplasm and to conserve these field genebanks. The International Coconut Genetic Resources Network (COGENT)/International Plant Genetic Resources Institute (IPGRI) is making efforts to establish a multisite International Coconut Genebank (ICG) and conservation of coconut genetic resources would become a long-term responsibility of institutions and governments in host countries such as Papua New Guinea (for the Pacific), Indonesia (for the Southeast and East Asia and China), India (for South Asia), and Cote d'Ivoire (for Africa and Indian Ocean Islands).

REGENERATION

Regeneration of germplasm is an important activity of any germplasm curator and must be part of routine activities of genebank. Much work has been done on regeneration of seed accessions conserved in genebanks and guidelines

for germplasm regeneration have been published. However, there are hardly any general protocols available for genebanks that maintain plantation crop genetic resources. Nevertheless, different crop curators have developed their protocols based on the specific needs of the genebanks and resources available to them. For example, in the case of oilpalm random pairwise crosses are made within each population to produce seed required for reestablishing the accessions in the new genebank. This methodology enables the preservation of coadapted gene complexes. In coconut generally, assisted pollination is carried out to produce seednuts from next planting, and when this becomes too expensive seed nuts are collected from the plants located in the center of the plot of the accession.

CONCLUSION

It is evident from the above discussions that the options available for conserving plantation crop genetic resources are very limited and limited to establishment and management of field collections or field genebanks. Establishment and maintenance of field genebanks is both expensive and labor intensive. However, the major advantages of field genebanks, especially for the perennial species that are being considered here, are that the germplasm can be continuously evaluated and utilized in crop improvement.

Keeping in mind the limitations of field genebanks, it will be prudent on the part of plantation crop plant genetic resources community to work rigorously to develop further the alternative methods as well, which can provide options for a complementary conservation strategy for these globally important plant genetic resources. In the area of ex situ conservation, increased efforts on cryopreservation of regenerable tissues of these crops will greatly enhance our capacity to conserve the genetic resources of plantation crops on a long-term basis. There is the scope as well for further progress to be made in DNA banking, although current situation precludes the use of such stored DNA. Development of on-farm

conservation strategies as well as in situ conservation in natural habitats, as most of the plantation crops do occur naturally in the wild, will further enhance the chances of developing a complementary conservation strategy for plantation crops genetic resources.

Exchange of Trace Gases Between Crops and the Atmosphere

Jürgen Kreuzwieser

Heinz Rennenberg

University of Freiburg, Freiburg, Germany

INTRODUCTION

The atmosphere mainly consists of nitrogen (78% by volume) and oxygen (21% by volume). The remaining 1% is known as trace gases, with the noble gas argon the most abundant. Concentrations of other trace gases are typically present in the range of parts per trillion by volume (pptv) to parts per million by volume (ppmv); they include the greenhouse gases carbon dioxide (CO₂), methane (CH₄), nitrous oxide (N₂O), ethane, water vapor, and ozone (O₃); the air pollutants sulfur dioxide (SO₂), ammonia (NH₃), nitric oxide (NO), nitrogen dioxide (NO₂), peroxyacetyl nitrates (PAN), nitric acid (HNO₃), and carbon monoxide (CO); and a number of volatile organic compounds (VOCs). Among VOCs are isoprenoids (mainly isoprene and monoterpenes) and many oxygenated species such as alcohols, aldehydes, and organic acids which, due to their reactivity, strongly affect the oxidation capacity of the troposphere and influence the concentration and distribution of several other trace gases, including CH₄ or CO. On a regional scale, VOCs significantly contribute to the formation of tropospheric O₃. The main source of VOCs (approximately 90%) is natural emission by vegetation.

IMPACTS OF TRACE GASES ON CROPS

The effects of atmospheric trace gases on crops are quite diverse and depend on the type of gas and its concentration (Table 1), the duration of exposure, and a range of plant internal factors. Direct phytotoxic effects due to exposure to high concentrations of pollutants such as O₃ and SO₂ on crop plants include, among others, visible leaf injury; changes in chloroplast structure and cell membranes; disturbances of stomatal regulation, respiration, and photosynthesis; and reductions in growth and yield.^[3] However, because sulfur (S) is an essential nutrient for plants, SO₂ absorbed by foliage may also be used as an additional sulfur source in polluted areas, in addition to sulfate from the soil.^[3] The same principle applies to nitrogen (N). Thus, effects of trace gases can be divided

into phytotoxic effects caused by protons, organic compounds, SO₂, NO₂, NH₃, and O₃; and nutritional effects caused by S- and N-containing gases, and CO₂.^[4]

FACTORS CONTROLLING TRACE GAS EXCHANGE

Trace gases can be exchanged between the atmosphere and aboveground plant parts by: 1) dry deposition as gases or aerosols; 2) wet deposition as dissolved compounds in rainwater or snow; or 3) interception of compounds dissolved in mist or cloud water^[5] (Fig. 1). The direction of the exchange (i.e., emission versus deposition) and its velocity are controlled by the physicochemical conditions and by internal plant factors.

The gradient in the gas concentration between substomatal cavities and the atmosphere is the driving force for gas exchange. The gas flux is a diffusive (passive) process and can be described by Fick's law. Accordingly, the net flux of a trace gas is zero when the substomatal concentration is equal to the concentrations in the surrounding ambient air. This concentration is referred to as the compensation point for the particular gas. When trace gas concentrations outside the leaves are higher than those in the substomatal cavities, a net flux into the leaves will take place (deposition), and vice versa. Therefore, crops may act both as a source (if ambient concentrations are lower than substomatal concentrations) or as a sink of a specific gas (Table 2). This dual behavior has been observed for a variety of gases (SO₂, H₂S, NO₂, NH₃, organic acids, and aldehydes). Compensation points for pollutants such as NH₃ range between 0.4 and 15 parts per billion by volume (ppbv).^[6] They depend mainly on the plant species or cultivar, development stage, temperature, and status of N nutrition of the plants. Generally, compensation points increase with increasing availability of nutrients in the soil, which suggests that this is one mechanism by which plants cope with excess nutrient supply.^[7]

Table 1 Range of ambient concentrations of different trace gases in the atmosphere

Trace gas	Ambient concentrations
Ar	9,340 ppm
CO ₂	365 ppm
CH ₄	1745 ppb
N ₂ O	314 ppb
Isoprene	ppt–several ppb
Monoterpenes	ppt–several ppb
Alcohols	1–30 ppb
Carbonyls (aldehydes, ketones)	1–30 ppb
Alkanes	1–3 ppb
Alkenes	1–3 ppb
Esters	ppt–several ppb
Carbonic acids	0.1–16 ppb
SO ₂	0.5–50 ppb
H ₂ S	0–0.2 ppb
NO ₂	4–200 ppb
O ₃	20–80 ppb

PLANT PHYSIOLOGICAL CONTROLS

The existence of a compensation point depends on the capacity of a plant to produce the trace gas to be exchanged, or to consume it. Therefore, compensation points do not exist for compounds that cannot be produced (e.g., O₃) or consumed (e.g., isoprene). It is evident that for each of the many gases exchanged between crop plants and the atmosphere, specific metabolic pathways exist, not all of which are considered here. As an example, and because of their increasing importance in recent years, some details on the exchange of nitrogen compounds are presented (Fig. 2).
